Anomalous Scattering: The change of atomic scattering amplitude due to a phase-angle shift for scattered x rays from a chemical element in a crystal, particularly noticeable when the element has an absorption edge near the wavelength of the radiation used for the diffraction study.

Crystal Structure: The arrangement of ions, atoms, and molecules in a crystal. The symmetry and geometry exhibited by their arrangement are part of the structural properties.

Crystal Symmetry: The balanced proportions present in cubes, hexagonal or rectangular prisms, and other polyhedra; see **Point Group**.

Diffraction: The interference phenomenon of waves when they travel through a grating in their path. In x-ray diffraction, the crystal is the grating.

Lattice: An infinite periodic array of points at the termini of vectors $\mathbf{L}_{uvw} = u\mathbf{a} + v\mathbf{b} + w\mathbf{c}$, where **a,b,c** are three noncoplanar vectors.

Miller Indices: Three integers enclosed in parentheses (h,k,l) used to represent a set of (parallel) crystal planes. When enclosed in brackets $[h,k,l]$, they represent a direction normal to the plane; and $\{h,k,l\}$ is a form representing a set of symmetry-equivalent planes.

Organic Compounds: Compounds whose molecules are made up mainly of carbon, hydrogen, oxygen, and/or nitrogen atoms. However, in terms of crystal structure classification, these compounds may also contain other elements such as metals, even though they are then called organometallic compounds by chemists.

Phase: A crystalline, liquid, or gaseous state of matter, as used in Gibbs's phase rule or phase transitions.

Phase Angle: A quantity used in the analysis of interferences of waves, for which sinusoidal models are used. However, most crystallographers simply call it a phase. This term is used here to avoid confusion between it and the Gibbs phase.

Point Group: A group consisting of symmetry elements: n-fold rotation axes, mirror planes m, and/or center of inversion i. The property that makes a crystal indistinguishable from its images after being turned (along an axis) by an angle of $2\pi/n$ is called an n-fold rotation axis. When two halves of a crystal are mirror images of each other, the plane separating the halves is a mirror plane m, and a point from which two opposite directions are equivalent is called a center of inversion i.

Space Group: A group consisting of symmetry elements: those of point groups (see above), screw axes, glide planes, and lattice translations.

Symmetry Element: A process that brings the crystal or object back to itself. For example, a threefold rotation is a rotation of the crystal by 120° ($2\pi/3$). For crystal structure description, symmetry elements includes n-fold rotations, mirror planes m, center of inversion i, glide planes, screw axes, and lattice translations.

Symmetry Group: A point group or space group consisting of symmetry elements. A group consists of a set of elements with a defined group pairing operation, and it satisfies four basic axioms: closure, identity, inverse, and associative; see **Point Group** and **Space Group**.

Unit Cell: The smallest parallelepiped which when stacked repetitively in three dimensions generates the entire crystal structure.

Wyckoff Notation: A letter representing a set of symmetry-equivalent positions in a space group. A general point in a unit cell of a crystal structure belonging to any space group has coordinates x,y,z. However, if one or more of the coordinates has a special value, the number of symmetry-equivalent positions is reduced. Most space groups have several sets of such points, and they are represented by letters a,b,c, etc., which are called Wyckoff notations.

INTRODUCTION

Chemical vapor deposition (CVD) is the process wherein a gaseous source species is decomposed to form a film upon a substrate. This process requires some form of energetic input, whereby the source species is dissociated in the course of film growth. This is distinct from a condensation process, where a vapor is condensed to form a solid, with the source species undergoing only a phase transition. In its most common form, CVD relies upon elevated temperatures to pyrolyze the gaseous precursor for film growth. However, in instances where high growth temperatures are incompatible with the substrate materials, or where metastable materials are to be grown, a wide variety of energetic inputs have been employed to facilitate film growth at reduced temperatures. Examples are plasma excitation (dc, rf, and microwave), photoexcitation (lamp and laser driven), and remote thermal excitation (direct heating of the gaseous source).

CVD is at present the method of choice for the deposition of both mechanical and electronic coatings in the industrial setting. This reflects the numerous desirable characteristics associated with the growth of a material from a gaseous source, key features being excellent film conformality, film uniformity, high crystalline perfection, tight compositional control, high process throughput, and relatively low cost. The intent of this article is to provide an overview of the state of the art in CVD, and to serve as a resource to those who require information on CVD methods for film deposition within a particular material system.

1. CLASSIFICATION BY EXCITATION

CVD processes, independent of the film to be grown, are commonly named employing two distinct strategies. One grouping is done in terms of the excitation source employed, thus the nomenclature plasma-enhanced CVD, photolytic CVD, photothermal CVD, etc. A second grouping is performed in terms of the characteristics of gaseous transport within the

Copyright © WILEY-VCH Verlag GmbH & Co KGaA. All rights reserved.

reaction vessel. First to be considered will be the grouping of CVD processes by excitation source.

1.1 Thermal CVD

The earliest forms of CVD relied upon the simple pyrolysis of a gaseous source to form film, and this remains the most commonly employed method to date. A wide variety of heating methods are employed, those being the use of an isothermal furnace, lamp-heated or rf-heated susceptors (energy-absorbing substrate holders), photothermal methods using lamps or laser radiation, or the Ohmic heating of a substrate itself. Variants include the heating of a gaseous source so as to prepyrolyze it, forming highly reactive radicals such that films may be grown on substrates held at temperatures lower than would otherwise have been required.

1.2 Energetically Enhanced CVD Processes

The second broad category encompasses those methods where electronic excitation is employed to activate film growth chemistry directly. The primary reason for the development of this methodology was the desire to go to ever lower processing temperatures, thus achieving the growth of nonequilibrium layers, and allowing the use of a wider variety of substrate materials. Two subcategories exist, those being techniques that are based upon electronic versus optical excitation.

When electronic excitation is employed, rf, dc, or microwave energy is imparted to a gaseous precursor. This can be a direct process, where the discharge is within the gaseous source itself, or may be remote, exciting another gaseous species which then equilibrates with the growth source above the substrate to be coated. The excited precursor molecules then decompose to form the layers desired. The use of remote excitation is particularly desirable when employing an unstable growth precursor, or depositing upon a substrate sensitive to the high-energy emissions (e.g., UV radiation) nominally present in the region of plasma excitation.

In the instance of photoexcitation, a light source is employed to impart energy to the gaseous precursor. Direct excitation requires that the growth precursor have an adequately strong absorbance at wavelengths readily accessible to conventional light sources. This coincidence is frequently absent, and many photolytic methods must therefore rely upon the use of a chemically inert sensitizing agent. As an example, minute quantities of mercury vapor may be entrained in a gaseous source, which can then be excited employing a high-power mercury light source. Photolytic CVD must be distinguished from simple photothermal methods, where a substrate may be locally heated with a focused IR source or the like. This is simply a thermally driven growth process, modified with the intent to localize film growth to a desired area.

For completeness, it must be noted that there will be as many energetically enhanced growth methods as there are ways to couple other than thermal energy into a gaseous source. An electron beam may also be employed to impart energy to an adsorbed species such that it decomposes to form film, but it and all other excitation methods share the common trait of decoupling the temperature/energy of the gaseous precursor from that of the substrate to be deposited upon.

2. CLASSIFICATION BY REACTANT TRANSPORT

Without regard to the method of excitation employed, a second commonality among the numerous CVD methods known is the mechanism of gaseous transport within the region of film growth. Reactant transport through a CVD apparatus is a key determinant in how one must approach the application and analysis of a given CVD method. The characteristic of gaseous flow through a reactor—viscous flow at the high-pressure limit, molecular flow in the low-pressure limit—determines such critical reactor parameters as reactant residence time, the homogeneity of reactant distribution, reactor memory of past gaseous content, and the rate at which the source species comes to chemical and thermal equilibrium with its environment. For historical reasons, reactant transport considerations have been included implicitly in the categorization of CVD processes by a nomenclature based around commonly employed operating pressures. This scheme is reasonable as gaseous transport and pressure are coupled for a given geometry. As such, the commonly employed terminology for classifying CVD processes is adhered to below. A cautionary note is that the true determinant of how gaseous species are transported within a given reactor geometry is the ratio between the mean free path (λ) and some typical system dimension (D). For example, where $\lambda/D \gg 1$, molecular flow, transport involving only molecule–surface interactions, dominates. It is possible in principle to achieve this at any given pressure, 1 atm for example, so long as D is appropriately small in value. This would be the case for the vapor deposition of a metallic catalyst on the interior of a pore in a catalyst pellet. This is an extreme case, but it is worth noting that this is a limitation of classifying CVD by any one system parameter.

2.1 Atmospheric-Pressure CVD

Atmospheric-pressure CVD (APCVD) processes are the simplest example of growth from a gaseous source. A gaseous source is flowed through a reactor configured as shown in Fig. 1, where a highly dilute gaseous source is made to flow at high velocity through the cooled quartz vessel. Cooling of the vessel is employed to prevent the desorption of contaminants from the vessel walls, to prevent the homogeneous nucleation of particulates due to gas-phase pyrolysis of the precursor, and to suppress the growth of film on the reactor vessel itself (to minimize particle generation). Gas velocity is maintained at a level adequate to prevent the back-diffusion of contaminating species into the reactor at the necked- down end of the apparatus. The simplicity of this apparatus belies the complexities of its chemical and hydrodynamic behavior.

APCVD processes can display complex flow geometries. Flow in an APCVD reactor, shown in Fig. 1, is a strong function of the boundary conditions of the reactor (e.g., wall temperature, gas velocity, entrance and/or exit geometries, susceptor position and temperatures, etc.). Employing the injection of smoke particles to trace flow contours in a horizontal APCVD reactor, early workers (Eversteijn *et al.*, 1970) demonstrated the existence of roll cells, where two symmetric vortices are formed along the reactor's flow axis. As seen schematically in view A of Fig. 1, roll cells spiral such that the source gas rises above the heated substrate, and returns to the bottom of the reactor cross section along the cooled walls. This greatly complicates film growth because of the associated variations of reactant thermal history. Contaminating species, dopant as an example, evaporated from the leading edge of a substrate and carried off in the spiral gas flow, may reincorporate at a point one full rotation of the cell further along the reactor axis, modifying the chemical composition of the film from that which was intended. An additional issue is that of heterogeneous (surface) versus homogeneous (gas-phase) reactor chemistry. In that conditions of viscous flow exist, the fluid stream (growth source) experiences drag due to nearby surfaces, and a slowly flowing layer of gas is found in the region ($\leqslant$1 cm) immediately above the heated susceptor. As the gaseous source in this slowly flowing region comes to thermal equilibrium with the hot susceptor and substrate, significant gas-phase pyrolysis of the source species may occur, forming a more or less reactive sequence of by-products. This leads to spatial variations of gas composition within the reactor, and complicates the attainment of layers of uniform composition. Thus, the proper design of reactor hydrodynamics is a key issue if uniform, reproducible film growth is to be achieved. To this end, extensive modeling of reactor hydrodynamics has been performed.

Gaseous transport within a reactor operating at or near atmospheric pressure has been studied by a number of workers (Coltrin *et al.*, 1984; Jensen *et al.*, 1989). Complex behaviors such as those in Fig. 1 are reproduced in

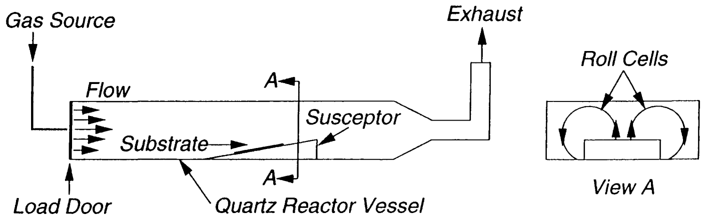

FIG. 1. Atmospheric-pressure CVD system. The tilted susceptor serves to enhance film uniformity. Shown in view "A" are two roll cells, induced by the heating of the gaseous source above the susceptor.

models, but such behavior cannot be generalized in that every reactor geometry produces a unique flow structure. The only generalization made is that of the mathematical formalism employed in the modeling of such complex systems. Hitchman and Jensen (Hitchman *et al.*, 1991) have recently reviewed the state of the art in the area of reactor modeling for a wide variety of reactor configurations.

2.2 Subatmospheric-Pressure CVD

The reduction of operating pressures has been a major factor in the advancement of CVD from a means to grow substrate-like blanket films to a method for the preparation of highly complex layered structures. A liability of many atmospheric-pressure growth processes is, as noted above, the complex hydrodynamic behavior of the system. Reactant residence times in such reactors can be long, in that recirculating flows act as storage nodes for reactants. This leads to an intermixing of layers deposited sequentially, where more abrupt compositional transitions would have been desired. In the instance where a substrate contains volatile species, such as the instance of dopants in silicon, these may be evolved into the gas phase, and reincorporate into film being deposited downstream. To reduce or eliminate such effects, a majority of CVD methods in use today operate in the subatmospheric-pressure regime.

For a fixed flow, an order of magnitude reduction in operating pressure results in an equal reduction of gas residence times within the reactor, facilitating the growth of films with controlled depth-varying compositions. Further, operating at reduced pressures has other fundamental advantages. Low-pressure operation eliminates deleterious flow effects such as the roll cells seen in APCVD. Also, by reduction of gas residence times, undesirable homogeneous chemistry is suppressed, eliminating one mechanism of reactant depletion and/or particle nucleation. When pressures reach the range of 1 to 5 Torr, difficulties encountered with vortices and other "dead spaces" seen in APCVD are absent. The resulting enhancements in the CVD process are remarkable. As an example, one may pack wafers at ever increasing density when gas-phase reactant transport is both rapid and uniform, as is the case at reduced operating pressures. Using an example from silicon technology, consider a process known generically as low-pressure chemical vapor deposition (LPCVD).

LPCVD is a hot-wall CVD growth method, where wafers are packed at high density in a quartz furnace tube. It is common to have 50 or more 125-mm silicon wafers packed coaxially at a spacing of less than 1 cm apart. Shown in Fig. 2, this high packing density makes such systems very efficient. In spite of the high packing density, film thickness across a wafer is uniform to 5% or better by this method for numerous growth processes. Unlike atmospheric pressure CVD, modeling of hydrodynamics in this system is relatively intractable, in that flow in this pressure regime is in transition from laminar, viscous flow to molecular transport (e.g., flow dominated by gas/surface interactions).

A very recent subset of subatmospheric-pressure CVD processes are those operating under conditions where gaseous transport is by molecular flow. In such instances, the assumptions of viscous transport break down, as molecule–molecule collisions become infrequent as compared to molecule–surface interactions. The onset of this condition cannot be specified by a pressure, but rather by the ratio of the molecular mean free path (λ)

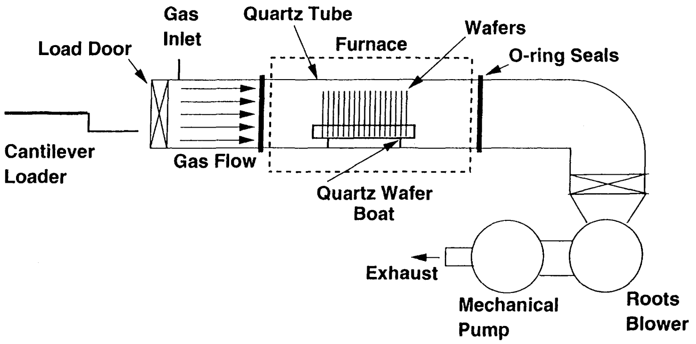

FIG. 2. A schematic of low-pressure CVD as applied to batch processing in silicon technology. High-density wafer packing is possible because of uniform gas distribution at low pressure, although other wafer carrier geometries may be employed.

to a typical system dimension (D), where $\lambda > D$. Using an interwafer dimension of 1 cm, such as in the LPCVD geometry, molecular flow will dominate for $P < 10^{-2}$ Torr. A growth method employing this approach in silicon technology is UHV/CVD (Meyerson, 1986). Similarly, molecular beam epitaxy (MBE) apparatus are being adapted to this approach, where beams of gaseous molecular growth precursors are made to impinge upon heated substrates to form film. This is in contrast to the conventional mode of MBE operation, where a beam of atoms from an evaporative source is employed (see MOLECULAR BEAM EPITAXY). CVD operated at this extreme of pressure creates significant opportunities, in that layer thickness is controllable to better than atomic monolayer dimensions, and applications exploiting this new capability will be discussed further on.

3. CHEMICAL VAPOR DEPOSITION

What has been elaborated thus far is a framework within which various methods of CVD will be discussed. However, it is not within the scope of this article to discuss at great detail any one method of CVD. Rather, this entry is to serve as a resource for workers requiring access to information about a specific growth technique or materials system. A single growth technique, plasma-enhanced CVD (PECVD), may be employed to prepare films of widely varying chemical and structural makeup. Similarly, a single materials system may be deposited employing widely varying deposition processes. Consequently, presented in Tables 1 and 2 are overviews of CVD. Table 1 is broadly organized by CVD growth technique, listing the ranges of operating parameters, and common applications for each method. The exceptionally wide range of operating conditions listed comes about from the large scope of applications for which each method is employed. Application-specific information is found in Table 2, covering silicon-technology-based processes, metal CVD, and compound semiconductor growth by CVD. These entries are organized by material system. It is common for one CVD growth technique to appear under several material systems, it being adapted to the differing requirements by modification of growth chemistry. Noted earlier was the proliferation of acronyms for various deposition processes. Such acronyms frequently attempt to give the reader a hint at the approach to film growth that is being employed. However, a tabulation by either material system or growth method acronym cannot reveal the strategy underlying the development of a given CVD process. For completeness, what follows is a series of entry-level summaries of representative CVD processes in current use.

3.1 Atmospheric-Pressure CVD

Atmospheric-pressure CVD (APCVD) is commonly employed for commercial, high-temperature silicon epitaxy, as well as to prepare materials in many compound semiconductor systems. Producing layers of extraordinary perfection ($\leqslant 10$ defects/cm^2), this method is appealing for its simplicity. High temperatures are employed for substrate preparation, desorbing contaminants, and stabilizing the substrate surface prior to deposition. Examples of this surface preparation chemistry for silicon materials would be the desorption of silicon monoxide at 1000 °C into a hydrogen ambient, while GaAs would be stabilized by a more moderate bake at 800 °C in an arsine-rich hydrogen carrier gas. Growth precursor, diluted in an inert ambient, is then flowed through the cold-walled reactor and pyrolyzed on a heated substrate. High deposition rates are readily obtained, of order several thousands of angstroms per minute. APCVD is primarily employed for the growth of thick, compositionally uniform layers, although work at the research level is under way to lower overall processing temperatures with the goal of producing highly controlled abrupt compositional transitions in film alloy and dopant content. The primary approach to the reduction of the thermal budget for APCVD is to employ rapid thermal processing methods, where samples may be cleaned at high temperatures, followed by rapid temperature reduction to the desired growth temperature. In parallel with this, efforts are under way to operate such reactors in the methodology of UHV, controlling chamber contamination levels by using load-locked introduction chambers and high-purity gaseous sources. Although total pressure remains atmospheric, the partial pressure of contaminating species in such reactors can be reduced to $\simeq 10^{-6}$

Table 1. Operating parameters of commonly employed chemical methods.

Growth technique	Deposition Pressure (Torr)	Deposition Temperature (°C)	Excitation	Film growth applications	Figure	Reference

Torr, with a remarkable improvement (Sedgewick *et al.*, 1991) in film quality at a given growth temperature.

3.2 Reduced-Pressure CVD (RPCVD)

Reduced-pressure CVD (RPCVD) is a term reserved primarily for the subatmospheric-pressure deposition of epitaxial silicon, as shown schematically in Fig. 3. RPCVD is identical to APCVD, other than in the utilization of moderate vacuum (10–80 Torr) to sharpen dopant transition widths in films deposited upon doped substrates. The use of high temperatures and resultant high growth rates are common to both techniques. In the MOCVD (metal-organic CVD) adaptation of this method, it has been shown that the reduction of operating pressures allows the fabrication of layered III–V superlattices, as well as lasers, which have overall quality approaching that found by earlier beam techniques such as MBE.

3.3 Low-Pressure CVD (LPCVD)

Low-pressure CVD (LPCVD) is one of the most versatile film growth methods. Widely used throughout silicon technology, this method operates at significantly lower pressure ($0.2 \leqslant P \leqslant 2.0$ Torr) and temperature ranges ($150 \leqslant T \leqslant 650$ °C) than APCVD or RPCVD. LPCVD is most commonly utilized to deposit noncrystalline layers such as silicon dioxide, silicon nitride, metals, polycrystalline silicon, etc. This method is favored for these applications by virtue of the coatings being both uniform and conformal when deposited. The level of vacuum employed here is moderate, being of order 1.0 Torr, requiring in general a combination Roots blower and mechanical pump to handle the gas loads ($\simeq 100$ std. $\mathrm{cm}^3/\mathrm{min}$) at these pressures.

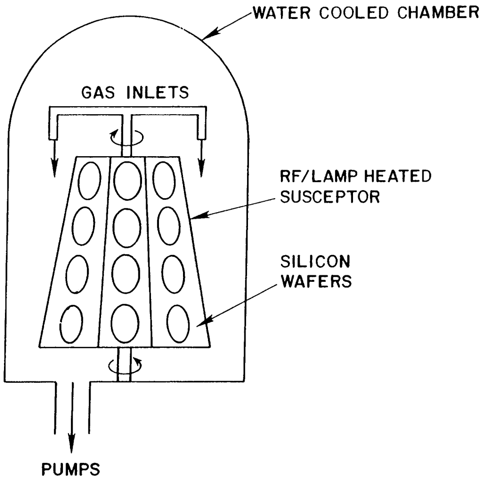

FIG. 3. A typical reduced-pressure CVD reactor as employed in silicon epitaxy or GaAs growth. The rotation of the growth susceptor, gas inlet, and in some cases the individual wafers themselves aids in attaining uniform film thickness and chemical composition.

3.4 CVD in Molecular Flow

There are now several CVD growth methods which operate in this low-pressure regime which accords them numerous desirable characteristics, and such processes constitute the most recent entry into the field of CVD. Gas transport for these processes is by molecular flow. The elimination of molecular collisions in the gas phase leads to reduced reactant depletion by homogeneous chemistry, and, where gas–surface interactions are inefficient, can result in films of extraordinary thickness and compositional uniformity. The appropriate view of a reaction chamber operating in this regime is that of a bath, where reactant distribution is completely isotropic. Transition widths between sequentially grown layers, no longer limited by gas-phase memory effects, become abrupt on the atomic scale, making feasible the large-area production of quantum-scale devices. This method has been employed in the III–V material system during chemical beam epitaxy, where a beam of metal-organic precursor molecules is made to impinge upon a heated substrate in a UHV chamber. UHV/CVD, a batch growth process in the silicon system, also employs reactant transport in this flow regime, as seen in Fig. 4.

Atomic-layer epitaxy (ALE) may also be performed under these flow conditions, where a beam is used to create a self-terminating monolayer of material A on a surface, at which time material B is deposited over A to form another self-limiting monolayer of material.

Self-limiting growth processes are most frequently encountered in polar systems, such as GaAs. Under commonly employed growth conditions, an upper bound of one complete monolayer of arsenic may be adsorbed on a free gallium surface. Upon completion of the monolayer, arsenic no longer accumulates, as

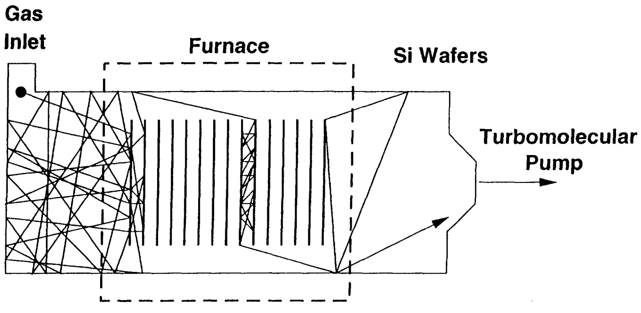

FIG. 4. Molecular transport in a batch-process reactor such as UHV/CVD. In that gaseous transport is to a good estimate similar to that of a particle in a box, concepts such as "upstream" and "downstream" are not applicable.

arsenic clusters are not stable at the temperatures employed in ALE. The gaseous source may then be exchanged for one bearing gallium, again allowing time for saturation coverage to be reached. In a similar way, other III–V species may be introduced with precision, so long as saturation coverage of the growth surface is achieved before the next gaseous source is introduced. This serves to produce artificially structured, highly ordered materials, and is applied most often to III-V systems. In such apparatus, the preferred pumping method is the use of a turbomolecular pump–mechanical pump combination. In processing at such low pressures, the choice of pumping strategy is critical for the following reason.

In the millitorr pressure regime, concepts such as upstream and downstream in a reactor fail. Any contaminant reaching the reaction vessel is uniformly distributed. There is no longer a laminar flow of gas, as in APCVD, which serves to prevent the backstreaming of contaminants. Thus, the maintenance of an appropriately clean reactor environment is determined solely by the nature of the vacuum and gas-handling equipment employed. Turbomolecular pumps, ideally suited to this application, are opaque to the backstreaming of contaminants such as hydrocarbon pump oil, and are unreactive, as pumping is purely by mechanical rather than chemical means as in an ion pump. The use of cryopumping with nominally toxic and explosive growth precursors is hazardous in that condensing out such species accumulates quantities of order many grams over time, which are then released rapidly during regeneration cycles. Thus, great care must be taken when working with CVD processes in this operating regime.

3.5 Plasma-Enhanced CVD

Plasma-enhanced CVD (PECVD) (see Fig. 5) is widely employed where a decoupling of substrate temperature from reactant temperature or energy is required. So that device dimensions may be reduced, semiconductor technologies require that the thermal budget of any given device fabrication scheme be minimized, and thus the trend toward the use of excitation schemes that allow a reduction of substrate temperatures. Plasma excitation for film growth has found application in virtually all aspects of semiconductor growth, insulator growth, metal deposition, and hardcoating deposition. Films are not generally as conformal or uniform as in thermally driven CVD processes, but engineering of discharge geometries has brought these issues to ade-

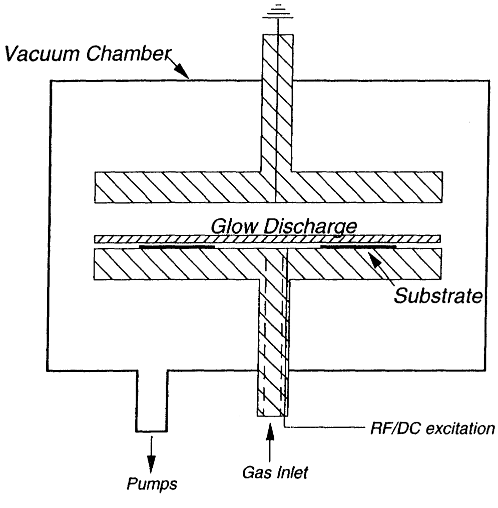

FIG. 5. Parallel-plate rf/dc plasma-enhanced CVD apparatus. Note that although wafers are shown on the powered electrode, this is not universally the case. Further, a dc bias voltage is frequently applied in addition to the rf excitation signal.

quate levels of perfection. A liability of plasma-enhanced methods is that the energies employed are adequate both to fragment the growth precursor, and to sputter impurities from chamber surfaces. Various means have been developed to minimize this effect, one being the confinement of a plasma via electron cyclotron resonance methods, or the formation of a plasma in a clean, remote chamber, from which a beam of excited species is extracted. In spite of some difficulties, PECVD is prevalent throughout the research environment, and in numerous commercial applications as well.

3.6 Photolytic CVD

Photolytic CVD (see Fig. 6) is an example of an alternative strategy for decoupling precursor temperature or energy from the temperature of the substrate. In contrast to PECVD,this method enables one to localize film growth, a trait utilized in most of the applications of this method. Direct photolysis of a source species, such as a metal-organic precursor, is frequently employed in industry to perform local repairs of circuit wiring or lithography masks. Although not well suited to large-area film growth, the prospect of directly writing a circuit by this method maintains a significant level of interest in this area. There are several methods of photo-CVD which employ large- area, high-fluence light sources to perform blanket deposition on wafer surfaces, but the control of film uniformity, and difficulties in eliminating undesirable film growth on chamber optical ports, have slowed the widespread implementation of this method.

4. MODELS—EQUILIBRIUM THERMODYNAMICS VERSUS KINETICS

Modeling of CVD is an active field, where general, accurate, predictive models are noticeably absent. The inability to generalize modeling of CVD comes about through the enormous complexity of the chemistries employed, coupled with the lack of fundamental data required to complete any given model. Moreover, before one even attempts to model a given CVD process, a basic choice must be made as to the approach to be taken. In the limiting case of a closed system, at low growth rates and high temperatures, it is frequently assumed that such a system is in a near-equilibrium state and may be characterized using thermodynamic equilibrium considerations. In the opposed limit of low-temperature, high-flow systems, it is often assumed that reaction kinetics are dominant (rate limiting). Both strategies have been employed in characterizing the CVD process. Hess *et al.* (1985) have recently reviewed this issue.

4.1 Equilibrium Thermodynamics

Equilibrium thermodynamics is frequently employed in the analysis, at least qualitatively, of a CVD process. It is attractive for its simplicity, as details of the exact growth mechanism drop out of the calculation. Rather, one must identify the number n_i of each atomic and molecular species present, as well as the chemical potential μ_i of each species. The Gibbs free energy of the system at a single operating point with well-defined temperature and pressure is simply

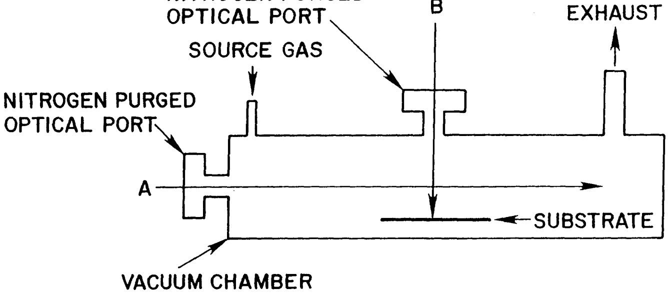

FIG. 6. Photo-CVD reactor shown in two configurations. Optical input via "A" is employed to produce gas-phase reactive intermediates for film growth over large areas. Input "B" is employed for local photothermal or photolytic CVD, allowing direct writing of features upon the substrate.

$$G = \sum_{i=1}^{i=N} n_i \mu_i .$$

Minimization of G for a given set of operating conditions, constrained by the initial values for species present, allows the calculation of the final distribution of species after equilibration with a new environment. The ability to compute the equilibrium distribution of chemical species in the reactor environment allows one to manipulate film growth in the following manner.

In the instance of silicon epitaxy, such a calculation has been performed by Bloem and Giling (1985), for the case of deposition in the silicon:hydrogen:chloride system. Figure 7 displays the calculated distribution of gaseous species present in equilibrium with solid Si over a span of temperatures, holding the Cl/H ratio fixed. From this data, one can compute the total solubility of Si in this gaseous mix when in contact with a silicon surface, shown in Fig. 8. The solubility of Si in the gas phase is limited by the atom count of silicon that may be bound in the computed distribution of hydride and halide species. As an example, for a fixed input of chlorine, conditions favoring the formation of hexachlorodisilane (Si_2Cl_6), at a resultant Si:Cl ratio of 1:3, permit the gaseous source to support a higher silicon fraction than conditions favoring the formation of silicon tetrachloride ($SiCl_4$), at a Si:Cl ratio of 1:4. Thus, using temperature to alter the distribution of silicon-bearing halide species, one may control film growth under near-equilibrium conditions. For example, when the Si-H-Cl chemical system is at equilibrium at 1300 °C, and then flowed into a reactor region held at 1100 °C, the Si content of the gaseous mix must decrease (see Fig. 8) to remain in thermodynamic equilibrium. The system therefore returns to equilibrium by reducing total silicon content by the deposition of Si onto any preexisting Si surfaces. The degree of Si supersaturation that is induced by the rapid temperature drop determines the resulting film growth rate. If this gas mixture were now allowed to equilibrate at 1100 °C, a subsequent reduction in temperature from 1100 to 800 °C would result in the etching of a silicon substrate placed in this flow. This is seen in Fig. 8, where the solubility of Si rises again at 800 °C. This ability to create controllably a supersaturation of Si in the gas phase has been widely employed in conducting selective Si epitaxy. Surfaces other than silicon, such as silicon dioxide, require a finite, non-

zero supersaturation of silicon such that film nucleation and growth proceeds. By contrast, silicon growth on silicon has no minimum requirement on supersaturation for growth to proceed. It is therefore possible to induce selective growth of silicon on silicon for small supersaturations, while silicon dioxide present in the same environment remains free of film. The trends predicted by equilibrium thermodynamic considerations as given in this example are indeed observed, but quantitative agreement between experiment and theory is rare. Further, a cautionary note is due here.

Another system where one may attempt to apply considerations as above would be the growth of III–V materials—e.g., GaAs. One of the difficulties in the growth of GaAs by MOCVD is the unintended incorporation of carbon into GaAs from the Ga precursor molecule, $Ga(CH_3)_3$. If one replaces trimethylgallium with triethylgallium, $Ga(C_2H_5)_3$, the ratio of carbon to gallium increases, and, to first order, one would expect an increase in film carbon content. The opposite occurs, as the use of triethylgallium greatly reduces the formation of surface-active methyl radicals, CH_3, and thus eliminates what was found to be an efficient source for carbon in GaAs. Using only equilibrium thermodynamic considerations to model this chemistry, even qualitatively, would predict the wrong result. This points to the power of having available a full chemical description of a reactive system, so that one may explicitly look at the dynamics of growth chemistry, rather than the equilibrated state, which may not in fact be attained in the time that a mixture is present within the reactor environment.

4.2 Kinetics-Based Reactor Modeling

In contrast to equilibrium-based models, models based upon the detailed chemistry of growth are by definition quantitative, and as perfect as one's choice of chemical model and one's knowledge of all relevant reaction rates. For precisely this reason, models based upon kinetic considerations are for the most part qualitative, and are not suited to general, predictive use. This seeming contradiction results from our lack of knowledge at present as to the exact reaction pathways and the relevant reaction rates for most CVD systems of interest.

The methodology of kinetic modeling requires that one set forth a chemical pathway by which a film is to be deposited. This must include all those reactions postulated to be relevant to film growth, both heterogeneous and homogeneous. The form such a chemical system would take for homogeneous chemistry during Si epitaxy from silane (SiH_4) could be

$$SiH_4 \rightarrow SiH_2 + H_2, \tag{1}$$

$$SiH_4 + SiH_2 \rightarrow Si_2H_6, \tag{2}$$

$$SiH_2 + Si_xH_{2(x+1)} \rightarrow \rightarrow \rightarrow Si_{x+1}H_{2(x+2)} (x \geqslant 2) \tag{3}$$

$$\cdot$$
$$\cdot$$
$$\cdot$$

The heterogeneous component would be described in detail as well, with adsorption (4), heterogeneous decomposition (5), and product evolution (6) represented as follows, where $*$ denotes an active adsite:

$$SiH_4(\text{gas}) + * \rightarrow SiH_4(\text{ads.}), \tag{4}$$

$$SiH_4(\text{ads.}) \rightarrow SiH_x(\text{ads.}) + (4-x)H(\text{ads.}), \tag{5}$$

$$SiH_x(\text{ads}) + (4-x)H(\text{ads}) \rightarrow Si(\text{cr}) + 2H_2(\text{gas}) + * \, (x \leqslant 3). \tag{6}$$

The six reactions enumerated here are a small fraction of the several hundred that need to be and have indeed been considered as part of such a model. It is found, via sensitivity analysis, that many reactions are superfluous to the growth process, and can be eliminated. However, this process relies upon one's making "reasonable" guesses as to the rate constants, forward and reverse, for each of the reactions enumerated above. Thus, though chemical kinetic modeling is potentially an exact science, it suffers from the lack of an adequate database for chemistries of general interest. In that the silane system is among the most intensely studied, Coltrin *et al.* (1984) and Jensen *et al.* (1989) have carried out the full finite-element treatment of silane-based CVD, solving a coupled hydrodynamic and chemical code from the system of reactions as above.

A more common application of kinetic modeling to CVD has been the study of rate-limiting phenomena during film growth. In this simple application of kinetic modeling, one prepares a skeletal series of growth-related chemical reactions, similar to the framework above, but assuming foreknowledge of the active growth species (e.g., the parent molecule, a homogeneously generated radical species, etc). Using what is assumed to be an accurate chemical model, one then derives the functional dependence of film growth rate upon a series of system parameters, such as reactant partial pressure, temperature, and total pressure. This approach will highlight those reactions that are rate-limiting bottlenecks in the film growth process, and has the longest history of application (Bloem and Claasen, 1980) in the analysis of CVD. Upon completion of a model, validation is by experimental verification of the projected dependence of growth rate upon process parameters. However, it must be understood that this does not prove the model to be correct, in that there is no assurance that the model assumed is unique. In spite of this considerable flaw, such early forms of kinetic modeling were frequently useful as qualitative guides as to the optimization of silicon-hydride- and -halide-based CVD.

5. APPLICATIONS

The applications of CVD are as varied as all those applications in which thin-film deposition is required. The current view of where CVD is the method of choice for film deposition is for applications that are mature, where large-area or high-throughput thin-film fabrication is required for commercial products. This is in contrast to beam techniques, notably MBE, where the emphasis is on research and early-stage development of materials and structures. Though this broad assessment has been true in the past, numerous recent applications of the CVD method have shown that the earlier designation of CVD as more of an industrial than a research tool is changing rapidly.

5.1 Passive Circuit Elements and Structures

In technology, CVD is employed to the exclusion of other growth methods in those instances where conformal coatings are required. An extreme example of the conformal nature of CVD growth is shown in Fig. 9. Shown is an advanced trench capacitor, the heart of a standard computer memory chip, and among the most common electronic components in the semiconductor industry. The aspect ratio of the trench shown is 16:1 depth to width. Fabrication consists of the use of anisotropic etching to form a periodic array of trenches in a silicon substrate. The walls of the trench are first thermally oxidized, then further insulated by the deposition of a thin layer of CVD silicon nitride. The trench is then filled conformally by the LPCVD growth of polycrystalline silicon, resulting in the trench capacitor structure shown here. The utilization of the inherent conformality of the CVD process is pervasive. Other applications are the CVD of hard coatings on tool bits employed in high-speed machining, scratch-resistant or antireflection coatings on complex optics, and the use of chemical vapor infiltration (filling of voids in woven carbon fibers in similar fashion to trench filling) to produce lightweight carbon composite parts such as disk-brake rotors.

5.2 Active Circuit Elements and Device Structures

CVD is most widely employed for the conformal growth of passive (e.g., dielectric) device and/or structure components as above. However, CVD is making rapid advances in the deposition of critical electrically active layers. MOCVD is now making inroads into the fabrication of III–V devices, and is of increasing importance at present as III–V (GaAs/GaAlAs) devices and integrated circuits are being commercialized. A more common application of MOCVD is for the fabrication of optically active devices, primarily LEDs and lasers, again in the commercial environment.

CVD, as applied in silicon device technology, has recently come into its own as a method by which active device regions themselves are formed. In existing silicon technology, CVD has long been employed as a means to prepare highly uniform substrate-like material upon which active device regions were defined by either diffusion or ion implantation. For the growth of substrate-like blanket epitaxial layers, straightforward high-temperature epitaxial growth methods were employed—e.g., APCVD and RPCVD. In the past five years, there has been a virtual revo-

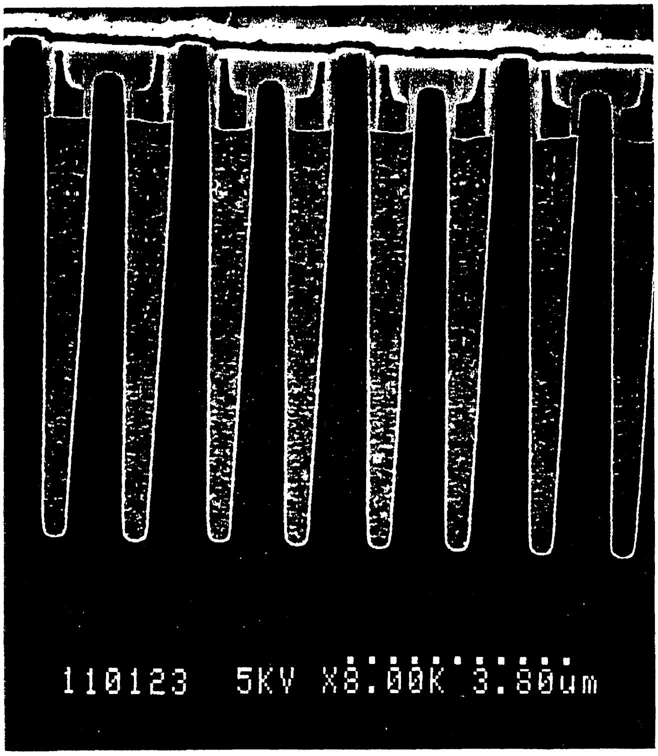

FIG. 9. The conformal nature of the CVD process was employed to fill the high-aspect-ratio features of this deep trench capacitor, the storage node in a modern dynamic random-access memory (DRAM) cell. These trenches are lined with a CVD silicon oxide/silicon nitride dual dielectric, and then filled by the CVD of polycrystalline silicon. The center-to-center spacing between neighboring pairs of trenches is 2.8 μm.

lution in silicon-based devices as a consequence of the application of CVD to this field.

With the advent of several methods of low-temperature silicon epitaxy as enumerated in Tables 1 and 2, new device designs have been implemented, employing *in situ* dopant incorporation, and utilizing as-deposited layers as the active regions of various bipolar and FET structures. The freedom of device design, and the precise control made possible, have rejuvenated the field of Si-based device design. Plate 1 is an example of a Si:Ge-based heterojunction bipolar transistor, and most noteworthy is that all colored regions of the plate represent layers prepared by CVD. Virtually all active and passive device components above the substrate are prepared by CVD, primarily because of the precision possible and the low thermal budget associated with those processes. By working at temperatures below those associated with dopant diffusion, $T \leqslant 700$ °C, the integrity of deposited dopant and alloy profiles is maintained throughout device fabrication.

As a result of advances in device design and materials deposition techniques, presumed limitations on the performance of Si-based devices have been overcome through the application of many of the band-structure tailoring methods applied earlier in the III–V system. One example of this trend was the recent fabrication, by UHV/CVD, of high-performance Si:Ge heterojunction bipolar transistors, having a unity-gain cutoff frequency of 75 GHz at room temperature (Patton *et al.*, 1990), and 94 GHz at 77 K (Crabbe *et al.*, 1990). In these devices, the nominally implanted base region of a bipolar transistor was replaced by a boron-doped, tailored Ge profile in Si. The Ge profile was tailored so as to produce a conduction band grading to accelerate electrons across the base region of the device, resulting in a doubling of previously observed Si device speed, and exceeding the projected limits of Si-based device technology.

5.3 Fundamental Materials Studies

At the forefront of the applications of CVD are those applications where film preparation is being performed (or attempted) for the creation of artificially structured materials.

The intent here is to generate, via atomic layering, materials having unique electronic and optical properties. In the least demanding (but hardly trivial) implementation, quantum-effect devices are fabricated, resonant tunneling diodes being an example (Chang *et al.*, 1983). Dimensional control in such structures must be on the order of a few atomic lengths along one dimension, film thickness in general. This field, heretofore dominated by beam methods (MBE), is now being broadened by the application of CVD methods, showing equal or better dimensional and compositional control in some instances. In the III–V system, atomic-layer epitaxy is employed to prepare structures with atomic-layer control along the growth axis, allowing the fabrication of artificially structured materials. In the case of silicon, recent work reporting the first electron-based double-barrier resonant tunneling diodes fabricated in the silicon system was CVD based, and room-temperature operation of these quantum-effect devices was demonstrated (Ismail *et al.*, 1991).

In the most aggressive application of materials fabrication, one attempts to alter the fundamental band structure of a given material system by appropriate interleaving of constituent atomic layers. This is going a step beyond quantum electronics, in that the operation of a given quantum-effect-based device is governed by the local electronic structure of the host material. Thus, one attempts to create a unique function in known device structures by alteration of the fundamental nature of the material system employed. An example is ongoing work where strain-symmetrized Si and Ge layers are interleaved in an effort to produce "zone folding," the artificial alignment of the valence-band maxima with the conduction-band minima, such that the material becomes a direct-gap semiconductor. The modification of this group-IV alloy system to produce structures with efficient optical activity would open the way for Si-based integrated optoelectronics, in the manner of the far more successful III–V-based systems. In that the outcome of this effort is far from clear, new growth techniques, CVD among them, are being brought to bear to facilitate the preparation of such demanding structures.

6. SUMMARY

What has been discussed in this article is an overview of a field that is evolving at an extremely rapid pace. Although CVD has long been employed in a variety of technical applications, it is now being widely employed within the scientific community as well. Recent advances in the field have allowed atomic-length scale control of materials properties with both abruptness and dynamic range heretofore unavailable, resulting in materials, structures, and devices having unique physical and electronic structure. There are individual articles in the *Encyclopedia* which focus on specific CVD methods discussed in broad terms above, and it is recommended that this text serve as an entry point to the field of chemical vapor deposition.

GLOSSARY

Adsite: Adsorption site at which an impinging species may bind to a surface.

Band Structure: The fundamental electronic structure of a given material, determining the transport properties of carriers in that material.

HBT: Heterojunction bipolar transistor, a bipolar transistor utilizing dissimilar semiconductor materials at its emitter-base or base-collector junctions.

Heterogeneous Chemistry: Reactions occurring at a gas/surface interface.

Homogeneous Chemistry: Reactions occurring in a single reactant phase, that being the gas phase as used in this article.

LED: Light-emitting diode.

Photolysis: Decomposition induced by the electronic energy imparted to a species by incident light.

Radical: A molecular fragment not fully coordinated, which is therefore highly reactive.

RTD: Resonant tunneling diode.

Susceptor: Energy-absorbing substrate holder employed inside a growth chamber to couple to an external energy source.

UHV: Ultrahigh vacuum, generally defined as pressure less than or equal to 10^{-9} Torr.

13.1
Introduction

The cyclotron is the first member of a class of cyclic particle accelerators that accelerate charged particles to high energies by repeated passage of the beam through one or more gaps across which a radio frequency (rf) voltage is maintained. It was conceived in 1929 by Lawrence, and the version built by Lawrence and Livingston at the University of California, Berkeley, campus in 1931 (Lawrence and Livingston, 1932) was the first machine to accelerate protons to an energy greater than 1 MeV. In a cyclotron, repeated traversal of the accelerating gap is achieved by the use of a DC magnetic field to deflect the particles in circular arcs whose radius increases as their energy increases. Operation of the Lawrence or classic cyclotron is based on the fact that if relativistic effects can be ignored, that is, when particle velocities are much less than the speed of light, the angular frequency of particle rotation is independent of energy and is determined only by the particle charge-to-mass ratio and the magnetic induction. So long as both are constant, the particle orbit frequency is constant. Acceleration is then possible if the oscillation frequency of the gap voltage is equal to the orbit frequency or is in some cases a harmonic of the orbit frequency.

At the time of its invention, the cyclotron significantly extended the range of particle energies available in the laboratory, and for many years this classic cyclotron, accelerating light atomic and molecular ions, was the mainstay of a number of nuclear research facilities. The restriction, however, to energies for which relativistic effects are negligible meant, for example, that proton energies were limited to about 15 MeV.

Over the years a number of improvements have been made to the original concept. Development of the synchrocyclotron in 1946 to overcome the nonrelativistic energy limitation of the classic cyclotron followed the enunciation of the principle of phase stability by Veksler (1944) and independently by McMillan (1945). This principle showed that stable bunches of particles could be accelerated to high energies by appropriate reduction of the frequency of the accelerating voltage in accordance with the reduction in orbit frequency due to the relativistic mass increase with increasing particle energy. Later in the 1950s an idea originally proposed by Thomas (1938), to employ a periodic variation of the magnetic field strength to provide a transverse focusing force on the beam, was revived. Such an azimuthally varying

ISBN: 978-3-527-40691-3

field (AVF) eliminated the need for a small negative radial gradient in the magnetic field, for focusing in the classic cyclotron. This then permitted the magnetic field to increase with the radius to maintain a constant orbit frequency (isochronism), and continuous wave (CW) operation, to the relativistic energies achievable with synchrocyclotrons, but with much greater beam intensities.

Rickey and Smythe (1962) successfully accelerated H^- ions, that is, hydrogen atoms with an extra electron, loosely bound, and extracted a beam of protons by stripping the associated electrons in a thin foil. This simple technique allowed a single cyclotron to deliver several extracted beams simultaneously with independently variable energy and inspired the construction of machines designed specifically for H^- acceleration.

The higher magnetic inductions achievable with superconducting magnets found an application in cyclotron design with the development of the superconducting heavy-ion (HI) cyclotron in the 1970s.

Today there are about 150 cyclotrons operating around the world, and this number is increasing at the rate of about five per year. The use of cyclotrons in nuclear research is less widespread than before; however, other fields of research and application have been developed. Many cyclotron laboratories offer customers an ion beam service. The beams are being used, for example, to label items with radioactive elements, to detect contaminants present in trace amounts, and to modify the properties of materials. Cyclotron beams can generate high fluxes of secondary particles, such as neutrons; several hospitals operate cyclotron-based neutron therapy facilities, and other cyclotrons are used in an industrial setting for neutron radiography. The majority of new cyclotrons, however, are intended to produce isotopes for incorporation into radiopharmaceuticals. These, and other, applications are described in Section 13.5.

13.2
Types of Cyclotron

13.2.1
Classic Cyclotron

A charged particle of mass m and charge qe, and moving with a velocity $\mathbf{v}$ in a magnetic field of induction $\mathbf{B}$, is subject to a force $qe\mathbf{v} \times \mathbf{B}$. For the special case of a uniform magnetic field with $\mathbf{v}$ perpendicular to $\mathbf{B}$, this results in a circular particle orbit in the plane containing $\mathbf{v}$ and normal to $\mathbf{B}$. Now a particle with an orbit radius r experiences a centripetal acceleration $\mathbf{v}^2/r$, so by Newton's second law of motion

$$qe\mathbf{v}\mathbf{B} = \frac{m\mathbf{v}^2}{r} \tag{1}$$

From this equation, it follows that the particle orbit radius is directly proportional to the particle momentum mv, and also, as Lawrence recognized, that the particle orbit frequency f_{ion} or angular velocity $\omega = 2\pi f$ given by

$$w_{\text{ion}} = \frac{qe\mathbf{B}}{m} \tag{2}$$

is constant, independent of particle energy, so long as relativistic effects are negligible and m may be considered constant.

These equations are the basis of the classic cyclotron illustrated in Figure 13.1. An essentially uniform magnetic field is generated between the circular poles of an electromagnet, and a hollow cylindrical

electrode, split along a diameter, is installed in this gap. In plan views, the two sections resemble the letter *D* and are therefore referred to as *dees*. By maintaining a high-frequency alternating voltage between the dees, an alternating electric field is established in the gap between them. During half the dee oscillation period, the electric field direction is appropriate for extraction of ions from the plasma created by an arc discharge in an ion source located between the dees near the center of the magnet. If the oscillation period of the applied dee voltage is chosen in accordance with Eq. (2), then particles extracted when the electric field is at or near its maximum travel in a circular path, shielded from the electric field while inside the dee, to return to the dee gap half a period later when the field is again at a maximum and in the direction of the particle motion. The beam, therefore, consists of a series of bunches of particles separated by the rf period. At each successive gap crossing the particle, energy is increased with a concomitant increase in orbit radius until the maximum energy and orbit radius, as determined by the magnet pole size, are reached. At this point, in early cyclotrons, the particle beam hit an internal target and initiated nuclear reactions. It is preferable, however, to extract the beam from the cyclotron and lead it to a separate experimental area. This reduces the activation of cyclotron components and permits a much wider range of applications.

The beam is extracted by means of an electrostatic deflector. This consists of a pair of curved electrodes, one a thin grounded metal plate, called a *septum*, which is interposed between the penultimate and final turns of the accelerated beam, and the other a matching electrode located at a slightly larger radius and carrying a high DC voltage. The transverse electric field between the two electrodes provides sufficient radial deflection to enable the beam to be clear of the magnetic field in less than one turn.

Ions that collide with gas molecules while being accelerated may be lost from the beam. To reduce this loss, the volume between the magnet poles, including the dees and other components, is enclosed in a chamber and evacuated.

To produce useful beam intensities in a cyclotron, it is essential that particles having orbits that deviate from the ideal trajectory should also be accelerated and be extractable. An elementary discussion of the beam stability required to achieve this may ignore the effects of acceleration and consider only the motion of particles of selected energies about their corresponding closed or equilibrium orbits. For the classic cyclotron in Figure 13.1, these are circles in the midplane, concentric with the magnet center. The magnetic field in this case is azimuthally uniform but may vary slowly with radius, resulting in curved field lines and nonzero radial field components $B_r(r, z)$ off the midplane, as illustrated in Figure 13.2. To obtain the conditions for focusing in the axial and radial directions, we begin by describing the local midplane field variation by an index $k(r)$ such that

$$B_z(r) = B_z(r_0)\left(\frac{r}{r_0}\right)^{k(r_0)} \tag{3}$$

Here B_z is the midplane magnetic induction, r_0 the equilibrium orbit radius, r a nearby radius, z the axial direction perpendicular to the orbit plane, and

$$k = \frac{\left(\frac{\Delta \mathbf{B}}{\mathbf{B}}\right)}{\left(\frac{\Delta r}{r}\right)} = \left(\frac{r}{B_z}\right)\left(\frac{dB_z}{dr}\right) \tag{4}$$

A particle displaced axially experiences a radial field component $B_r(r, z)$ (Figure 13.2), and an axial force F_z. By retaining only the linear term in the Taylor expansion for B_r about the midplane, $z = 0$, and using the fact that curl $\mathbf{B} = \mathbf{0}$ in the magnet gap, we find that

$$\begin{aligned} B_r(z) &= z\left(\frac{\partial B_r}{\partial z}\right)_{z=0} + \cdots \\ &= z\left(\frac{\partial B_z}{\partial r}\right)_{z=0} + \cdots \end{aligned} \tag{5}$$

and the axial force is

$$F_z = qev_\theta B_r = m\ddot{z} = qev_\theta z\left(\frac{k}{r}\right)B_z + \cdots \tag{6}$$

Particles with small displacements from the magnet midplane experience a linear restoring force, provided k, or more specifically the gradient, $\partial B_z/\partial r$, is negative. Using Eqs (1) and (6), the equation of motion may be written as

$$\ddot{z} - w^2 k z = 0 \tag{7}$$

which, when k is negative, describes simple harmonic motion about the midplane with frequency $\omega_z = \omega_z = \sqrt{-\omega^2 k}$. The oscillation frequency is more commonly expressed in terms of the ion rotation frequency,

$$Q_z = \frac{\omega_z}{\omega_{\text{ion}}} = \sqrt{-k} \tag{8}$$

and Q_z termed the axial betatron frequency, since the theory was first developed

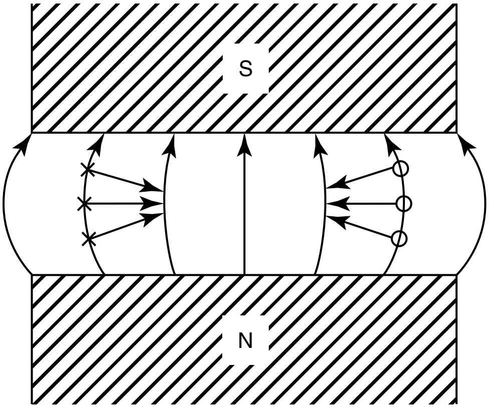

Fig. 13.2 The vertical focusing effect of a radially decreasing magnetic field. The figure shows lines of magnetic induction and the forces experienced by protons traveling in clockwise orbits when seen from above.

for the betatron accelerator. Should k be positive, Eq. (7) describes a steadily increasing axial displacement and particles would eventually collide with the dee or other structures.

A somewhat more complex derivation shows that particles displaced radially from their equilibrium orbits are focused provided that $k > -1$ and that they execute linear betatron oscillations with $Q_r = \omega_r/\omega_{\text{ion}} = \sqrt{1+k}$. (The origin of the restoring force may be comprehended by noting that the centripetal force required for circular orbits decreases as $1/r$ (Eq. (1)). Should the magnetic field decrease more slowly than this, then a particle at a radius larger than its equilibrium orbit will be bent more and focused back toward the equilibrium orbit.) Values of $k < -1$ occur in the edge field of the magnet, the orbit unwinding in a strongly defocusing (radially) field.

For both radial and axial motions to be stable, the midplane field must decrease with radius such that

$$-1 < \left(\frac{r}{B_z}\right)\left(\frac{dB_z}{dr}\right) < 0 \tag{9}$$

A radially decreasing field means that the resonance condition, that is, the equality between the orbit frequency, as in Eq. (2), and a fixed dee frequency, cannot be satisfied everywhere. If $\omega_{\text{rf}} = \omega_{\text{ion}}$ at the cyclotron center, then the revolution time of particles with higher energy will exceed $2\pi/\omega_{\text{rf}}$ and the particles arrive at the dee gap at progressively later times with respect to the peak of the accelerating voltage. If we write the energy gained each turn in the two-dee cyclotron of Figure 13.1 as

$$E_G = 2qe2\widehat{V}\cos\phi \tag{10}$$

where V is the peak voltage on one dee and ϕ is the voltage phase when the particle crosses the dee gap center, then progressively later arrival times correspond to a progressive increase in ϕ until, eventually, the accumulated phase slip exceeds $\pi/2$, at which point acceleration ceases and particles begin to decelerate back toward the machine center where they are lost. The lack of isochronism and its consequent phase slip is exacerbated by the relativistic increase in mass, $m = \gamma m_0 = (1 + T/E_0)m_0$, which causes the rotation time to increase as the kinetic energy T increases. To postpone the inevitable deceleration to the highest possible energy, classic cyclotrons operated with the highest sustainable dee voltage. However, the practical limit corresponded to 100 or 200 turns and $\gamma_{\text{final}} \approx 1.02$.

The U-150 machines built in the Soviet Union are examples of late-period classic cyclotrons. Protons were accelerated to 12 MeV, deuterons to 20 MeV, and α particles (^{4}He) to 40 MeV in a 330-ton magnet with a pole face diameter of 1.5 m. The dee voltage was 85 kV at 10 MHz and the electrostatic deflector held 70 kV. Beam currents up to 250 μA (1.5×10^{15} proton s^{-1}) were obtained.

13.2.2
Synchrocyclotron or Frequency-Modulated Cyclotron

Two methods have been devised to deal with the problem of phase slip and thus permit acceleration to high energies. Frequency modulation, described subsequently, was implemented first; an alternative method, due to Thomas, will be discussed in Section 13.2.3.

In the frequency-modulated (FM) cyclotron, or synchrocyclotron, the frequency of the accelerating voltage is lowered progressively so that it matches the rotation frequency of a hypothetical reference ion, termed the *synchronous particle*, as it is accelerated. A cluster of bunches captured at about the same time can thus be accelerated to energies far beyond the synchronism limit of the classic cyclotron. Following extraction of the cluster, the rf oscillator is returned to its starting frequency, another batch of ions captured, and the process repeated.

If it were essential that the ion orbit frequency and the accelerating frequency match exactly, then the phase acceptance and capture time interval would be small and the beam current low; it would also be difficult to program the rf. Fortunately Veksler (1944) and McMillan (1945) showed independently that exact matching is not necessary because, within certain limits, ions whose energy or phase deviate somewhat from the synchronous ion will oscillate, in energy and phase, about that particle and gain energy at the same average rate. This behavior, termed the *principle of phase stability*, makes synchrocyclotrons and also synchrotrons and linear accelerators practical machines.

The principle was first demonstrated experimentally by Richardson *et al.* (1946). The first synchrocyclotron to surpass the classic cyclotron limit operated at Berkeley, also in 1946, and accelerated deuterons and α particles to 95 MeV amu^{-1}. About 20 synchrocyclotrons have been built. The repetition rates for frequency modulation range from 50 to 4000 Hz, while ions are captured into phase-stable orbits typically for 0.01–0.1 ms; consequently the duty factor and beam intensity are about 1% of that from a cw cyclotron. The long acceleration time means that ions make many turns, and dee voltages are low, typically 10–50 kV.

The highest proton energies, 1000 MeV, are achieved in the synchrocyclotron at the St. Petersburg Nuclear Physics Institute, Russia. The machine at the European Centre for Nuclear Research (CERN), Geneva, Switzerland, has accelerated 7 μA of protons to 600 MeV and ~0.2 particle μA of carbon, oxygen, and neon to ~80 MeV amu^{-1}. The 3000-ton magnet has a 5-m pole-tip diameter and a field falling from 1.94 to 1.81 T. A single dee is used with a voltage 20 kV. A frequency swing between 30.4 and 16.6 MHz for protons and, for example, 7.6–6.6 MHz for ^{20}Ne^{5+} is provided by a rotating capacitor at 360 Hz.

Synchrocyclotrons pioneered research in meson physics, studies of nucleon–nucleon forces, and particle therapy for cancer and other diseases. These roles are being taken over by AVF machines, although there are proposals to build new synchrocyclotrons for therapy since currents of a few nanoamperes are adequate, and the simplicity of construction and operation may give some competitive advantage.

13.2.3
The Sector-Focused, Isochronous, or AVF Cyclotron

To maintain an ion rotation time that is independent of energy (isochronism), the midplane magnetic induction B_z of the classic cyclotron should increase with radius as

$$\begin{aligned} B_{\text{isoch}}(r) &= \gamma(r) B_0 \\ &= B_0 \left(1-\beta^2\right)^{\frac{-1}{2}} \\ &= B_0 \left[1-\left(\frac{r\omega}{c}\right)^2\right]^{\frac{-1}{2}} \end{aligned} \tag{11}$$

where γ and β are the usual relativistic quantities. Such a field is axially defocusing. To overcome the defocusing force and provide adequate axial focusing, Thomas (1938) proposed that an azimuthal variation in B_z be introduced by installing three or more wedge-shaped iron sectors (often called hills) on opposing pole faces of the magnet, as in Figure 13.3. The particle path has a smaller radius of curvature in the hill and a larger one in the intervening valley. Therefore, the closed, or equilibrium, orbit now has a radial modulation, termed *scalloping*, about its average value. Particles have a radial velocity component v_r at the sector edges. Those particles displaced from the midplane experience an azimuthal component of induction $\mathbf{B}\theta$, resulting in an axial force $qev_r\mathbf{B}\theta(r,\theta,z)$ that is focusing at both edges of a sector.

Additional focusing can be realized by having the sectors follow a spiral rather than a radial locus. The curved hill edges then produce a radial component of $\mathbf{B}$ off the midplane that results in an axial force $qev\theta B_r(r,\theta,z)$. This force focuses at the convex hill edges and defocuses at the concave edges. Following the well-known principle of classical optics for a series of focusing and defocusing lenses of equal strength (the strong-focusing principle), the net effect is focusing. In fact, the focusing is even stronger because, as detailed calculations for cyclotron beam optics show, the focusing edge is stronger than the defocusing one.

A Fourier series can be used to describe the midplane induction and the orbit scalloping:

$$\begin{aligned} B_z(r,\theta) = \overline{B}_z(r) \Bigg[1 + \sum_p \big(H_p(r)\cos p\theta \\ + G_p(r)\sin p\theta \big) \Bigg] \end{aligned} \tag{12}$$

$$\begin{aligned} r = \overline{r} \Bigg[1 + \frac{1}{p^2} \sum_p \big(H_p \cos p\theta \\ + G_p \sin p\theta \big) \Bigg] \end{aligned} \tag{13}$$

The magnitude of the azimuthal variation of midplane induction is termed the *flutter* $F(r)$, where

$$\begin{aligned} F &= \frac{1}{2} \sum_p \left(H_p^2 + G_p^2 \right) \\ &\approx \left(B_{\text{hill}} - \overline{B} \right) \frac{\left(\overline{B} - B_{\text{valley}} \right)}{\overline{B}^2} \end{aligned} \tag{14}$$

The betatron frequencies cannot be given in a closed form for the AVF cyclotron; however, several authors, for example, Hagedoorn and Verster (1962), have obtained

Fig. 13.3 (a) Equilibrium orbits in a sector-focused (AVF) cyclotron. The inner orbit (i) experiences Thomas focusing from radial sectors; orbit (ii) also experiences strong focusing from spiral sectors. (b) Vertical forces seen by orbit (i) at sector boundaries.

expressions for Q_z and Q_r in the form of infinite series, the leading terms of which are useful approximations, such as,

$$Q_z^2 = -\overline{k} + \left[\frac{N^2}{(N^2-1)}\right] F\left(1 + 2\tan^2\xi\right) + \cdots \tag{15a}$$

$$Q_r^2 = 1 + \overline{k} + \cdots \tag{15b}$$

where $k(r)$ is now the average field index, N is the number of sectors, and $\xi(r)$ is the spiral angle (Figure 13.3(a)).

For perfectly isochronous machines k may be replaced by $\gamma^2 - 1$. From Eq. (15a) it can then be seen that the axial focusing strength will tend to decrease with increasing particle energy. To counteract this, especially in high-energy cyclotrons, designers increase the spiral angle with radius, up to a practical limit of ~70°.

Isochronous cyclotrons can both accelerate a wide variety of ion species and vary the energy of the beam extracted by altering the dee frequency and making the appropriate adjustments to field strength and shape. The relation between the kinetic energy T, the field, and radius may be obtained by writing Eq. (1) in its relativistic form, $\overline{Br} = \beta\gamma m_0 c/qe$, and recalling that $m_0c^2\gamma = E_0 + T$, where E_0 is the rest energy of the ion. The result

$$\overline{Br} = \frac{\left(T^2 + 2TE_0\right)^{\frac{1}{2}}}{qec} \tag{16}$$

is sometimes more conveniently expressed in terms of energy per nucleon T/A, where A is the ion mass in atomic mass units. This relation is plotted in Figure 13.4 for several charge/mass ratios. The diagram can be made more useful for defining the operating range of a cyclotron by adding a scale corresponding to fr, where f is the ion orbit frequency. The radio frequency range required can be reduced by operating, for some T/A, at a harmonic of the rotation frequency, that is, $f_{\mathrm{rf}} = hf_{\mathrm{ion}}$. Two isochronous cyclotrons of the type discussed earlier, which have accelerated many different ion species are the 88-in. AVF cyclotron at the Lawrence Berkeley Laboratory and the Variable Energy Cyclotron at the Atomic Energy Research Establishment, Harwell, UK; both were built in the early 1960s.

The maximum energy attainable by an ion in a given magnet may be set either by its ability to bend the trajectory into a closed orbit (Eq. (16)) or by its ability to provide axial focusing (Eq. (15a)). The bending power is sometimes characterized by K_b, where, in the nonrelativistic approximation, $T/A \approx K_b(q/A)^2$. Saturated iron gives fields in the region of 2 T; however, superconducting excitation coils can contribute an extra 4 T and $K_b \approx 1000$ T m can be achieved in compact, single-pole machines with extraction radius 1 m. The iron sectors in these superconducting cyclotrons are saturated at all working fields; the field modulation is constant and therefore the flutter is inversely proportional to $\overline{B}^2$. This behavior led Blosser and Johnson (1974) to introduce a second magnet parameter K_f to characterize the focusing limit and, for superconducting cyclotrons, the maximum energy per nucleon is the lesser of $K_b(q/A)^2$ and $K_f(q/A)$. The situation is different for cyclotrons using unsaturated iron; for these the flutter is almost independent of excitation. Superconducting machines to accelerate heavy ions began operating at the National Superconducting Cyclotron Laboratory (NSCL-MSU), East Lansing, Michigan, and at Chalk River National Laboratories, Canada, in the 1980s.

Before this, during the 1960s, the concept of the separated-sector cyclotron (SSC) had been developed, first at the

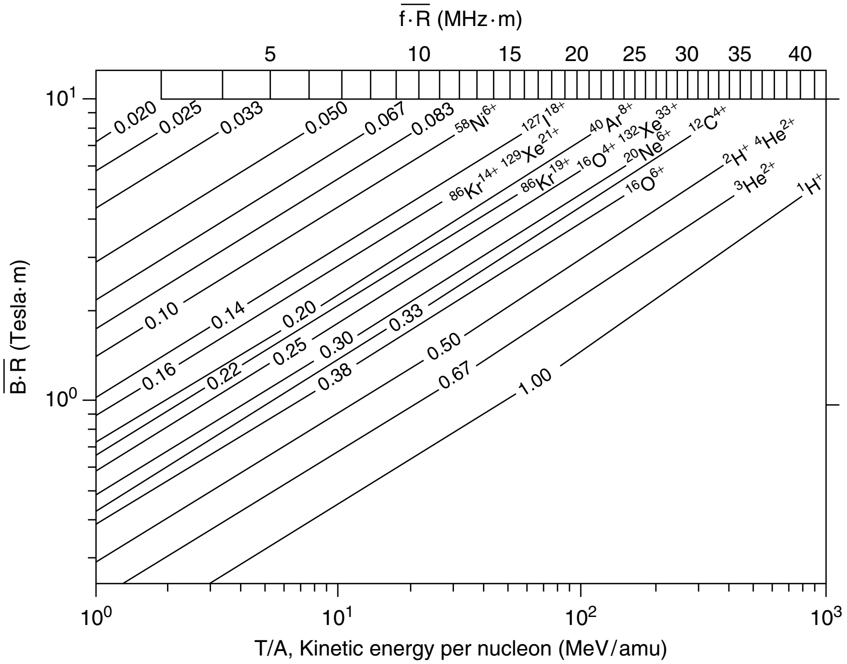

Fig. 13.4 A chart useful for initial design showing the relationship between kinetic energy, magnetic field, extraction radius, and orbital frequency for ions with different q/A. A laboratory with an operating machine may redraw such a figure using axes of field and dee frequency/harmonic.

Paul Scherrer Institute (PSI), Villigen, Switzerland (Willax, 1963), and then at the Indiana University Cyclotron Facility (IUCF), US. In these machines individual sector magnets are arranged in a pinwheel manner (Figure 13.5) and powered in series. The absence of iron in the valleys provides easier access and space for other equipment, especially for efficient, high-Q, rf cavities operating at high voltage that, in turn, lead to more efficient beam extraction. The valley field is small and the flutter F approaches unity. The lower average field, however, means a larger, more costly, cyclotron, and the absence of a conventional center region means that ions must be pre-accelerated to an energy corresponding to the first turn.

Sector-focused cyclotrons are examples of fixed-field alternating-gradient (FFAG) accelerators. This term, however, is usually reserved for machines with magnets of SSC style and with a field shaped such that the betatron frequencies are independent of radius (energy). This would allow ions to be accelerated to high energies, GeV amu^{-1}, while avoiding resonances in betatron motion, but since the field is no longer isochronous, the accelerating frequency must be modulated as in a synchrocyclotron. Several proton FFAG machines of the latter type have been proposed but only models, accelerating electrons, have been built.

More than 100 AVF machines have been built since the first isochronous

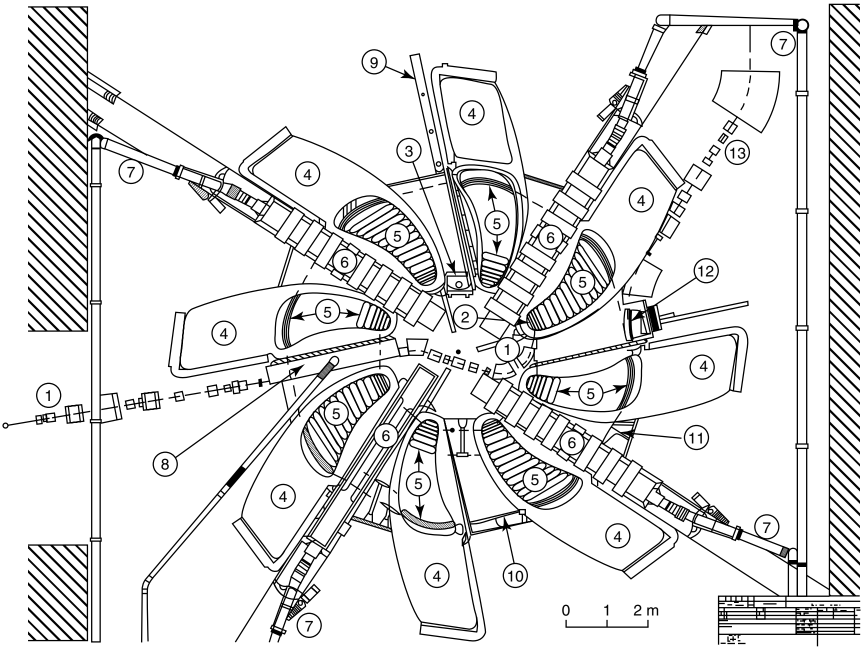

Fig. 13.5 The PSI separated-sector cyclotron. This machine accelerates protons from 72 to 590 MeV. cyclotron, equipped with radial sectors and accelerating protons to 12 MeV, operated at Delft, The Netherlands, in 1958. They range from small machines accelerating protons to a few mega electronvolts to machines several meters in diameter, some of which accelerate intense beams of protons to hundreds of mega electronvolts, while others are capable of accelerating virtually any element in the periodic table to energies of $\sim$100 MeV per nucleon. The distribution of K values for machines currently operating is given in Figure 13.6. Virtually all new cyclotrons are of the AVF type, and some older machines have been converted; for example, the synchrocyclotrons at the Joint Institute of Research, Dubna, Russia, and the University of Uppsala, Sweden, now have sectors added to their magnet poles to improve performance. Many new cyclotrons accelerate negatively charged hydrogen ions, H^-, in order to exploit the simple and versatile stripping process for extraction. They are intended for nontraditional fields of research and commercial applications. One such machine is illustrated in Figure 13.7, and the parameters of another are given in the appendix.

Perhaps the most novel cyclotron under construction is a separated-orbit cyclotron, called *TRITRON*, at the Technical

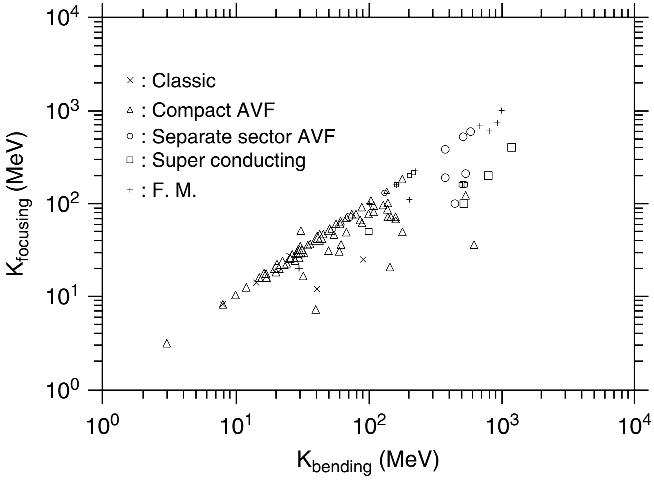

Fig. 13.6 Parameters describing the maximum energy per nucleon attainable in 143 cyclotrons of different types. The symbol size is proportional to the number of machines with the same parameters; however, cyclotrons manufactured commercially are underrepresented. $(T/A)_{max}$ in MeV amu^{-1} is the lesser of $K_b(q/A)^2$ and $K_f(q/A)$. (From the compendium attached to the proceedings of the 11th International Cyclotron Conference).

University, Munich, Germany. It employs 12 superconducting sector magnets and 6 superconducting rf cavities, each capable of 0.5 MV. Ions are injected from a potential-drop accelerator and their energy increased fivefold in only 20 turns. Orbits are separated by ∼4 cm; conductors can be placed around each turn in each sector and the magnetic field and gradient, and hence steering and focusing, adjusted at each step.

13.2.4
The Microtron (Electron Cyclotron)

Microtrons are constant-field, constant-rf, cw electron accelerators. The low electron mass ($m_0c_2 = 0.511$ MeV) means that the particles are relativistic at very low energies and that the orbit frequency is (28 GHz T^{-1})$\mathbf{B}/\gamma$. Electrons would rapidly lose synchronism in a conventional cyclotron; however, Veksler showed in 1944 that a suitable energy gain E_G could be found for which the phase slip for each turn corresponded to an integral number of rf cycles and, that the principle of phase stability applied. The orbits are not concentric but arranged to have a common tangent at which point an accelerating cavity is placed. This cavity may even be a small linear accelerator. The relative energy gain per turn is high, orbits are well separated, and extraction is straightforward. The highest-energy microtron is the 850-MeV stage at Mainz, Germany, which is intended for nuclear research. Most microtrons operate at tens of mega electronvolts and are used as injectors for other electron accelerators or as compact sources for radiation therapy. Currents are of the order of 100 μA. Although occasionally termed electron cyclotrons, microtrons are usually considered to be a separate field and the reader is referred to the general references at the end of the chapter.

13.3
Design Considerations and Subsystems for an AVF Cyclotron

The design of a cyclotron is an iterative process during which many parameters, which interact with one another, are brought to an overall optimum. Some design considerations are introduced in the following text, but the most complete sources of information are the published proceedings of conferences on accelerators and related topics referred to for further reading.

13.3.1
Beam Physics

13.3.1.1 Resonances

Ions accelerated in an AVF machine undergo many transverse oscillations that can exhibit the same phenomena, for example, amplitude growth at resonance or coupled motion, seen in other periodic systems. For example, the inclusion of higher-order terms in the field expansion (Eq. (5)) transforms Eqs (6) and (7) from a description of free to one of forced oscillations. For a field harmonic p (Eq. (12)), the general resonance condition is

$$mQ_r + nQ_z = p, \quad m, n, p \text{ integers} \tag{17}$$

Energy may, in principle, be transferred between transverse and longitudinal motion; however, while the phase in an AVF cyclotron may deviate from an average value it does not perform periodic oscillations. This is not the case for synchrocyclotrons, and a term involving the frequency of phase oscillations would be included in Eq. (17).

Resonances in betatron motion influence the choice of Q_z, the number of magnet sectors and accelerating gaps, and the tolerances of manufacture and assembly.

In an isochronous cyclotron, $Q_r \approx \gamma$ and so may start near 1 and increase with energy; also Q_z frequently rises from a low value near the center of the machine where the field modulation F is small and changes again on approaching the focusing limit or the fringe field where k deviates from the isochronous requirement. In superconducting cyclotrons, different magnet excitations have a marked effect on F and Q_z. Consequently, one or more resonances may be crossed. The Mathieu–Hill differential equation describes particle motion with periodic focusing; analysis shows that the phase shift of a betatron oscillation is $2\pi Q_{r,z}$ per N per sector and that motion becomes unstable when this phase shift is π. Consequently, stable radial motion is not possible in a two-sector cyclotron; at least three sectors are required at low energy. For each N there is a corresponding limiting value for Q_r. Should $N = 3$, for example, then $Q_r \leqslant \frac{3}{2}$, which, in the case of protons in an isochronous cyclotron, corresponds to 469 MeV. In practice, the limit is somewhat lower.

Low-order – m (or n) $= \pm 1$ or ± 2 – resonances may be crossed provided the pth amplitude or gradient is small; small coils are often placed in the resonance region and their currents adjusted empirically to cancel any magnetic field errors remaining after assembly. Higher-order resonances, $m = \pm 3, \pm 4, \pm 4, \cdots$, correspond to nonlinear terms and may be traversed, provided the betatron amplitudes are small (Hagedoorn and Verster, 1962).

Cyclotrons intended for nuclear physics research may be required to preserve polarization of the beam during acceleration. The angular momenta or spins of atomic nuclei are usually randomly distributed. Polarized ion sources select and populate one spin orientation. These ions are injected with spins aligned with the magnetic field and precess about this axis at the Larmor frequency. Those particles whose motion causes them to experience, in the rest frame, a quasi-constant transverse field component will begin to precess about the resultant, nonvertical axis. Conditions for depolarization exist whenever

$$\gamma G + mQ_r + nQ_z = p \qquad (18)$$

where G is 1.79 and -0.143 for protons and deuterons, respectively, and -3.79 and -1.86 for H^- ions and D^- ions. Driving terms arising from field imperfections can, again, be compensated by coils. Depolarization has not been observed in positive-ion cyclotrons, but the large negative G values for H^- and D^- make resonances with the sector symmetry more likely, and H^- polarization changes of 7% have been observed at the six-sector TRIUMF cyclotron, Vancouver, Canada, and complete depolarization at the University of Manitoba, Canada, four-sector machine.

13.3.1.2 Electric Forces

The forces exerted on an ion by a magnetic field are proportional to both charge and velocity, while those from an electric field depend on the charge alone. The two are equivalent when $E = (300\,\mathrm{MV\,m^{-1}\,T^{-1}})\beta\mathbf{B}$. Electric fields, therefore, are relatively more important at low energies.

The electric field at an accelerating gap is illustrated in Figure 13.8. An axially focusing kick is experienced by particles entering the gap, a defocusing kick on

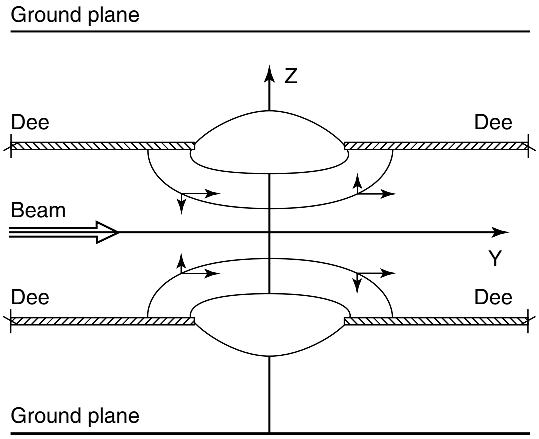

Fig. 13.8 Electric field lines and their components in the acceleration gap.

leaving it. At low energies the transit time may be a substantial fraction of the rf period, leading to a net focusing effect for particles in the gap when the voltage is falling (positive phases). Flutter vanishes at the magnet center, and electric focusing can so dominate the first few turns that the defocusing of ions with negative phases can lead to their removal from the accelerated beam. Another defocusing force arises from the mutual repulsion of the ions. This space-charge force, which is proportional to the charge density, is the major factor limiting the beam current at low energies. At any energy the distribution of accelerating impulses around a turn may have a *p*th harmonic satisfying Eq. (17); gap-crossing resonances may also be driven by the beat frequency arising from the combination of dee and sector symmetries.

The forces from the accelerating structure depend on the ion phase; so do the space-charge forces, usually.

13.3.1.3 **Charge-Changing Phenomena**

An ion that picks up an electron, or has one stripped from it, will alter its charge/mass ratio, drop out of synchronism, slip in phase, and eventually be decelerated and lost. Either may follow from a collision with a residual gas molecule however, and except in highly ionized heavy ions, stripping dominates once acceleration has begun. The cross section per atom $\sigma(T)$ for stripping H^- to H^0 in air is usefully approximated by $7 \times 10^{-19}/\beta^2\,\mathrm{cm}^2$ and the fraction lost by $2.36 \times 10^4\ P(E_0/E_G)R_e$ where P (bar) is the operating pressure and R_e (m) is the extraction radius for a cyclotron with $\gamma \approx 1$. The cross section for stripping in hydrogen is eight times smaller. A vacuum of 10^{-10} bar seems adequate for compact HI or H^- cyclotrons, and 7×10^{-11} bar for larger machines.

At high energies, the Lorentz electric field $\mathbf{E} = \gamma \mathbf{v} \times \mathbf{B}$ lowers the potential barrier of weakly bound negative ions sufficiently to allow quantum-mechanical tunneling to occur and an electron to escape. Measurements and theory are in good agreement, the lifetime for an H^- ion under such conditions being

$$\tau = \left(\frac{a}{\mathbf{E}}\right) \exp\left(\frac{b}{\mathbf{E}}\right) \tag{19}$$

where $a = 2.47 \times 10^{-6}\,\mathrm{V\,s\,m^{-1}}$ and $b = 4.49 \times 10^9\,\mathrm{V\,m^{-1}}$. Figure 13.9 gives, for H^- ions of several energies, the fraction

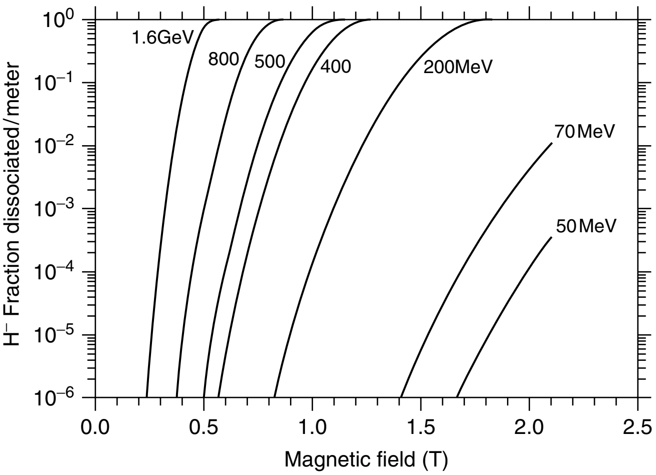

Fig. 13.9 Dissociation of H^- ions as a function of field strength and energy (path length = 1 m).

dissociated per meter path length as a function of the magnetic field strength. The steepness of Eq. (19) means that this electromagnetic stripping is localized to the hills and the highest energies of a given cyclotron.

13.3.1.4 **Computer Codes**

Analytic methods are complemented by the extensive use of computer codes. These are especially important in calculating trajectories of ions in electric and magnetic fields and thence the betatron frequencies and deviation from isochronism (Gordon, 1984). The fields themselves, when they cannot be measured, may be calculated using two- or three-dimensional finite-element codes.

13.3.2
Magnet

The maximum magnetic rigidity ($\overline{Br}$) required can be obtained by use of Eq. (16) or Figure 13.4. The peak hill field is usually at or near magnetic saturation. The field increase required for isochronism and the required flutter F then determine the maximum central field value B_0. This is generally used in order to minimize magnet size and cost. Exceptions are the higher-energy H^- cyclotrons where ion dissociation (Figure 13.9) restricts the hill field. The gap field of a magnet falls rapidly, approaching a pole edge; consequently the maximum isochronous orbit radius is smaller than the pole radius by at least half the hill gap width.

The yoke serves as a low-reluctance flux-return path. Early cyclotrons employed the H-frame design illustrated in Figure 13.1. Beam ports, dee stems, and other services were inserted through the open sides, and modifications were easily made. Superconducting machines and modern compact cyclotrons have a more efficient flux-return structure that surrounds the pole and has midplane and vertical penetrations for extracted beam and other services. This provides, also, some shielding from induced radioactivity (Figure 13.7 and Appendix). Access to the interior of the vacuum vessel is obtained by raising the upper yoke, pole, and vessel lid.

Both the poles and yoke are fabricated either from low-carbon mild steel in the form of forgings or rolled plate, or from soft iron castings. The magnetomotive force is provided by coils fitted around the poles, generally wound from hollow, water-cooled, copper conductor. Power consumption ranges from 30 kW for a minicyclotron to almost 1 MW for separated-sector machines with large K_b.

Two- or three-dimensional finite-element codes can be used to determine flux distributions in the pole and yoke, the ampere-turns required for excitation, and to some degree, the average flux distribution in the gap. With their aid, magnets can be designed that generate fields within 1% of a specified design objective. This is generally not precise enough for cyclotron operation, and an iterative process of field mapping followed by shimming, that is, adding or removing small amounts of iron at various locations in or near the gap, must be included as part of magnet fabrication and commissioning. This procedure reduces deviations from the ideal field to a few milliteslas, which may be adequate for low-energy cyclotrons. For others with tighter tolerances, auxiliary coils are included for empirical adjustments of the isochronous field, or correction of field harmonics, based on measurements of beam properties. These are termed *trim coils* and are wound on the pole face or vacuum vessel (e.g., Figure 13.5). Similar coils of larger power are used to produce the changes in $\mathbf{B}(r)$ required for isochronous operation with different γ_{final}.

The superconducting cyclotron employs superconducting windings in a magnet with iron yoke and poles at room temperature. The high current density, typically 3000 A cm^{-2}, achievable in superconductors makes magnets with large (6 T) gap inductions possible. This results in a considerable economy when designing a cyclotron to accelerate, for example, partially ionized heavy ions with low q/A and high magnetic rigidity. All coils built to date use copper-stabilized multifilament NbTi superconductor, and, because of the large stored energies involved, all are cryostatically stable. A high copper-to-superconductor ratio, typically 20 : 1, is used to make a winding with many internal channels, allowing good thermal contact between the liquid helium bath coolant and the conductor. The iron of the hills and pole is completely saturated and can be treated as uniformly magnetized volumes for design purposes. The coils contribute directly to the gap induction and are generally divided into a pair of coils close to the midplane and a more distant pair; each pair is energized independently to provide some control over the radial variation of $\overline{B}(r)$. Design currents range from 700 to 2300 A, and the stored power from 18 to 60 MJ.

At the Chalk River superconducting cyclotron laboratory, an array of 13 cylindrical steel rods with axes perpendicular to the midplane penetrate the hills. Axial adjustment of a rod produces a local change in the hill fields to provide both radial variation of the field and harmonic adjustment.

13.3.3
Accelerating Systems

Isochronous cyclotrons do not necessarily require a large dee voltage to reach high energies, and in some cases the second dee of Figure 13.1 is replaced by a narrow grounded electrode termed a *dummy dee*. A large energy gain per turn E_G, however, relaxes magnetic field tolerances, opens the center region geometry, assists in conventional extraction, and reduces stripping losses. The dees of an AVF cyclotron are often triangular or spiral shaped, designed to fit within the valleys of the magnet poles. The increased number of gaps increases E_G. The smaller hill gap improves magnet efficiency.

The dees are made part of an rf resonant circuit, usually as the capacitive termination of a shorted quarter-wave line resonator. This generates higher dee voltages and also facilitates impedance matching to the power source. The resonator can also provide the mechanical support for the dees, obviating the need for failure-prone insulator supports. The shorting plate is usually movable for coarse frequency tuning adjustment and to accommodate different operating modes. The high thermal and electrical conductivity of copper makes it the preferred material. The center conductor of the resonator is usually water cooled; other surfaces are also often water cooled to minimize dimensional changes due to thermal expansion and to maintain a stable resonant frequency.

The accelerating fields for many SSCs are developed in more efficient resonant cavities installed in several of the spaces between magnet sectors (Figure 13.5).

Radiofrequency power is coupled to the dees or cavities by either terminating the drive line from the rf source with a plate that is located in a high rf electric field region near a dee or by terminating the drive line with a loop near a magnetic field maximum, for example, the short. Plate or loop dimensions and orientation are adjusted to match source and load impedances.

Cyclotrons tend to operate between 5 and 75 MHz and rf power requirements range from about 15 kW–1 MW. To generate these, a variety of gridded tubes manufactured for use in shortwave broadcasting or telemetry are available. They are used in either of two basic circuits. The earliest and simplest circuit is the self-excited oscillator, illustrated schematically in a grounded-grid configuration in Figure 13.10. It uses positive feedback to

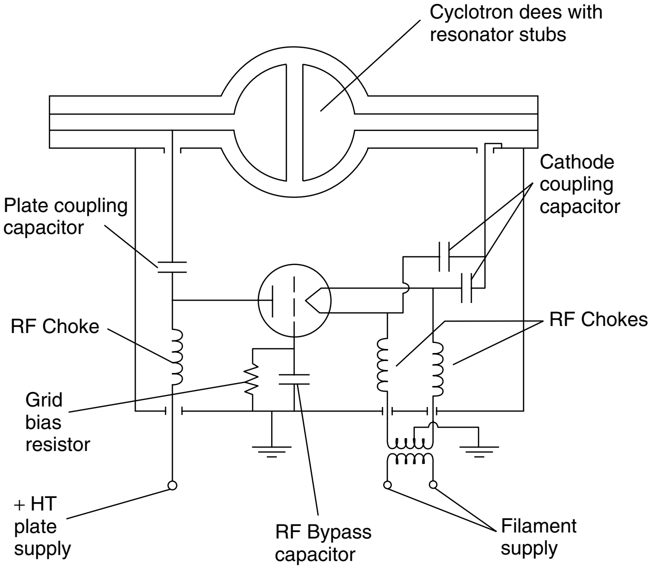

Fig. 13.10 A simplified grounded-grid self-excited oscillator circuit for cyclotron dee excitation.

the power-tube cathode, and the dee and line resonator then determine the resonant frequency. The second type of circuit is the master oscillator–power amplifier. In this case, the feedback line is replaced by a signal obtained from a drive chain consisting of a crystal oscillator and several stages of amplification. In either case, an automatic motor-driven capacitor is usually installed near the dee to maintain the desired resonant frequency by fine tuning.

For a synchrocyclotron, rf power must be supplied as the frequency sweeps over its operating range. A self-excited oscillator system is often used with the transmission-line short replaced with a variable capacitor, either a motor-driven rotating capacitor or a vibrating vane, and the high-power rf is swept in frequency in accordance with the varying resonator capacitance.

13.3.4
Ion Sources for Cyclotrons

Cyclotron ion sources must operate continuously, unlike those used with pulsed machines. Until the 1960s, most ion sources were variants of a type developed at the Oak Ridge National Laboratory, Tennessee, based on the Penning ionization gauge (PIG). In these sources (Figure 13.11), an arc discharge is maintained inside a hollow chimney (anode), aligned parallel to the magnetic field, and passing through the midplane near the cyclotron center. A cathode is placed at one end of the chimney and biased by a few hundred volts with respect to the anode. Electrons drawn from the cathode are constrained by the magnetic field to pass through the arc chamber toward an anticathode placed at the other end of the chimney that reflects them back toward the midplane. The cathode may be a filament or a block heated indirectly by electron bombardment. Each electron can oscillate through the arc chamber many times before collision, thus increasing the probability of ionization. A current of 0.1–10 A at 100–1000 V maintains the discharge. The flow of gas (or vapor) to be ionized is carefully regulated through a small line to the arc chamber. The electric field of the dee penetrates a small slot in the chimney to extract ions from the plasma. The system is otherwise closed and a relatively small gas flow maintains an adequate pressure. These sources provide both light and heavy positive ions and negative hydrogen and deuterium ions. Higher electron energies produce multiply charged ions; however, the cathode lifetime decreases because of ion bombardment. The chimney diameter must be small so as not to interrupt any of the early turns; the relatively small source volume limits the maximum input arc power and consequently the maximum charge state.

An ion source can produce several ion species, with different q/A, at the same time. The requirement that the rf be equal to, or a harmonic of, the orbit frequency means that only certain species will be accelerated. The selection of species can be refined further by placing posts between early turns.

High-charge states, more current, or polarized beams can be provided by larger sources placed outside the cyclotron. These inject their ions either through a valley (Figure 13.5) or down the magnet axis. Axial injection was first demonstrated at Birmingham University, UK, in 1964. A hole is bored along the axis of the magnet yoke and ions, with tens of keV amu^{-1}, led through an evacuated tube to a point just before the magnet midplane (Figure 13.12). They are bent into the plane of acceleration by means of either an

electrostatic mirror (a grounded grid placed above a biased electrode, both at an angle of about 45°) or, preferably, by an inflector consisting of a pair of curved electrodes carrying voltages of opposite sign. Some electrostatic or magnetic focusing elements may be required in the tube. Detailed field calculations are necessary to ensure a smooth match between cyclotron and injection system optics.

Electron cyclotron resonance ion sources (ECRIS) were developed at the Centre d'Etudes Nucléaires, Grenoble, France, in the 1970s and are used by most new HI cyclotrons. Microwaves at a fixed frequency, somewhere between 2 and 20 GHz, are fed into a cavity located within a solenoid. The solenoid is designed to provide at least two surfaces where field and rf satisfy the resonance condition (Eq. (2)) for electrons and where power can be transferred from microwaves to electron motion. In the absence of collisions, the electrons can reach energies of several mega electronvolts. When gas or vapor is introduced, these high-energy electrons collide with atoms or molecules yielding ions and more electrons for the microwaves to accelerate. Multipole (sextupolar or octupolar) magnetic fields confine the plasma radially, which increases the ion lifetime and hence the probability of multiple collisions and consequently the maximum charge state. Several charge states are extracted and the desired species is selected by a bending magnet and slits before injection. The source contains neither filament nor cathode, nor is an arc required to obtain a plasma. Elements that do not easily vaporize may be ionized by placing solid pieces in the resonance zone.

Plasma can be confined within a cylindrical chamber by rows of permanent dipole magnets; a row with north poles facing the plasma alternates with a row with south poles. The shape of the magnetic field flux lines led to the term cusp or multicusp ion source. The chamber is the anode and a heated filament is the cathode. The source chamber may be divided into two regions by a small transverse magnetic field allowing independent optimization of two-step processes. An arc of 25 A at 100 V provides very intense continuous beams of negative hydrogen and deuterium, particularly suited for isotope-producing cyclotrons. The source shown in Figure 13.12 delivers 7 mA of H^-. The Paul Scherrer Institute has developed a proton version capable of 25 mA.

Nuclearly polarized ions of ^1H, ^2H, ^3H, and ^3He are primarily produced by the three different types of source discussed subsequently, namely, atomic (ground state), Lamb shift (metastable), and optically pumped.

An atomic source uses an rf discharge to dissociate $^1H_2$ or $^2H_2$ molecules. The atomic beam is passed through a tapered magnetic sextupole that deflects out of the beam one-half of the hyperfine states that have a particular electron spin direction (Stern–Gerlach effect). The remainder then pass through an rf field that induces transitions from states containing unwanted nuclear spin alignments to the just depopulated hyperfine states. A pass through a second tapered sextupole removes those atoms that have undergone rf transitions. The result is a beam of nuclearly polarized atoms that may now be ionized to $^1H^+$ or $^2H^+$ in helium or to negative ions formed by charge exchange with alkali atoms. Proton currents are about 500 μA, H^- currents are of the order of 10 μA, and polarization is usually about 90%.

Lamb-shift-type polarized-ion sources begin by directing a 550-eV proton beam (or equivalent velocity ^2H, ^3H, or ^3He beam) through a cesium-vapor charge-exchange target. About one-third of the atoms emerging from the cesium are in the $2S_{1/2}$ metastable state. This atomic beam then passes through a magnetic solenoid containing an rf electric field. The magnetic field and rf frequency are chosen such that metastable states with an unwanted nuclear spin become degenerate with the $2P_{1/2}$ state and quickly decay to the ground state. Finally, the atomic beam is passed through an ionizer (iodine for positive ions, cesium for negative) that selectively ionizes the metastable atoms rather than the ground-state atoms. Polarizations of about 80–85% are obtained at currents of 1–2 μA.

An optically pumped polarized-ion source is used at TRIUMF for experiments requiring more intense proton beams. Circularly polarized light from dye lasers tuned to the rubidium D_1 line polarizes the outer electrons of the atoms in a rubidium-vapor charge-exchange target immersed in an axial magnetic field. Protons at ~3 keV have a large probability of picking up a polarized electron in this target to produce an electronically polarized beam of hydrogen atoms. The atomic beam leaves the first solenoid to enter a second solenoid whose magnetic field is in the opposite direction and for which the field gradients on axis have been designed to induce a Sona type transition (i.e., only those atoms with the hyperfine states having opposed electron and nuclear spins change their nuclear spin direction). This results in a nuclearly polarized beam of hydrogen atoms that may then be ionized to positive or negative ions. Polarization of 78% has been achieved to date with 10 μA of H^-; positive-ion currents should be 10 times larger.

13.3.5
Extraction

The two principal methods for extracting the beam from a cyclotron are electrostatic and magnetic deflection and extraction by stripping. In the latter process, the beam passes through a charge-changing medium, usually a very thin foil, located so that particles with altered q/A leave the machine between magnet yokes. A simple change in the radial position of the foil changes the energy extracted; several narrow foils, or ones partially inserted into the beam, allow the simultaneous extraction of several beams with different energies. This method is now chiefly used for negative ions of hydrogen but, in the past, has been used for molecular ions $H_2{}^+$, HD^+, and so on.

The stripped electrons dissipate their energy in the foil; passage of ions both heats the foil and causes radiation damage. Refractory materials, such as carbon or aluminum oxide, are commonly used. Amorphous graphite foils, 200 μg cm^{-2}, extract up to 200 μA from a Cyclotron Corporation CP-42 cyclotron, operated by Nordion International, Canada, at energies between 20 and 40 MeV. Fifteen foils, each lasting about 10 mA-h, are mounted in a cartridge.

Deflecting systems are used for more highly ionized ions or when the charge state must be preserved. The electrostatic deflector of Figure 13.1 may be followed by one or more magnetic channels, which produce a local field reduction to augment the deflection. These channels may be coils powered to oppose the main field or iron bars placed on either side of the deflected beam to divert magnetic flux. The fringe field from such channels often perturbs the orbits before extraction, and additional coils are incorporated to cancel such effects.

Any beam incident on the septum of an electrostatic deflector causes local heating and makes both the septum and neighboring components radioactive. Secondary particles affect voltage holding. Unfortunately the turn-to-turn separation arising from acceleration falls rapidly with energy, as $(B_{0\beta\gamma}{}^{3})^{-1}$, and turns normally overlap at extraction radius. The turn width depends on both radial emittance and the energy spread associated with the phase band being accelerated. Some machines eliminate extraction losses by eliminating overlap between turns at the deflector entrance. This may be achieved by a combination of

1. slits near the machine center to restrict emittance and phase width at the cost of intensity,
2. a large energy gain per turn, and/or
3. the excitation of a coherent radial betatron oscillation.

The latter alternately adds to and subtracts from the turn spacing resulting from acceleration.

The relative alignment of beam and deflectors is quite critical and is usually adjusted empirically. Once set up, this system demands a better machine stability than that required just for acceleration to the final energy or that required for stripping extraction.

The magnet fringe field is a powerful lens, and optics calculations should be performed to ensure that the beam matches smoothly into the external beam transport system.

13.3.6
Vacuum

The tightest constraints for vacuum in cyclotrons arise from either the inability of electrodes to support high voltage or unwanted charge-changing collisions between ions and residual gas molecules. Acceptable operating pressure ranges from 10^{-8} bar for a small proton machine to 10^{-11} bar for H^- or high-charge-state heavy ions. The initial outgassing rate for clean stainless steel or nickel-plated mild steel is about 10^{-8} bar L s^{-1} m^{-2}, and consists chiefly of water vapor. Over several days the evolution of water declines to match the steady-state evolution of hydrogen of $10^{-10}\,\mathrm{bar\,L\,s^{-1}\,m^{-2}}$. Provided that little organic material is incorporated, there are no leaks, and there is no internal ion source, these gases usually constitute the continuing gas load.

The speeds of pumps commonly used lie between 10^3 and $10^5\,\mathrm{L\,s^{-1}}$; to achieve this pumps should be close to, or preferably inside, the cyclotron and be unaffected by magnetic field. Cryopanels cooled to 20 K with 80 K baffles are preferred to the older oil diffusion pumps. Additional hydrogen pumping may be provided by charcoal or zeolite at 20 K or by condensate cryopumps. Initial pump-down is provided by mechanical pumps located in regions free from magnetic field. The magnetic field may also affect the calibration of ion gauges or the operation of mass spectrometers used to analyze the residual gas. Pump-down time can be shortened by venting with dry nitrogen and warming the vacuum tank while roughing. New equipment should be cleaned with solvent or detergent and baked before installation to remove volatile organics and adsorbed water from the surface.

13.3.7
Beam Instrumentation

The beam parameters measured, in a rough order of frequency of measurement, are as follows:

1. both the amount of charge delivered and that lost;
2. the transverse position of the bunch center, its energy, and its phase with respect to rf;
3. the beam size and distribution as a function of these coordinates;
4. polarization; and
5. emittance and correlations between parameters.

In general, these quantities may be measured directly in a beam line, whereas in a cyclotron they must sometimes be inferred by observing the dependence of a related parameter on a machine variable. Most cyclotrons have at least one movable probe giving beam intensity, phase, and density as functions of radius. However, a cyclotron whose operating tolerances are comfortably within the precision of manufacture may monitor only current and the position and size of the beam spot near the production target. A research facility will have the most extensive array of instrumentation.

The sensing instrument may intercept all or part of the ion beam or detect the electromagnetic field associated with a moving bunch of ions. Scintillation screens glow when hit by a beam with density $\sim 1\,\mathrm{nA\,cm^{-2}}$. This glow, when observed through a window by a TV camera, gives an inexpensive display in a control room of beam position, size, and transverse correlations. The system is, however, nonlinear and subject to radiation damage. The beam can be stopped in an electrically insulated conducting target and the incident charge taken via a vacuum feed-through to a measuring instrument that may be a meter, amplifier, oscilloscope, and so on. Information on transverse distributions may be obtained from a subdivided target or from a wire target swept through the beam. At higher energies, the thickness to stop the beam may be inconveniently large, and secondary particles, for example, electrons or X rays, escaping from the surface of a thin target may be detected. Electrons in a cyclotron, including those stripped from H^- ions, spiral along magnetic field lines until collected. In most environments, an incident current >1 nA may be measured. Ion chambers or electron multipliers that boost incident charge have been used for lower currents. Plates or loops placed near the beam detect the electromagnetic field to give information on intensity, position, and phase without perturbing the ions. Various signal-processing techniques enhance the signal-to-noise ratio, but, in general, they are less sensitive than intercepting methods. At IUCF, a monitor that capacitively senses the beam provides a 0.3-mm resolution at 50-nA current.

The cyclotron operating conditions for an ion species sparsely produced by an ion source may be found by using a more intense species with very similar q/A (analog beam).

It is important to be able to bring signals generated by beam users for their own purposes into the central control room. They are concerned that beam properties match their requirements and may be able to generate information beyond the resources of the cyclotron crew.

13.3.8
Computer Control and Monitoring

This is a rapidly changing field. Simple cyclotrons are operated using commercial process controllers. Control systems in research laboratories, however, have to service many more set points and need more frequent revisions to incorporate new equipment or modes of operation; online data-reduction algorithms are also common. These systems, therefore, should be compatible with off-line software development. The performance of some devices should be logged regularly and automatically for fault diagnosis and failure prediction. Closed-loop regulation of subsystems frequently includes microcomputers that exchange data with the main control system; however, closed-loop operation of the entire cyclotron is still rare.

13.4
Cyclotrons as Injectors or Post-accelerators

Several laboratories generate relativistic beams using two or more accelerator stages. This is because a single-stage cyclotron that provides a large energy increase and has a peak field chosen to satisfy the requirements of isochronism and turn spacing at extraction and to avoid saturation will also have a low central field B_0. Relatively few turns take place in the center, and magnets and accelerating structures can be used more economically by a two-stage process that separates the optimization of injection and initial acceleration from the extraction of a high-energy beam. The beam transport line between two machines provides an opportunity to trim off unwanted particles or to increase the charge state of partially ionized atoms by stripping.

The momentum of the beam from an energetic pre-accelerator is too high for axial injection into a cyclotron, and injection schemes tend to mirror the extraction schemes of Section 13.3.5. Fully stripped ions may be directed roughly radially along the valley of an SSC (Figures 13.5 and 13.13) and an electrostatic inflector used to steer them onto the accelerated equilibrium orbit. The radius gain per turn should be such that the next turn clears this inflector. Partially stripped ions may be directed across the face of a solid-pole magnet onto a foil placed at the common tangent of their path and the orbit of stripped particles of the same energy.

The rf of a second cyclotron should be the same as, or a low multiple of, the

Fig. 13.13 Plan view of accelerator facilities at the Indiana University Cyclotron Facility. The figure shows four stages of acceleration from the ion-source terminals, which are potential-drop accelerators, through two cyclotron stages to a cooler/synchrotron. (Courtesy of D. Friesel, Indiana University).

frequency of the injector cyclotron and the phase width of the injected beam much less than the half-period of the new machine. An rf "bunching" cavity is often installed between machines. This buncher improves beam capture by decelerating the beam during one half-cycle and accelerating it during the other to produce a "focus in time" at the first accelerating gap of the next machine.

While cyclotrons are natural partners, with 11 pairs in operation worldwide, other machines have also been used as pre- or post-accelerators. Four laboratories use potential-drop machines as injectors; they have the advantage, for negative ions, of an external ion source and the opportunity to strip off electrons in the terminal, thus increasing q/A. Two laboratories use potential-drop post-accelerators to provide simple and precise energy control over a wide range. A 70-MeV amu^{-1} variable-frequency linear accelerator provides heavy ions for the $K_b = 540$ SSC operated by the Institute of Physics and Chemistry (RIKEN), Saitama, Japan.

Cyclotron beams are also injected into storage rings where they may be accumulated over many turns and ''cooled,'' that is, have betatron and synchrotron oscillation amplitudes reduced either by applying a series of small transverse or longitudinal kicks to the beam or by transferring oscillation energy to an electron beam that shares part of the ring circumference. The experimenter's target is also placed within the ring. The recirculation of the beam through the target increases the interaction rate while the cooling system removes the ''heating,'' or beam degradation, caused by the target so as to maintain the beam size and narrow energy spread. Most rings include an rf cavity so that, after accumulation, the magnet and rf may be ramped, as in a synchrotron, and the beam accelerated to higher energy. Five cooler/synchrotrons have been built, or are under construction, the first (Figure 13.13) being at Indiana University with $K_b = 560$. The first cooling of a beam from a cyclotron occurred in 1984 at the 8-MeV amu^{-1} test accumulation ring TARN I at the Institute of Nuclear Study, Tokyo.

It is proposed, at TRIUMF, to produce 100 μA of 30-GeV protons using the existing cw cyclotron as an injector for a chain of rapid-cycling synchrotrons. Since synchrotrons, like synchrocyclotrons, capture particles over a relatively short injection period, an interjacent storage ring would be necessary in order to utilize most of the cyclotron beams. H^- ions would be extracted from the cyclotron at ~450 MeV and injected into the ring by stripping to protons. The protons would be accumulated, at 450 MeV, over ~20 ms (~10^4 turns) and extracted in one turn for transfer to a synchrotron, whereupon accumulation would start again. The synchrotron would have a 50-Hz repetition frequency.

In general a post-accelerator demands better beam quality and stability of operation from an injector than most other applications.

13.5
Applications of Cyclotrons

The development of early cyclotrons was driven by the needs of basic research in physics and chemistry; however, workers in other fields were soon experimenting with the use of isotopes as tracers and particle beams in medicine. Construction of cyclotron-based facilities intended primarily for use in fields other than nuclear physics began in the 1950s. A number of them were intended specifically for isotope production (e.g., Amersham International (UK)), some for general science and engineering (e.g., Harwell), and others for neutron therapy (e.g., Hammersmith Hospital, London (UK)). The characteristics of cyclotron beams overlap those of potential-drop and linear accelerators, and the machines share some common applications.

In the past, cyclotrons have been designed and sold by large engineering companies, for example, Philips (The Netherlands), A.E.G. (Germany), Thomson–CSF (France), and Japan Steel Works. They have been joined, in the past 15 years, by smaller specialized firms such as Scanditronix (Sweden), IBA (Belgium), RDS–Siemens (US), and Ebco Technologies (Canada).

13.5.1
Interaction of Particle Beams with Matter

Most cyclotron applications depend on the way their beams interact with matter–these processes are summarized subsequently.

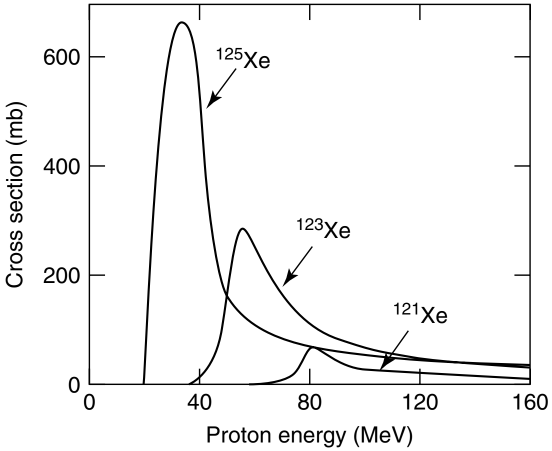

Fig. 13.14 Production of xenon isotopes as a function of bombarding energy; reaction ^{127}I(p, xn)Xe. (After Syme *et al.*, 1978).

Charged particles with energies up to a few mega electronvolts interact chiefly with the Coulomb field of electrons and nuclei. Sufficient momentum may be imparted to atoms to lead to lattice dislocations. Electrons may be detached from atoms (ionization) or excited to more energetic states with subsequent emission of characteristic X rays. Molecules may be dissociated (radiolysis), and the resulting ions or radicals may be very reactive chemically. Detached electrons or displaced atoms may be sufficiently energetic to cause further ionization or dislocation.

At energies above the Coulomb potential barrier (4 MeV for protons on oxygen), charged particles may enter the nucleus and increase nucleon orbital energy with subsequent emission of characteristic γ rays, or initiate a reaction transforming the atom to a different isotope or element. The deuteron binding energy is only 2.2 MeV; at energies above this the nuclear Coulomb field may polarize, and then dissociate, an incoming deuteron. The component neutron may enter a nucleus, since neutrons are not inhibited by the Coulomb barrier, and initiate reactions.

Particles with tens of mega electronvolts may eject several nucleons or light nuclear fragments from a nucleus. Figure 13.14 shows the probability of multiparticle ejection and the creation of different isotopes as the bombarding energy increases. At higher energies, copious numbers of energetic secondary particles are emitted and cascade reactions ensue. Meson production begins around their rest energy, 106 MeV for muons and 140 MeV for pions.

Atomic interactions are many orders of magnitude more likely than nuclear interactions and ions lose their energy in many small steps. The energy deposited along the track, averaged over many samples, is shown in Figure 13.15. Ions, in contrast with neutrons, photons, and electrons, have a specific range, at the end of which there is a peak, the "Bragg peak," in differential energy loss. There is a statistical variation in range caused by absorption reactions and angular scatter. Very low energy π^- are captured in a nucleus that disintegrates into short-range fragments and neutrons enhancing the Bragg peak. Figure 13.16 shows the energy

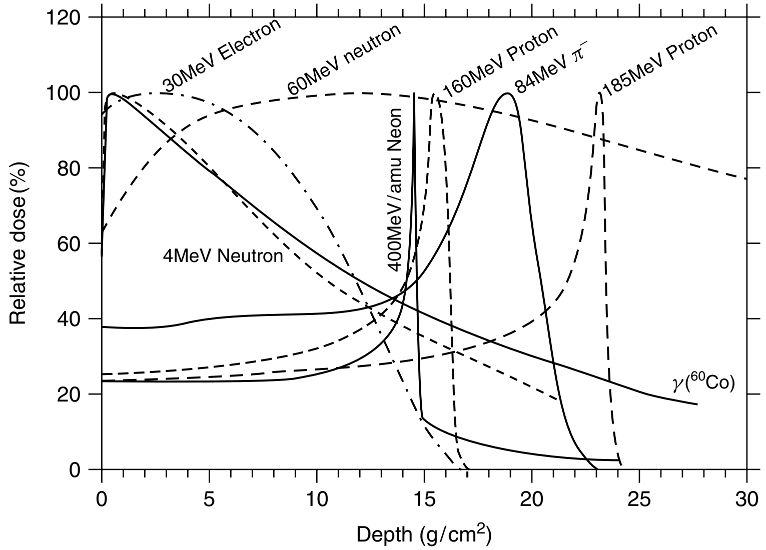

Fig. 13.15 Dose (related to local ionization) as a function of penetration depth in water or tissue for several particle beams and γ rays (1.17 and 1.33 MeV) from ^{60}Co.

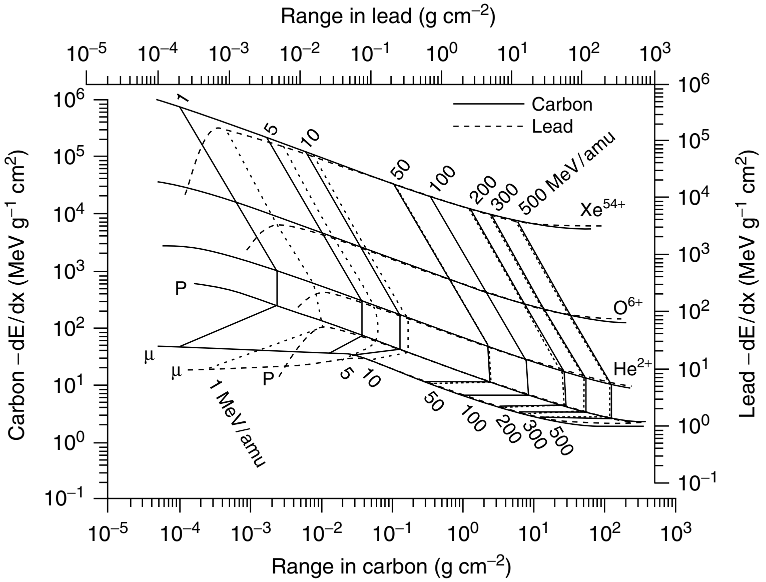

Fig. 13.16 Range and stopping power of muons, protons, α particles, oxygen, and xenon ions in carbon and lead (vertical lines join particles with the same energy per amu and are not intended for interpolation).

dependence of the differential energy loss, or stopping power, and the mean range for several particles in carbon and lead.

13.5.2
Basic Research in Nuclear Science*

The first generation of AVF cyclotrons, with $K \sim 100$ and accelerating light ions ($A < 7$), contributed beams that were more intense and higher in energy than were available from potential-drop machines. The energy resolution could be made comparable by the use of slits to reduce phase-space volume and by magnetic analysis of the extracted beam coupled with magnetic analysis of reaction products. The beam bunch length could be made small enough that reaction products could be identified from their differences in flight time from target to detector. On the other hand, the quasi DC macro duty factor, when compared with that of a pulsed linear accelerator, gave better rejection of uncorrelated events for those experiments that depend on the coincident detection of several correlated reaction products. Some examples of fields investigated using these cyclotrons are quantitative descriptions of nuclear potentials, identification of nuclear states excited at tens of mega electronvolts, and reactions with several emergent nucleons.

Nuclear structure and reaction mechanism studies continue at the higher-energy SSCs and meson factories where, for example, the nucleon–nucleon potential could be explored using spin-polarized beams and the charge distribution within nuclei obtained by comparing π^+ and π^- scattering. The new, cyclotron-injected, coolersynchrotrons offer nuclear physicists superior energy resolution ($\Delta E/E \sim 10^{-5}$) at high energies, from tens of mega electronvolts per amu to 2 GeV. The high flux from meson factories facilitated particle physics experiments, in particular the search for those rare decay modes of mesons that may violate the presently accepted model of strong, weak, and electromagnetic forces or hint at conservation laws not yet included. At bombarding energies of hundreds of mega electronvolts, many different isotopes are produced, many of which are short lived. An electromagnetic analysis system that can isolate individual species online is used by hundreds of experimenters at the CERN synchrocyclotron.

Beams from HI cyclotrons may have less energy per nucleon than from meson factories, but their higher total energy makes them suitable for study of the bulk properties of condensed nuclear matter in a background relatively free from the products of competing, for example, nucleon–nucleon, reactions. Heavy projectiles can generate excited nuclear states with high rotational energy or extreme modes of vibration. A large energy input creates compound nuclei with high thermal energy; subsequent evaporation of nuclear matter produces transuranic elements and nuclei far from the line of stable elements on the A–Z diagram.

Astrophysicists and nuclear chemists are interested in reactions initiated by unstable isotopes and have proposed facilities to produce, collect, ionize, and accelerate radioactive particles. The first such facility in operation is at the Université de Louvain, Louvain-la-Neuve, Belgium, where ^{13}N, with a 10-minute half-life, is generated using 30-MeV protons from one cyclotron, ionized in a radiation-hard ECRIS placed next to the production target, and then accelerated in the adjacent $K = 120$ variable-energy cyclotron CYCLONE.

---

*Chapters 6, 9, and 10 give a general treatment of this subject.

13.5.3
Basic Research in Other Physical Science

Neutrons have long been used in condensed matter research. Accelerator-based neutron sources now complement the traditional reactors and are more easily licensed at present. Storage-ring/synchrotron sources produce pulses of neutrons with a higher instantaneous flux and offer good resolution through time-of-flight techniques. The integrated thermal-neutron flux from the beam dump of a cw-cyclotron meson factory approaches that from research reactors ($2 \times 10^{14}\,\mathrm{cm}^{-2\cdot}\,\mathrm{s}^{-1}$); the cold-neutron flux is superior. An ambitious project under construction at PSI will direct a 1.4-mA beam from their 600-MeV proton cyclotron vertically into a lead target surrounded by horizontal neutron guide tubes. Liquid D_2 or H_2 moderators are placed close to this almost point source. The neutron flux at the experiments, per mA of protons, is $10^{10}n$ $(\mathrm{cm}^2\ \mathrm{s\ nm})^{-1}$ at 0.1 nm to $10^{9}n$ $(\mathrm{cm}^2\,\mathrm{s\,nm})^{-1}$ near 1-nm wavelength.

The muon, μ^- or μ^+, has a mass 206 times that of an electron, or one-ninth that of a proton. It experiences electromagnetic and weak forces but not the strong (nuclear) force. The μ^- mimics the response of a heavy electron to such forces, but the μ^+ acts more like a light proton, often forming the ‘‘element’’ muonium (μ^+e^-) that has almost the same size and binding energy as the chemically reactive hydrogen atom but only one-ninth the mass and three times the thermal velocity. The proton radius is 10^{-13} cm, whereas the μ^+ is pointlike. The muon half-life, 2.2 μs, vastly exceeds the thermalization time (of order 1 ns) when stopping in matter and is long with respect to many chemical and physical processes. Their range may be estimated from Figure 13.16.

The muon beams originate from pion decay and are spin polarized along, or opposite to, their direction of motion. In a local magnetic field, $\mathbf{B}$, a muon will precess at a Larmor frequency of $(135.5\,\mathrm{MHz\ T}^{-1})\mathbf{B}$. The precession of the triplet state of muonium at low fields is $(13.9\,\mathrm{GHz\,T}^{-1})\mathbf{B}$. Muons themselves decay into a neutrino, an antineutrino, and an electron or positron; the latter are emitted preferentially along the muon spin axis with energies up to 52.8 MeV and are easily detected. In a typical muon spin-rotation experiment, a sample is placed in a homogeneous magnetic field and the time interval between a μ^+ entering the sample and its decay positron entering a detector nearby is recorded for millions of events. In the example shown in Figure 13.17, a fast precessional signal is seen to be superimposed on the slower muon decay. The precession frequency depends on the microscopic magnetic environment in which the muon finds itself, for example, a certain crystal lattice site or chemical species. The amplitude depends on the number of muons finding such sites, which may be related to their availability. The term μSR also includes longitudinal spin relaxation experiments carried out in zero field or with a bias field (anti) parallel to the spin direction and muon spin resonance where transitions between states are detected by the absorption of microwave power. Data acquisition may be triggered by a step change in the sample environment, for example, illumination from a pulsed laser. Negative muons are more likely to depolarize during capture by atoms and to undergo nuclear capture. When not captured, they probe magnetism at sites different from μ^+SR.

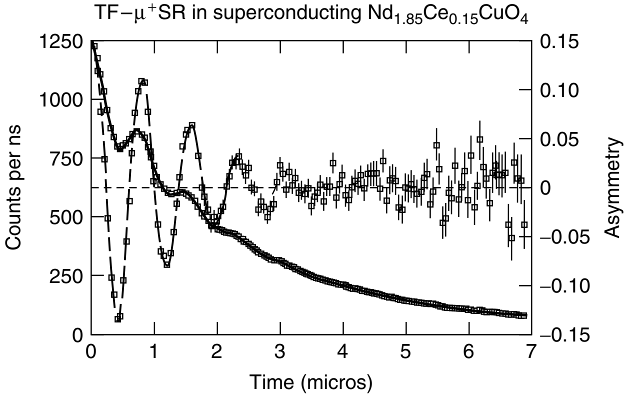

Fig. 13.17 Solid line: Positron counting rate from μ^+ stopped in a superconducting compound immersed in a 0.01 T transverse magnetic field. Dashed line: The same data corrected for background and muon decay. (Courtesy of J. Brewer, University of British Columbia).

Currently μSR is used as a probe of structure (e.g., measurement of magnetic penetration depth in superconductors, or the study of defect states in semiconductors) and dynamics (e.g., quantum diffusion in solids, or following μ^{+-} substituted radicals in chemical reactions).

Muons can bind certain nuclei sufficiently closely, for example, 700 fm for $^2H\mu^{-3}H$, that nuclear fusion may occur. The μ^- is released to participate in about 150 similar events before decay. Muon-catalyzed fusion may be a distance source of energy, and the process is being studied in detail at several laboratories.

The present meson-factory beam lines deliver μ^+ fluxes from 10^5 to 10^7 cm$^{-2\cdot}$ s^{-1}. Upgraded facilities at PSI will increase this severalfold, while the proposed kaon factories would provide a further increase.

The local structure of materials is also examined using heavy ions, for example, at the Hahn-Meitner Institute, Berlin, Germany. Hyperfine structure depends on both nuclear and atomic parameters and the latter are influenced by the solid-state environment. Nuclear probes, which may be constituent or impurity ions, are implanted and the hyperfine levels measured by nuclear techniques such as the Mössbauer effect or magnetic resonance.

13.5.4
Isotope Production

Radioactivity is a well-established field, discussed in Chapter 11, and radioisotopes have been used for decades, primarily as tracers and for nuclear medicine. Most commercial products incorporate isotopes from reactors. Neutron-deficient isotopes, however, require accelerators, and the accelerator of choice is a high-current cyclotron with variable-energy beam. The international trade in cyclotron products amounts to $100 million annually, mostly of radiopharmaceuticals, and is increasing. Some targets are used as irradiated – for example, in wear studies of machine parts – but usually the radioisotope has to be separated from the original target material and other reaction products and synthesized into a chemical compound. For example, ^{18}F-labelled 2-fluoro-2-deoxy-D-glucose is used to study glucose metabolism of the brain; ^{13}N- and ^{15}N-labelled compounds are used to study the fast and slow uptake of nitrates by plants. The investment in hot cells and radiochemical equipment can be compared to the cost of a cyclotron. The target, bombarding particle, and energy (Figure 13.14) are usually chosen to optimize the desired cross section and to reduce contamination from competing reactions. Table 13.1 lists several commercial isotopes and their production reactions.

Short-lived isotopes give a stronger signal with less environmental dose; the use of cyclotron-produced ^{123}I in thyroid studies reduced patient dose 50-fold compared with the longer-lived, reactor-produced ^{125}I or ^{131}I. Production, however, must be sited near a user or near excellent transportation facilities. The isotopes ^{11}C, ^{13}N, ^{15}O, ^{18}F, used in positron emission tomography, have half-lives of minutes. Fortunately they can be produced by low-energy (<20-MeV proton) cyclotrons that can be installed in a hospital. Production facilities at TRIUMF are 2.5 km from the university hospital; however, radiopharmaceuticals are transferred within 2 minutes by means of an underground pneumatic tube (rabbit).

In addition to research laboratories and hospitals with radioisotope production facilities, there are also several companies that make, process, and distribute isotopes and isotope-labeled compounds. These include Amersham International (UK), DuPont-Merck and Mallinckrodt

Tab. 13.1 Examples of popular cyclotron-produced medical isotopes.

Isotope	Production reaction	Beam	Use[a]
Thallium-201	$^{203}\mathrm{Tl}(p, 3n)^{201}\mathrm{Pb}$ $^{201}\mathrm{Pb} \longrightarrow {}^{201}\mathrm{Tl}$	29-MeV protons	Heart studies (SPECT)

(US), Nihon Medi-physics (Japan), and Nordion International (Canada). Most use proton beams below 50 MeV and have two or more cyclotrons to guarantee production. Isotopes from spallation reactions, for example, ^{82}Sr and ^{127}Xe, require much higher energies; however, they are sometimes made parasitically, for example, in targets placed just before the beam dump of a line with primary targets, devoted to other work, upstream.

A modern low- or medium-energy cyclotron can produce 15-kW beam power, which is more than most production targets can withstand. A multifoil H^- or D^- cyclotron can simultaneously share this beam between several targets at the same or different energies.

13.5.5
Particle Beams in Medicine

Cancerous tumors and other structures inaccessible to conventional surgery have been eradicated by using penetrating radiation to ionize and destroy malignant cells. Most treatments employ X rays or γ-rays. Some tens of thousands of patients, however, have been treated with neutron or charged-particle beams that, although less tractable, can offer improved localization of dose and interact differently with tissue. Proton and α-particle treatments were developed, starting in the mid-1950s, at the Berkeley, Uppsala, and Harvard synchrocyclotrons and at the ITEP (Moscow) synchrotron. Neutron studies, begun at Berkeley, were revived at the Hammersmith cyclotron in the 1960s. HI and π^- therapy began in the 1970s.

To reduce the dose to intervening tissue, a patient is irradiated from two or more sides with the beam energy adjusted to place the Bragg peak (Figure 13.15), where applicable, at the treatment site. The energy may be altered and the beam steered transversely to distribute the dose over an irregular volume. The choice of particle is influenced by

1. radiobiological effect (HI, π^-, and neutrons have high linear energy transfer (LET) at the treatment site),
2. the ratio of end-of-range to transit dose (favors π^-, protons and HI),
3. the absence of dose beyond a sharp range end (favors protons and α), and
4. dose delineation (primary beams are smaller than secondary).

A therapeutic dose is 10–50 Gy, delivered in several fractions. Moderate energies are required –250-MeV protons reach the deepest tumors – and since 1 nA cm^{-2} delivers 1 Gy min^{-1}, synchrocyclotrons or synchrotons are adequate for primary beams. Secondary beams, π^- or neutrons, require cw cyclotrons or linacs.

There are 20 neutron treatment centers worldwide, out of which 13 are with cyclotrons. Attention has been focused on neutron radiobiology, especially at hypoxic sites. A typical installation would accelerate 100 μA of deuterium to 50 MeV, and bombard a beryllium target to obtain 20- to 40-MeV neutrons that are then collimated into a fixed beam for treatment. A gantry-mounted, 50-MeV deuteron, superconducting cyclotron, however, designed by H. Blosser and installed at the Grace Harper Hospital, Detroit, is able to rotate completely around the axis of a patient (Figure 13.18).

About a dozen laboratories operate adjunct medical facilities performing radiosurgery by means of charged-particle beams. Charged-particle treatments have been especially advantageous where dose localization is important, for example, in the pelvic region, for tumors of the pituitary (adjacent to the spinal chord and

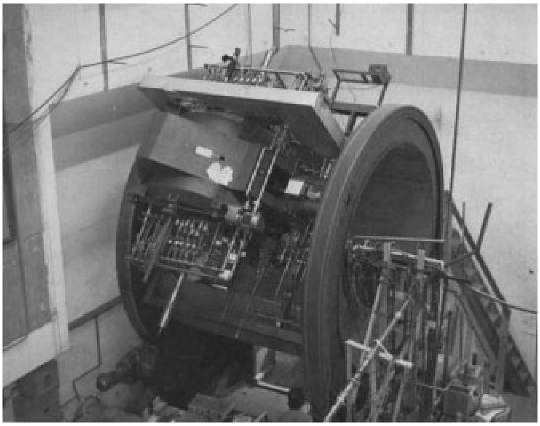

Fig. 13.18 A superconducting, 50-MeV deuteron, cyclotron being mounted on a cylindrical rotating gantry at the Harper Hospital (Detroit). Neutrons are directed toward a patient located near the cylinder axis. The patient position is adjustable and irradiation can take place from all sides. (Courtesy of H. G. Blosser, NSCL-Michigan State University).

brain stem), in choroidal melanoma (adjacent to the optic nerve), and in destruction of arteriovenous malformations in the brain. During the last 6 years, 1000 patients with ocular melanoma have been treated using 70-MeV protons from the PSI injector cyclotron. The success rate, 95%, is the same as for the traditional treatment, which involves removal of the eye, but proton treatment also preserves vision in most cases. Recent improvements in medical imaging (computerized axial tomography (CAT), magnetic resonance imaging (MRI), etc.) make it possible to exploit the 1-mm dose delineation possible with proton beams. Ten new charged-particle treatment facilities are under construction, half with dedicated medical accelerators, six associated with proton cyclotrons.

13.5.6
Elemental Analysis of Materials

Many physical and chemical methods are used to determine the elemental constituents of a material. Those associated with accelerators include

1. the identification of atoms from their characteristic X rays emitted under bombardment (particle induced X-ray emission (PIXE)),
2. the identification of nuclei from their decay products following irradiation,
3. the identification of nuclei from elastic scattering cross sections and angular distributions, and
4. mass analysis following ionization and acceleration of a small sample, a technique termed *accelerator mass spectrometry* (AMS).

These techniques are frequently nondestructive and may be considered when only a small sample (milligrams) is available, when isotopes, and not just the elements, must be identified, or when the spatial distribution within a matrix is required. Absolute resolutions are of the order 1 ppm or less, that is, subnanogram quantities; AMS isotopic ratios, for example, $^{14}C/^{12}C$, have a resolution of $\sim 10^{-14}$. They are primarily the domain of low-energy potential-drop machines; however, cyclotrons have advantages in certain cases and, worldwide, more than 10 cyclotron laboratories offer service to external users and some derive a substantial fraction of their income in this way.

The proton microprobe uses a collimated incident beam focused into a spot of $\sim$10 μm diameter, and X-ray analysis takes place as the beam slowly scans over the sample. The cross section for *K*-shell X-ray production is greater at cyclotron energies, but so is the background; *L*-shell X rays are also produced, however, which may resolve ambiguous cases. A cyclotron beam penetrates further into a sample; however, the spatial resolution is somewhat worse than the standard potential-drop laboratory arrangement. Cyclotron laboratories offering PIXE services include the University of Hamburg and the University of California, Davis Campus. Applications include analysis of thousands of specimens of airborne pollutants per day and the distribution of aluminum in biological tissue.

Proton-induced radioactivity is suited to the detection of trace amounts of light and medium-mass nuclei, whereas neutron activation offers better resolution for heavy elements. Some medium-energy cyclotron laboratories offer both techniques and also irradiation by other ions. Resolutions range from 1 ppb to 10 ppm, depending on the element of interest and the matrix. Commercial applications include the determination of oxygen in metals and impurities or dopants in semiconductors. Many laboratories engage in this work; the more experienced include the Radiation Studies Centre (CERI), Orleans, France; University of California, Davis (US), and RIKEN (Japan).

Cyclotrons have been used as mass spectrometers since, at any one time, only ions whose q/A lies within a narrow band can be accelerated and extracted. However, the measurement of a ratio, say $^{14}C/^{12}C$, for dating purposes would require changes in frequency or field, and potential-drop machines are preferred by AMS facilities that process many samples. The mass resolution of a conventional cyclotron, $\Delta m/m \sim 10^{-3}$, can be enhanced by further analysis of the extracted beam or by designing a machine with very tight synchronism tolerances. The Institute of Nuclear Research, Shanghai, is constructing such a compact and inexpensive cyclotron that can distinguish between ^{14}C, ^{13}CH, and $^{12}CH_2$.

The resolution of isobars, nuclei with the same mass, is effected by measuring another physical property, for example, stopping power. Such measurements are easier at the higher energy available from cyclotrons.

13.5.7
Transmission Radiography

The absorption and scatter coefficient for X rays increases smoothly with atomic number, whereas the coefficient for neutrons is scattered over 5 orders of magnitude and varies considerably from element to element, even from isotope to isotope. This selectivity enables neutron radiography to reveal the distribution of those elements with high cross section, for example, hydrogenous or nitrogenous explosives encased in materials of high *Z*. The isotopic sensitivity makes it possible to observe the distribution of enriched uranium in fuel rods. In other materials neutrons have high penetrability, and large castings can be inspected for voids and aircraft structures for stress cracks and corrosion. The object is backed by material to convert neutrons to electromagnetic radiation, and radiographs are made with X-ray film or pictures recorded in real time using a TV camera. The neutron flux from an easy-to-operate 50-μA, 20-MeV compact cyclotron approaches that from a 5-MW reactor. Japan Steel Works and Sumitomo Heavy Industries have both installed cyclotron-based radiography systems. Oxford Instruments (UK) manufactures a transportable, superconducting, 200-μA, 17-MeV H^- cyclotron. The machine consumes only 20 W, weighs 2 tons, and may be mounted on a "cherry picker" device. The flux of thermal neutrons is estimated to be $2 \times 10^{11}\ n\,\mathrm{cm}^{-2\cdot}\,\mathrm{s}^{-1}$.

Proton radiography is used less extensively; it requires energies above 100 MeV for a useful range. Marginal-range radiography depends on the rapid change in differential energy loss near the end of the Bragg peak. The proton energy is adjusted to match the thickness of the object and resolutions of 0.1% for objects a few millimeters thick and 1% for 50 mm are obtained, which is almost 10 times better than for X rays. In scatter radiography, a broad, parallel beam illuminates the object. Protons passing through the object near the edge will be scattered into the unperturbed stream, enhancing the delineation of the edge. This subject has been developed extensively at the Harwell 160-MeV synchrocyclotron.

These techniques leave little residual activity and are thus nondestructive. Since neither protons nor neutrons are common products of radioactive decay, the methods discussed may be used, with appropriate detectors, on radioactive objects.

13.5.8
Wear and Corrosion

The rate of wear caused by operation of equipment can be measured by irradiating part of the surface that is subject to wear, and then reassembling and operating the equipment while monitoring the radioactivity. In some cases, abraded material may be carried by lubricants or other fluids past a radiation detector to give a dynamic measure of wear as a function of machine operating conditions. In cases where this is not possible, for example, locomotive wheels, the activity remaining is measured periodically while logging the amount of use. The amount of activity required is small; the irradiated area may be large or as small as 1 mm and limited to 0.1 mm. Thickness changes may be measured to 1 nm. Different radionuclides may be created on different components of the same machine and relative wear observed in a single experiment. The Kernforschungzentrum Karlsruhe (Germany) cyclotron has treated 500 parts per year for many years and for different customers. A recent development in this field is the implantation of radioactive ^{7}Be and ^{22}Na carried out at NSCL-MSU.

13.5.9
Materials Modification and Processing

The dislocations, ionization, and reaction products from ion bombardment can alter the physical properties, for example, conductivity, of a target and also lead to chemical change. Normal chemical incompatibilities may be overcome and unusual alloys and compounds may be formed at low temperature and in the solid state. The bombarding energy may be chosen to concentrate the changes at the surface or in a layer buried beneath. Chemical change may be minimized by using one of the target elements as the ion beam; conversely, physical dislocations can often be removed by annealing. The $K \approx 100$ cyclotrons at the Oak Ridge National Laboratory, Harwell, KfK Karlsruhe, and the Joint Institute of Research, Dubna, have exploited such processes for decades. The newer, high-K machines, in particular, the chain of cyclotrons at GANIL, Caen, France, extend the range of ion species and energies, and consequently the depth of dose and LET, available. Irradiations may take place under vacuum, but the majority of them are carried out in air, the beam emerging through a thin metal window at the end of an evacuated beam pipe.

Light- and heavy-ion beams are used to render stainless steel surfaces more resistant to corrosion, friction, and wear. Heavy-ion and α particle beams are used to simulate the damage caused by neutrons in fission or fusion reactors. The neutrons cause dislocations in structural materials, and helium from (n, α) reactions accumulates in the voids. Ion bombardment produces similar effects, but at much higher rates, and also allows mechanical tests to be performed during irradiation.

Ionizing particles may cause intermittent malfunctions in electronic circuits; heavy exposure may lead to failure. Ion beams are used to measure the radiation resistance of military or space-bound electronics in the laboratory. The French agency MATRA ESPACE simulates space radiation effects by using 5–50 MeV per amu carbon to xenon ions from the GANIL cyclotron to obtain penetration depths from 5 to 1300 μm and LET between 0.2 and 68 MeV $(\mathrm{mg\,cm^{-2}})^{-1}$.

Micropore filters are used to remove contaminants from fluids (e.g., the water used in printed circuit manufacture), to separate biological cells, and as semipermeable membranes to preserve the freshness of fruit and vegetables. Superior filters (Figure 13.19) are manufactured at Dubna and also by the company Biopore using beams from GANIL. Rollers feed polycarbonate film, 10–50 μm thick, through $10^{12}\ \mathrm{s^{-1}}$ beams of 5–10 MeV $\mathrm{amu^{-1}}$ xenon or krypton and then into etching and washing solutions. These preferentially dissolve material around the ion path to produce cylindrical holes with a high degree of uniformity and a diameter determined by choice of ion species, energy, and etching process. Diameters range from 0.05 to hundreds of microns. Filters may have 10^9 holes $\mathrm{cm^{-2}}$, whereas membranes used for cell counting have a single hole.

Embryonic commercial processes include the generation of color centers in crystals, and the manufacture of field-emission surfaces and nonreflective glass and plastic. Multi-MeV beams can bury oxide or nitride layers deep in a semiconductor, thus permitting the development of three-dimensional integrated circuits, optical circuits in semiconductor sandwiches, and the micromachining (via etching) of mechanical devices in silicon.

13.6
Facility Design and Shielding

Cyclotron laboratories employ conventional construction methods for the most part, but have the additional requirements of shielding personnel and experimental equipment from primary and secondary particles and of monitoring and minimizing radioactivity in the workplace, at points of egress, and in air and water exhausts.

For beam energies above 10 MeV $\mathrm{amu^{-1}}$ a shielding wall thick enough to attenuate the neutrons produced to a safe level will also attenuate γ rays and stop charged particles. The number of fast neutrons rises rapidly with beam energy (Figure 13.20). They are slowed, initially, by nuclear elastic or inelastic scattering in the shield and some nuclear reactions may occur. They reach thermal equilibrium at some distance from the point of origin and are

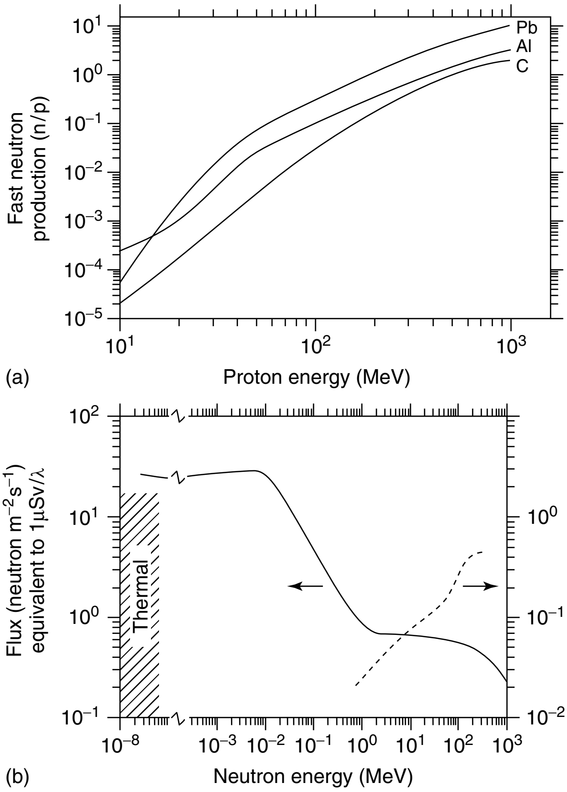

Fig. 13.20 (a) Yield of fast neutrons produced by protons stopping in thick targets. (b) (Solid line) Neutron flux giving unit dose and (dashed line) the thickness of concrete (density 2.4 g cm^{-3}) required to halve the neutron flux as a function of neutron energy.

ultimately captured in a nucleus, usually with the release of a γ ray that may necessitate an additional layer of shielding.

The maximum permissible dose for radiation workers is currently 0.05 Sv/year. This may be transformed to neutron flux and an approximate estimate of shielding thickness made with the aid of Figure 13.20(b). While hydrogenous materials have high neutron-scattering cross sections, materials with high atomic number are better attenuators of γ rays. Concrete is the usual low-cost compromise. Shielding calculations can be quite complicated since both particle production and absorption are multibranched energy-dependent processes, and Monte Carlo simulations are often used.

In practice the greatest dose to humans comes from induced radioactivity, from activities such as processing targets, and from cyclotron or beam line maintenance. Some beam loss is inevitable; good design minimizes the amount and concentrates its deposition in absorbers such as carbon, which minimize residual activity, and where the loss can be monitored by cyclotron operators. Particles likely to be lost, that is, those with large betatron amplitude or extreme phase, may be trimmed at low energy. The absorbers may be removed quickly and safely during maintenance or themselves shielded by a portable lead curtain. Lead of 10 cm thickness attenuates 10-MeV γ rays 100-fold and stops β and α particles. Impurities in construction materials can cause significant residual radiation problems; two important examples are sodium in concrete (which may be a small percentage unless controlled) yielding ^{24}Na and trace amounts of cobalt in steel producing ^{60}Co. The vault and high-intensity beam lines should be sealed and volatile radiation products and airborne radioactivity pulled through a monitored exhaust. The cooling water for components in areas of high loss should recirculate through ion exchangers to remove products of radiolysis. Personnel exposure should be considered at the equipment design stage. For example, screws may be superseded by quick-release clamps, quick disconnects used for electrical and fluid services, and remote removal and handling features incorporated.

Most organic materials and electronic equipment begin to deteriorate at an accumulated dose of 10^4 Sv. Some are more resistant, for example, ethylene/propylene O rings (10^5–10^6 Sv), fiberglass, and certain epoxies (5×10^6 Sv). At higher levels inorganic insulators and metal vacuum seals are used.

Ancillary equipment, such as production targets or particle detector arrangements, is reconfigured quite frequently and may not be commissioned to the same level of reliability as the cyclotron. Some targets may be more radioactive than the cyclotron itself. These facilities are best placed outside the cyclotron vault in their own shielded rooms that can provide low-background areas for experiments requiring them, easier access for maintenance of both cyclotron and equipment, and, when magnets can switch the beam between two or more such areas, a more productive use of cyclotron time. The switching magnets and any initial collimation or common beam-focusing elements are best placed in the cyclotron vault. Site plans for all types of facilities may be found in the proceedings of conferences; Figures 13.13 and 13.21 are examples. While poured-in-place concrete is cheaper and services may be conveniently attached, movable blocks are commonly used to subdivide areas and for some outer walls

Fig. 13.21 TRIUMF site plan showing the 520, 42, and 30 MeV H^- cyclotrons. The meson production beam line, BL1 A, services secondary particle channels M8 (π^- therapy), M20, M15 and M13 (μSR), M9 (particle physics), and M11 and M13 (π^- nuclear physics). Spallation isotope production and neutron applications take place at the beam dump. The dump window limits proton currents to 200 μA. Beams of energy 65–100 MeV are used in BL2 C for isotope production. BL4 A, 4B, and 1B accept beams from 180 to 520 MeV with maximum currents of 10, 0.2, and 0.01 μA, respectively. Polarized H_2 and $^2H_2$ targets in 4 A are used for nucleon–nucleon physics; a liquid $^2H_2$ target produces polarized neutrons for BL4 C. The magnetic spectrometers MRS and SASP are used for nuclear physics studies. Large equipment is assembled and checked out in the E and W extensions; the whole area is serviced by a pair of 50-ton cranes. Power supplies, data acquisition and control equipment, control rooms, and offices are located at several levels in the service annexes and the north side of the meson hall. Hot cells for isotope separation and manufacture of radioisotopes are located in the chemistry annex. Speckle indicates concrete poured in place; the unshaded shielding is movable concrete blocks.

in order to facilitate future rearrangement and expansion.

Appendix 13.A Description of a Typical Isotope-Production Cyclotron

The TR30 500-μA, 30-MeV H^- cyclotron (Figure 13.A.1), built by Ebco Technologies, Vancouver, Canada, is located at the TRIUMF site (Figure 13.21), and operated by Nordion for isotope production.

The compact design has four radial sectors. The magnet is approximately square in shape, 2.3 m from side to side and 1.26 m high, and weighs approximately 46 tons. It is split at the midplane, allowing four hydraulic jacks located in the magnet supports to elevate the upper part for access to the cyclotron interior. Two 37 000 A-turn coils mounted on the upper and lower poles provide the magnet excitation. No trim coils are used. Tolerances for isochronism, vertical focusing, and avoidance of resonances were met by a

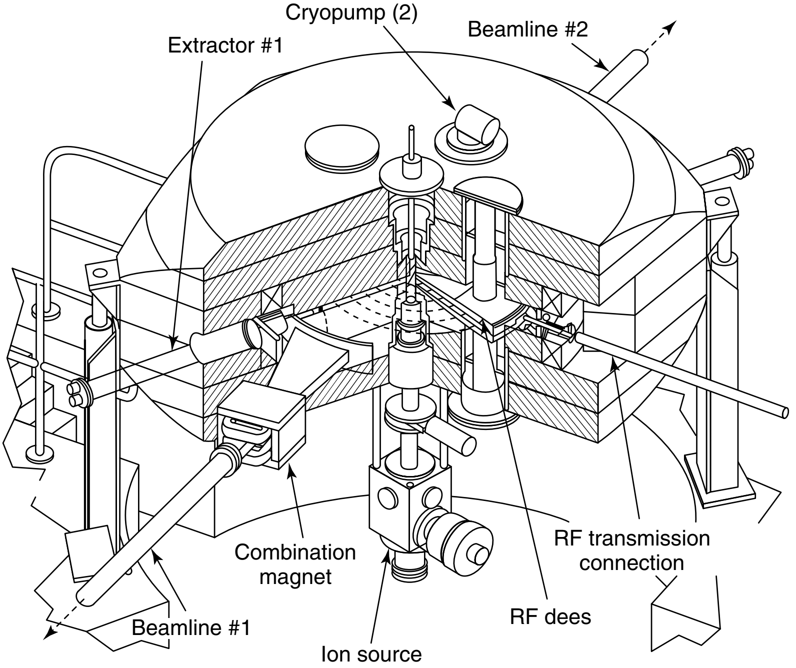

Fig. 13.A.1 Major components of a 30-MeV H$^-$ cyclotron intended for isotope production. (Courtesy of Ebco Technologies, Canada).

slight modulation of hill gap and by shims attached to the hill sides; the latter received their final machining following magnetic measurements.

The cyclotron is mounted over a pit to allow installation of the external H$^-$ ion source below and thus minimize cyclotron-vault head-room requirements. The H$^-$ beam is injected vertically upward toward an electrostatic spiral inflector that bends it into the median plane. Two 45° dees located in opposite valleys operate at 73 MHz, the fourth harmonic of the orbit frequency, and provide acceleration at four gap crossings per orbit. The dee voltage is 50 kV. Radiofrequency power is delivered to the dees through a capacitive coupling to a 50-Ω transmission line that passes through a port in the vacuum-tank wall. For ease of maintenance, the entire 35-kW rf amplifier system is located outside the cyclotron vault.

Four large holes through the yoke in the dee valleys accommodate the coaxial dee resonator stubs. To maintain fourfold magnetic symmetry, there are four additional holes in the unoccupied valleys. Two of these are used as vacuum pump ports in which two 8-in. cryopumps are installed. The vacuum enclosure is defined by the nickel-plated upper and lower pole surfaces and a cylindrical aluminum wall that is sealed to the poles by a double O-ring gasket. The operating vacuum is 7×10^{-10} bar.

Thin graphite stripping foils mounted on two extraction probes traveling in opposite hill gaps deliver two independent,

variable-energy external beams. The basic cyclotron parameters are given in Table 13.A.1.

Acknowledgment

The authors gratefully acknowledge the assistance of those colleagues who provided information for this chapter and helped with proofreading.

Glossary

amu: Atomic mass unit, $\frac{1}{12}$ of the mass of the carbon isotope ^{12}C.

AVF Cyclotron: An isochronous cyclotron with an aziumthally varying field to provide focusing and thus permit cw operation at relativistic energies.

Betatron Motion/Frequency: Oscillations in the transverse (axial (z), radial (r)) planes executed by the particles constituting a focused beam. The frequency of such oscillations expressed in terms of the particle rotation frequency ($Q_{z,r} = f_{z,r}/f_{\text{rot}}$).

Bunch: A collection of particles accelerated within one rf cycle.

cw Cyclotron: One with a constant accelerating frequency, and hence a continuous pulse train and macro duty factor of 1.

Dee: A hollow electrode, semicircular in early cyclotrons, carrying the rf accelerating voltage. Part of the beam path lies within the dee, acceleration occurring at entrance and exit.

Emittance/Acceptance: A quantitative description of the quality of a beam. The transverse emittance is a combination of the beam size and divergence; the longitudinal emittance, a combination of momentum spread and bunch length. The acceptance of an accelerator corresponds to the emittance of the beam that would just fill it.

Equilibrium (closed) Orbit: A conceptual unaccelerated particle trajectory closing smoothly on itself after one turn. Betatron oscillations can be imagined to take place about this orbit.

FM Cyclotron or Synchrocyclotron or Phasotron: A cyclic particle accelerator in which the accelerating frequency is varied during acceleration to match the particle rotation frequency. The beam is produced in a series of pulses with macro duty factor (0.1–10)% at repetition rates from 0.02 to 2 kHz.

Isochronism: Equality between particle rotation frequency and accelerating frequency.

K-Factors: Parameters associated with a cyclotron magnet. The maximum energy of an ion, charge qe, mass A, which can be contained in a closed orbit is $((T/A) = K_b(q/A)^2$ MeV amu^{-1}; the maximum energy which can be focused axially is $(T/A) = K_f(q/A)$ MeV amu^{-1}.

Macro Duty Factor: The ratio of pulse length to repetition time.

Meson Factory: An accelerator laboratory where intense beams of particles are produced whose energy is well above the threshold for meson production.

Particle Microamp: Cyclotron beam intensities are usually expressed as an electric current, for example, 1 μA being 6.24×10^{12} electronic charges/s. For an ion of charge qe the intensity may be expressed in particle microamperes where 1 pμA is 6.24×10^{12} particles s^{-1}, the electrical current being q times larger.

Pulse (Train): A sequence of bunches.

Stripping: Removal of some, or all, of the atomic electrons from an accelerated ion.

Synchrotron Oscillations: Oscillations in energy and phase about those of an ideal, synchronous particle.

INTRODUCTION

For the most part, the world we live in is complex, and most events stem from situations which have many degrees of freedom. One approach we use to deal with this is to average over quantities; for example, thermodynamics is used to attempt to describe a system in terms of a few variables such as temperature, pressure, and flow velocities. Even in systems such as these, variables of interest may vary rapidly in space and time. If these variables are recorded in any detail, a data set for a given case can easily contain tens of millions of numbers. As an example, consider an experiment in plasma physics done by the author (Gekelman *et al.*, 1987) in which a fully three-dimensional magnetic field changes its topology rapidly (within 100 ms). The vector field is measured at 4000 locations and sampled at thousands of time steps at each position. Magnetic-field data sets in excess of 10^9 numbers are commonplace. If the experiment is fully characterized by measurement of the electric field, $\mathbf{E}(\mathbf{r},t)$, and particle distribution functions, $f_\alpha(\mathbf{r},\mathbf{v},t)$, gigabyte (GB) data sets are collected for each set of initial conditions. This enormous influx of data is becoming the rule in experimental physics as elaborate detectors capable of detailed measurement are designed. This trend in measurement is most welcome since with it comes the opportunity for detailed comparison with theory, but it is no accident that the theories and

experimental techniques have evolved in parallel with data-acquisition technology.

The list of environments which rely heavily on data-acquisition systems is nearly endless, but the following are a few examples: plasma physics and fusion, high-energy physics supercolliders, wind tunnels, laser physics and optics, process monitoring and control in manufacturing, etc. Many devices, such as commercial aircraft and automobiles, have *intelligence* built into them. This is nothing other than one or more sensors attached to a microprocessor which uses the data collected to feed back to the machine operation and report malfunctions. As these data-acquisition systems become cheaper, more and more ordinary devices will contain them. One day we may have "smart" toasters.

The data-acquisition systems (DAS's) that have evolved to meet these demands can range from relatively simple turnkey commercial packages to incredibly complex ones. The former are used in small laboratory experiments, and the latter are used at facilities such as CERN, where high-energy physics detectors with several hundred thousand channels deliver 500 MB of raw data per second (Rüden, 1989). This article will introduce the components within a DAS and attempt to explain how they interact with the experiment and with each other, and finally how data might be stored and reduced. There are, of course, a variety of approaches to this which depend on the speed required, the number of data channels, and on-line processing requirements. Several of these will be reviewed. Examples of DAS's of varying complexity will be presented, and in doing so we will discuss several important elements, such as digitizers, pulse counters, clocks, and control devices. Finally, we will speculate on what will happen in this arena in the near future.

1. DEFINITION AND CRITICAL COMPONENTS OF A DATA-ACQUISITION SYSTEM

A data-acquisition system is anything which accepts a signal from a detector and stores it so that it may be analyzed at a later time. Its basic elements are shown in Fig. 1. Here, the signal source is shown to occur in an experiment, but this definition is too narrow. Anything worth understanding or diagnosing serves as the experiment. This could be the chemicals pouring from a smokestack, the temperature and gas mixture in an automobile engine, or the vital signs of a patient on an operating table. The detector is a device which responds to something within the experiment (fluid flow, temperature, presence of an electric charge, etc.), and usually presents a voltage at its output which is related to that thing. Sometimes the detector output is easily interpreted. The output voltage of a thermocouple is directly proportional to the temperature of the thermocouple. In other cases, the detector output bears no simple relationship to the measured quantity and has to be analyzed on a computer. This is the case for Thomson laser scattering diagnostics in fusion experiments, where the final results are the plasma electron temperature and density. Since detectors vary enormously from case to case, little more will be said about them here. A detector may produce an output signal which is a time-dependent voltage, charge, or current or optical signal. In plasma physics research, for example, sensors typically generate output voltage wave forms. Data acquisition consists of digitizing and recording these rapidly varying analog signals, with a voltage-sensitive

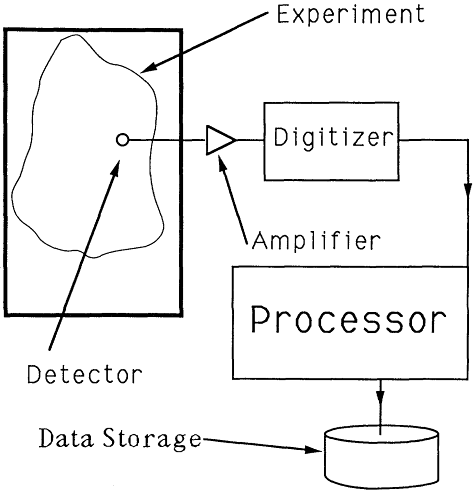

FIG. 1. The basic elements in data acquisition. A detector generates a signal which is usually conditioned by an amplifier and then input to a digitizer. The analog signal is converted to a binary number and then sent via a processor to storage media such as a computer disk or tape.

device, after a start trigger, or before a stop trigger is issued. The gain of any signal-conditioning amplifier is a dimensionless number since the sensor output and digitizer input are both voltages.

In high-energy physics experiments, photomultipliers or wire detectors are used to record the passage of particles. These events produce pulses of charge at the detector output, although the signal generated by each varies and must be separately conditioned. In this case analog-to-digital converters with charge-sensitive input amplifiers are used to encode the signal. The charge present at the amplifier input is integrated over a short period of time ($50\text{ ns} \leqslant t_{\text{gate}} \leqslant 2\ \mu\text{s}$) determined by an input gate pulse. The output of the digitizer is proportional to the number of picocoulombs (pC) of input charge. This is very different from a digitized wave form which may represent the time history of a magnetic field. The gain of charge-sensitive amplifiers is expressed in units of V/pC; that is, the peak output voltage is proportional to the charge received. A third type of conditioning amplifier, the transimpedance amplifier, takes current as the input signal and produces an output voltage proportional to it. The gain of this device has units of V/A or resistance. These amplifiers may have to operate in an electrically noisy environment, and elaborate shielding, or the transformation of the electrical to an optical signal for the purpose of transmission, may be necessary at this stage.

The next operation is signal storage. Sometimes the signal is processed in real time before storage to save storage space. There are a number of ways to accomplish this, and some will be discussed in the next section. In this article, we will concentrate on digital data storage. This involves the transformation of the analog voltage to a time series of digital numbers sampled at various positions on the input wave form. Although, as will be discussed later, information is always lost during sampling, the digitized signal is perfect for use by a computer. In most cases, digitizers have their own local memory and the data must be subsequently transferred to a computer where it may be analyzed mathematically, plotted, or stored on a disk or tape after acquisition.

2. THE EVOLUTION OF DATA-ACQUISITION SYSTEMS

2.1 NIM

Until the 1960s, commercial products such as digitizers did not exist, and the only way to record nonrepetitive, rapidly varying data was by taking pictures from an oscilloscope screen. The budget of a research laboratory may have included tens of thousands of dollars per year for fast Polaroid film. Data analysis involved laboriously measuring the amplitude of the recorded signals from the scope traces with a ruler and entering them by hand into computers when necessary. This meant that experimental researchers generally eschewed the use of computers, and data were sparse. Most experimental results were easily plotted as line drawings. Needless to say, detailed comparison between experiment and theory was not possible.

There was, however, a need for uniformity in the measurement equipment utilized in large high-energy physics experiments. A power supply for devices such as counters and amplifiers with a fixed instrument input voltage and specifications for signal input and output levels was agreed upon by the Nuclear Instrumentation Methods (NIM) committee in the United States. The power supply was cratelike in appearance and allowed for the easy insertion and removal of a variety of modules. The NIM crates had no provision for data readout and any device control had to be done via inputs on the devices themselves.

2.2 CAMAC

The biggest breakthrough in data acquisition occurred with the advent of large-scale integrated (LSI) circuit chips and the introduction of microcomputers which relied on them. This new technology allowed for the control and readout of devices in crates and an interface standard for CAMAC (computer automated measurement and control) was developed in 1969 by the European Standards on Nuclear Electronics Committee and then with further collaboration from the NIM committee in the U.S. (Horelick and Larsen, 1976; U.S. NIM Committee, 1981). The CAMAC standards were updated several times to allow for multiple crate systems that could be connected in parallel and series, and to allow for

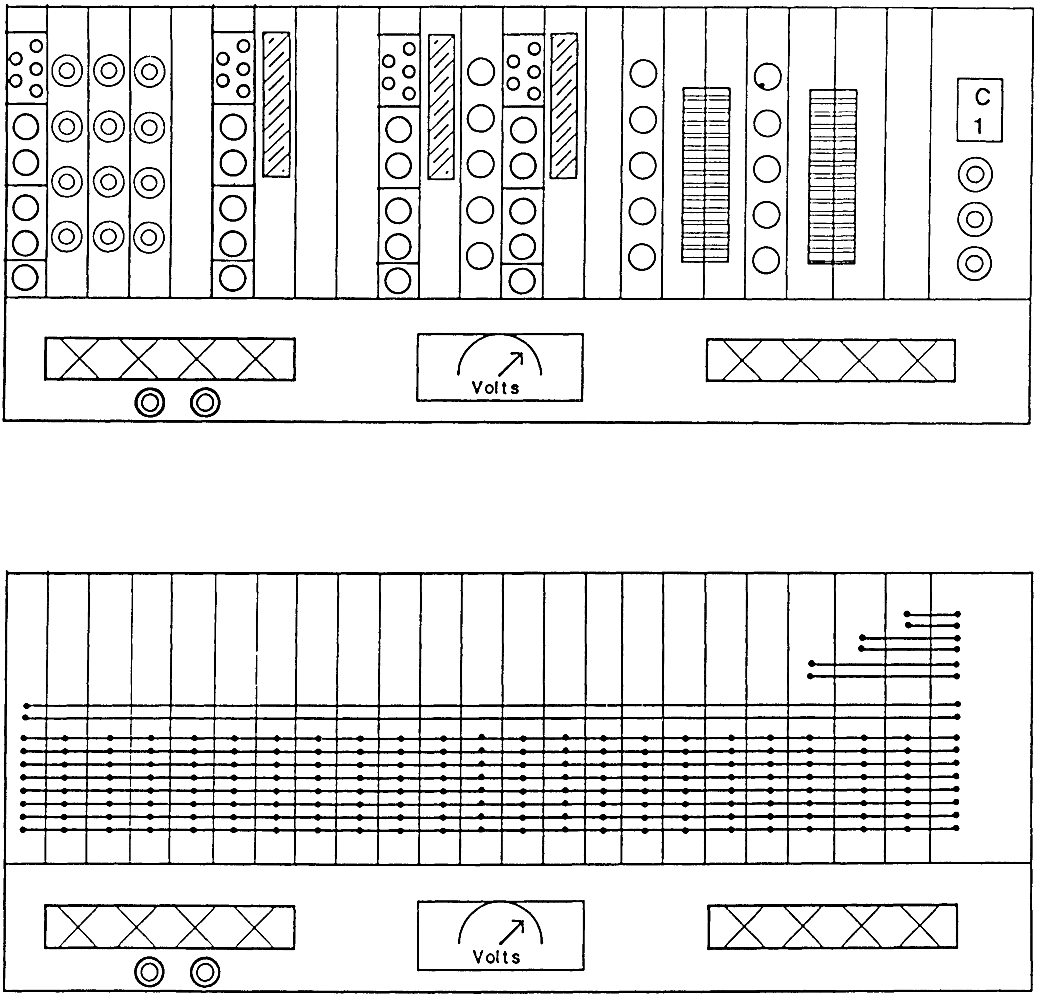

FIG. 2. (a) The front view of a CAMAC crate. There are a number (usually 25) of slots into which various devices such as analog-to-digital converters, memory modules, or clocks (see Table 1) may be placed. The leftmost slots are reserved for the crate controller module(s). (b) A view of the bus arrangement for a CAMAC crate. The top shows four of the point-to-point wires. These go from the controller to each slot and are used for individual addressing. One of the wires is the *N* line, used for station addressing, while the second is the *L* line, used for interrupts. The bussed wires, shown on the bottom, connect all the modules and are used for data transmission.

distributed processor intelligence. These techniques will be discussed in this article. The latest standard was issued by the Institute of Electrical and Electronic Engineers (IEEE, 1982).

CAMAC crates differ from NIM crates in that the former have a built-in computer bus called a CAMAC dataway. The crate has as many as 25 slots, each a standard size, with power and signal contacts at its rear specified by the IEEE convention. The slots are made to house data-acquisition or experimental control devices [Fig. 2(a)]. The variety of devices that can be inserted into CAMAC crates is large and ever growing. An example, which is not exhaustive, is provided in Table 1.

2.2.1 CAMAC Bus. The first slot, or the first and second slots, in a CAMAC crate is usually occupied by a *crate controller,* a microprocessor enabling it to communicate with external computers or other crates. On the back of the slot is an 86-pin connector to the dataway [Fig. 2(b)]. The dataway has two point-to-point wires for each station within it, as well as 24 read and 24 write lines which are shared by all the modules. These lines permit 24-bit parallel data transfers. The point-to-point lines are used to send commands to an individual station or to allow that station to send a signal, such as "now I have data, look at me," a LAM. Other bus lines concern themselves with clock signals and status information about data transfers. The clock signals, or strobes, are generated by the crate controller, which is also the source for all commands to the devices in the crate as well as a funnel through which the device's data move to an external computer. All the CAMAC devices are controlled by issuing instructions to the crate controller, which in turn reissues them to the entire crate or an individual device within it. The commands have been given standard names but always result in words with specific bit patterns being sent along the dataway.

2.3 GPIB and VME

At some point, the crate must interact with a computer to get instructions and send data for storage. The simplest interface is an RS-232 serial port. For this interface, one must buy an RS-232 module for the crate and plug the output from this module into the com-

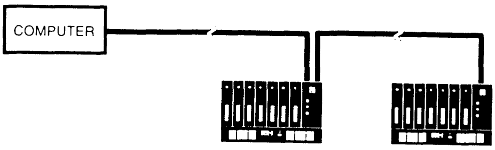
Table 1. A sample list of devices used in CAMAC and FASTBUS crates.

Device	Purpose	Properties
Analog-to-digital converters	Analog-to-digital signal	16 bit 30 kHz to 8 bit 1 GHz
Programmable amplifier	Computerized signal gain	125-MHz gain, offset, impedance
Digital voltmeter	Digitize many (64) input channels	Slow, 1 mV to 10 V autoranging
Programmable clock	Dynamically control digitization rates	Multiple outputs, 5 ns to 1 ms/tick
Memory modules	Storage of data from digitizers	May be partitioned up to 1 Mbyte each
Stepping motor controllers	Digital control of motors	To move detectors in experiments
Digital-to-analog converters	To operate relays, analog device control	Multiple output channels, 16 bits in
Programmable trigger generator	Generates reliable recording and stop triggers	Variety of triggers, multiple outputs can be combined
Multichannel input gates	Determines electrical state of contacts	32 or more channels; 0=closed contact
Spincoder	Measures shaft rotation	Can feed back to a stepping motor
Gated integrators	Integrates charge	Multichannels (32) for phototube output
Multiplexer	Combines up to 16 input channels	600-ns switch time sequence by computer
Contact closure	Closes physical relays	12 contacts controlled by computer command
Histogrammer	Creates histogram from memory data	10^6 inputs @ 4096 counts/input

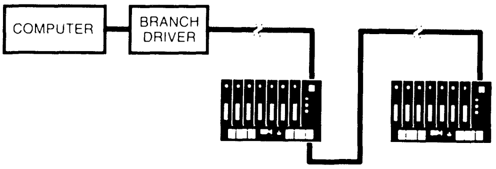
puter. The computer then regards the crate as a terminal. The transfer rate is extremely slow (maximum of 19.2 kilobits or 800 24-bit words/s). The next step up is the general purpose interface bus (GPIB). This was first developed by Hewlett Packard in 1965 (and called the HP-IB), and, because of its popularity, it was accepted as an IEEE standard interface. One may now purchase GPIB interface modules for CAMAC crates, available from several vendors. Although quite slow, they are a widely used interface to IBM personal computers and their clones, as well as a number of instruments such as digital oscilloscopes, spectrum analyzers, etc. A faster way for crate/processor communication is to connect the crates directly to the bus of the computer, as shown in Fig. 3(a). There are a variety of standard busses (see BUS SYSTEMS AND COMPUTER INTERFACING), e.g., the Unibus, Qbus, and BI bus for DEC computers, and the VME bus for 32-bit workstations such as SUN computers. Several companies market CAMAC interfaces for these busses. The interface consists of a board set (one for the crate and one for the computer) and software programs called drivers that permit data-acquisition software to allow command and data transfers to occur.

2.4 Microprocessor Control

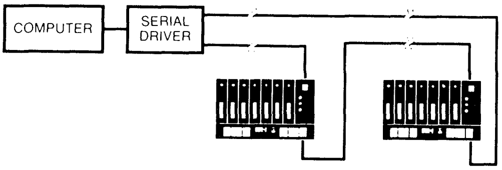
The introduction of cheap, powerful microprocessors, namely the PDP-11 series by the Digital Equipment Corporation (DEC), enabled a computer to be installed directly in the crate, as shown in Fig. 3(d). This made it possible to deal with situations requiring rapid response, if data had to be preprocessed or moved out of the digitizer's local memory in time to handle the next event. A number of startup companies bought processor chips from DEC and packaged them to fit in the crates along with a crate controller. These intelligent crate controllers had serial ports so that terminals and printers could be connected. This arrangement became an immediate success and is still used in many laboratories. However, new technologies drive the insatiable need for more (in this case, channels of data), and it became necessary to configure systems containing many crates.



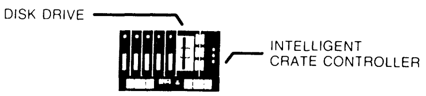
a. One or more crates on a computer bus.



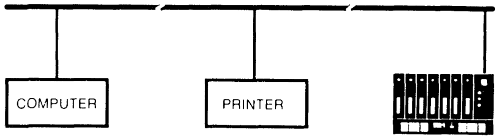
b. Standard CAMAC Parallel Branch Highway.



c. Standard CAMAC Serial Highway.



d. Stand-alone CAMAC crate with microcomputer.



e. LAN-interfaced CAMAC crate.

FIG. 3. Several approaches to CAMAC computer interfacing.

2.4.1 CAMAC Processor Connections. A number of CAMAC crates may be connected in series (serial highways) or in parallel (parallel branch highways). A CAMAC serial branch highway is shown in Fig. 3(c). A serial driver board is installed in the host computer and then connected to the first of up to 64 crates. Each crate has a controller in it which examines the command from the host computer. If it is to one of its modules the command is carried out, if not the command is passed on to the next crate. One of the lines from the host is a clock line to set the timing for all of this. The clock rate can be as high as five MHz, and block transfer rates as high as 2.8×10^5 24-bit words/s have been measured (Cleary, 1985).

It is always faster to interact with many devices in a parallel mode and so parallel branch highways for CAMAC came into being. To handle this the crate interconnections are done by use of a 66-pair ribbon cable as shown in Fig. 3(b), and a special driver board in the host computer. Only seven crates may be connected to the interface (as opposed to 66 in the serial mode), and there is a 50-m length limitation of the cabling, but the data-transfer rate is an order of magnitude higher in this mode.

2.4.2 CAMAC LAN Connection. It is possible to hook a CAMAC crate directly to a local-area network or LAN, with the appropriate crate controller [Fig. 3(e)]. This has the advantage of having the crate accessible by more than one computer on the network. The LAN can be fiber-optics based which makes it immune from electromagnetic noise. This is a very important consideration in many environments. A LAN based on Ethernet hardware can run at up to 10 megabits/s and crate controllers for this are available now. The next technology for LANs is FDDI (fiber distributed data interface) and will be about ten times faster. It is expected that crate controllers for this will be available by mid-1992.

2.5 FASTBUS

The high data rates from some modern experiments have strained serial and parallel CAMAC highways. A response from the industry has been the introduction of FASTBUS which is an IEEE standard (standard No. 960-1986) which allows for the fastest, highest-density data acquisition and transfer today. In addition, researchers in the past few years have taken advantage of the introduction of powerful and inexpensive 32-bit workstations to the computing scene. Since the CAMAC dataway is 24 bits wide, it is incompatible with these processors; 32-bit transfers would take more than one CAMAC cycle. The industry responded with a new type of crate for FASTBUS. Like CAMAC it is a modular data bus but it is 32 bits wide; the crate has additional lines for timing and control status. The FASTBUS crates can be interconnected in a variety of ways which will be outlined in a section to follow. The FASTBUS backplane achieves a bandwidth of 40 MB/s as compared to CAMAC which saturates at about 5 MB/s. For example, a single crate might have analog-to-digital converters with 5 MB of memory to be transferred after the analog-to-digital converters (ADCs) are filled and generate a LAM. At a maximum transfer rate of 1×10^6 24-bit words/s (Cleary, 1985) it would take at least 5 s to move the data to a computer. The actual number depends upon the clock rate of the computer and the software employed, and this is a best-case scenario. One must also consider that a large experiment may have more than one crate delivering data to the host computer. FASTBUS can transfer 32-bit words at about 8 times the above speed. This difference can be critical in experiments with a high repetition rate. There is, however, a cost tradeoff; FASTBUS crates are more expensive than those for CAMAC, and there are far fewer modules available for them at this time. Research groups wishing to use them often are faced with designing their own FASTBUS ADCs.

2.6 Speed

The revolution in 32-bit microcomputers has led to the standardization of several computer bus architectures. Some computer manufacturers have opened up the details of their architectures so that others could build peripheral devices to connect to their machines, thus enhancing the popularity of their product. Two such busses are Multibus and VME. The latter has been made popular by the success of SUN Microsystems, which makes the largest selling workstations in the United States. Crates containing both these busses in their backplanes have been manufactured. The VME crate supports 32-bit transfers just as FASTBUS does. The difference here is that now the crate is an integral part of the host computer. No intermediary crate controller is required. Since VME has been widely adopted there are a large number of cheap memory and processor cards and other modules. It is possible, therefore, to buy your own processor and build a powerful computer directly into the crate. The raw speed of the VME bus is quite high, up to 100 MB/s. This system can stand alone for real-time data processing. A VME interface to a disk can allow for data storage. Unfortunately, there are no fast ADCs which are commercially available for VME busses. Those who require them have had to build their own, which is quite a task. Just as in the case of CAMAC the VME crates can have local processing power, and, in addition, a direct memory access (DMA) interface to the memory of a larger computer which can do further data processing and graphics. We note here that data can be transferred between the memories of two autonomous devices in one of two ways. The first, and much slower, method involves one device placing a single number in a memory register which is mapped into a single memory register of the second device. A flag is raised by device 1 advising the second that the number is there; device 2 copies the number into its memory and sends acknowledgment to the first. The second and much faster way is a DMA data exchange. Device 1 requests the use of the device-2 bus and some of its memory. When the request is granted (usually after device 2 is finished with its latest chore) device 1 fills the allocated memory of device 2 with a stream of data. In this method the handshaking that goes with the transfer of every number is eliminated.

Multiple crates can be connected using a network such as Ethernet (which runs at 10 Mb/s). One such system employing multiple VME crates with 96 8-bit, 100-MHz flash ADCs per crate has been built for a nuclear experiment at CERN, in Geneva (D'Isep *et al.*, 1989). The network can be fiber-optics based and, therefore, immune to electrical noise. In addition, networks even faster than Ethernet, such as FDDI, have developed in parallel with these systems. Interfaces to VME for FDDI already exist. Experimental networks with Gb/s rates are under development, and although there are as yet no standards for them, one company (ULTRANET) has a commercially available product. The trend in the high end of data-acquisition systems is toward systems with networked distributed processing.

Just as important as the leading-edge technology is the availability of very inexpensive and easy-to-use data-acquisition systems for personal computers (PCs). Some inexpensive modules can be installed directly on the backplane of MS-DOS machines and Apple computers. The latest generation of NeXT computers, as well as a new product from Silicon Graphics, have both voice and data digitizer hardware as well as the software needed to use them easily. Menu-driven software packages for DOS computers, that allow the user immediately to acquire data and plot it, are available from a number of third-party vendors. There also exist interfaces and CAMAC crate controllers for PCs, along with the appropriate software. These systems cannot support high-speed data transfers, and are limited by the speed of the PC, but they are perfect for small experiments or student teaching laboratories. In the following sections we present, in greater detail, the elements of some of these systems and give specific examples.

3. TRIGGERS

A simple trigger is an electrical pulse which is issued to stop or start data acquisition at a critical moment during an experiment. Large-scale experiments may involve many levels of triggering. This is the case in high-energy physics or fusion physics where thousands of detectors may be involved in a single experiment. These detectors may generate a signal pattern which, if of interest, may be stored or used to trigger other groups of detectors. In high-energy physics a great number of uninteresting events occur, and these data must be rejected. Multilevel triggers with successively complex discrimination logic are employed in this task. This is interwoven with the need for accurate timing and triggering at each stage. The results from one set of detectors could be compared to a data mask; if a valid event has occurred a secondary trigger is generated and delivered to other parts of the data-acquisition system which are working in parallel. Each trigger level provides a filter for the next level of acquisition.

3.1 Specialized Instrumentation

Generally, these decisions have to be made on microsecond time scales. A great deal of specialized equipment has been developed for this (LeCroy, 1990). Fast-pulse instrumentation often uses discriminators which take input pulses with varying wave forms and produce output pulses of standard amplitude and duration. Discriminators must deal with the varying duration and rise time of the input pulses as well as bursts of pulses which can exceed their own input bandwidth. Logic units are also employed in triggering decisions. These generate an output pulse whenever a number of input pulses occur within a preselected time interval. Logic circuits may produce an output which is either reinforced or inhibited by associating the input pulses to them with preprogrammed logic diagrams. Time intervals between events are measured by time-to-digital converters, which generate binary output. The temporal resolution is a function of the number of digitization bits available and the total time interval involved. Accuracy of tens of picoseconds, which is necessary in time-of-flight measurement, is possible. Internal buffering in time-to-digital converters allows for counting to be resumed before previous data are read out.

4. DIGITIZERS

A great variety of modules are available for CAMAC-based data-acquisition systems. A sample of these is presented in Table 1. The elements listed in the table can be roughly grouped into two categories. The first comprises modules used for timing and control of the experiment. The second, and the key component in data acquisition, includes the digitizers or analog-to-digital converters. The signal to be recorded from the experiment and later processed is assumed to be a current or voltage wave form. Since all digitizers require an input voltage (usually in the range of 0.0–0.5 V) the signal must be properly conditioned before applying it to the digitizer. This conditioning process can be as simple as placing the signal across a resistive voltage divider, if it is too large, or may involve the use of differential amplifiers with variable gain if there is an impedance mismatch between the source and digitizer. Signal conditioning is an enormous topic and is best left to a reference (Horowitz and Hill, 1989).

4.1 Resolution

There are three main features to any digitizer which warrant discussion here. They are the number of bits of resolution, the resident memory, and the digitization rate. In general the more of each feature that a unit possesses, the better it will perform, and the more expensive it will be. Digitizers work by mapping the value of an analog signal (i.e., a voltage) measured at a particular time into an n-bit binary number between 0 and 2^n-1. The number of times per second that a signal is measured and translated into binary is called the digitization rate. Since the measured signal is assigned a discrete value there will always be a quantization error associated with the process. In general, this error is one part in 2^n for an n-bit converter. For example, consider an 8-bit converter which accepts a signal of $0 \leqslant V \leqslant 0.5$ V. The number is stored in the converter as an integer between 0 and 255. One bit, which in this case is roughly 2 mV, is about 0.4% of the maximum signal value. If the signal is close to the maximum that the digitizer can handle, the stored signal will closely resemble the input signal as shown in Fig. 4(a). However, if the signal (or a portion of it) is small, it will appear as a staircase of discrete steps and a considerable error is introduced [Fig. 4(b)]. If the signal exceeds the input range of the converter, it will be assigned the maximum value and information will be lost as shown in Fig. 4(c). There are two ways to avoid large digitization error. The first is to ensure that the input signal is close to the full operating range of the digitizer. This may be accomplished with the use of a preamplifier or, in the case of a signal which may change slowly in time, a computer-controlled programmable preamplifier. The second way to attack the problem is to use analog-to-digital converters of 12 and 16 bits. A 16-bit converter has only a 0.000 15% error. For low digitization rate devices (< 50 kHz) these converters are inexpensive, but their price escalates with frequency. At the time of this writing, there are no digitizers with greater than 8-bit accuracy with sampling rates above 200 MHz.

4.2 Sampling Rate

The second criteria for digitizers is sampling rate. Many inexpensive PC-based data-acquisition systems come with digitizers that work at speeds below 100 kHz (10^5 samples/s). This speed is more than adequate for digitizing voice signals (the human ear generally cannot hear above 20 kHz) and sampling signals of many everyday phenomena. A car

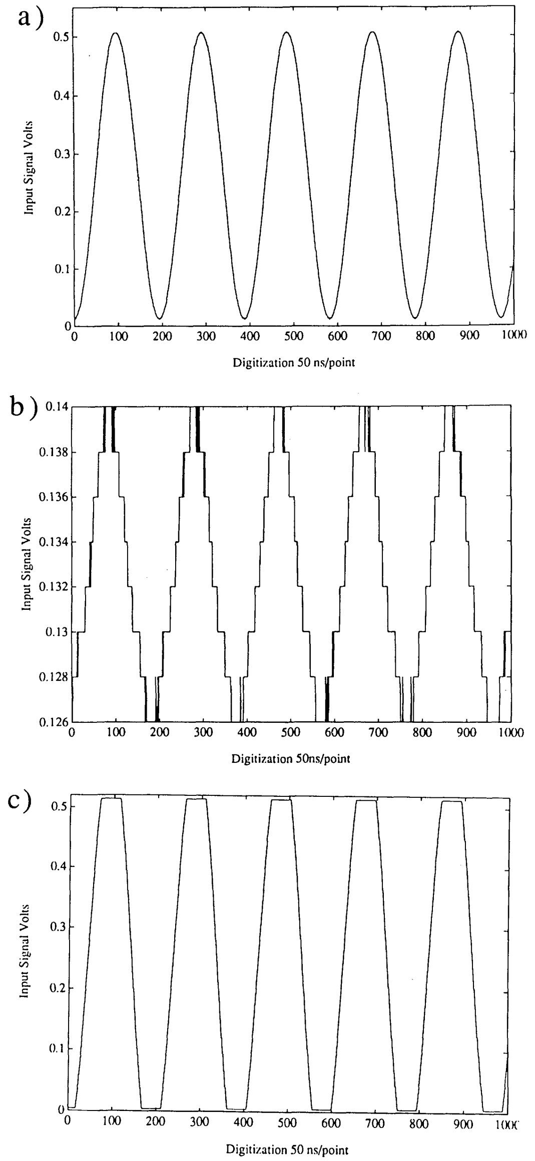


FIG. 4. (a) A digitized 100-kHz sine wave. The digitizer has 8-bit accuracy and can accept a signal of $0 \leqslant V \leqslant 0.5$ V. Since the digitizer is used over its full working range, signal reproduction is excellent. The 1000 samples correspond to a time interval of 50 μs. (b) The same digitizer is used on a signal of very small amplitude. The signal is less than 3% of the 0.5-V working range so that bit noise is apparent. (c) A signal in excess of the 0.5-V limit on the digitizer results in clipping.

moving at 60 mph will move 2.7 mm in one sample time. However, there are a great number of other phenomena such as the oscillations of electrical circuits, or the change of parameters in a plasma, that occur on much briefer time scales. The fastest digitizers today work at about 1 GHz (10^9 samples/s) and are about 100 times too slow for some of these applications. One must, therefore, consider what happens if there are elements present in a wave form which are above the maximum frequency that the digitizer can handle. Figure 5(a) shows an example of a 110-kHz signal digitized at a rate of 1 MHz (1 μs/sample). There are 11 samples on each cycle of the wave form. The theoretical limit for a particular sampling rate is called the Nyquist limit (Bendat and Piersol, 1971). At the Nyquist limit there are only two samples on every cycle, and the wave form, as shown in Fig. 5(b), is not discernable to the unaided eye. Finally, if one introduces a wave form of higher frequency than the digitizer can handle, a curious phenomenon occurs. As shown in Fig. 5(c), a lower-frequency component, which is nonexistent in the original data, appears. The occurrence of this spurious signal is explained in Fig. 6. In the upper graph the original high-frequency signal is shown with dots on it. The dots correspond to the sampling times of the slow digitizer. Suppose it is known that the input signal is a pure sine wave. If the sampled signal points (the dots) are used to reconstruct a sine wave, as shown in Fig. 6(b), a lower-frequency, incorrect wave form results. It is therefore important to exclude all signals of bandwidth greater than that of the digitizer. This can be accomplished with the use of a low-pass filter. Failure to filter the input signal properly can result in a corrupted stored signal, as seen in Fig. 7. The first part of the figure shows the power spectrum of the correctly digitized 10-kHz signal of the type shown in Fig. 5(a). The power spectrum is a measure of how the input signal power varies as a function of frequency, and is found by Fourier transforming the original time-series signal and multiplying by its complex conjugate. In Fig. 7(a) there is a clear peak at 10 kHz corresponding to the input signal. (There is always a peak at zero frequency which is suppressed in these plots.) When an improper digitization procedure is used, such as 1-MHz sampling of a 20-MHz signal [as in Fig. 5(c)], a signal not present in the original wave form appears, as shown in Fig. 7(b). No signal should have been detected at $f < 0.5$ MHz, but the undersampling gives a nonexistent peak at lower frequency.

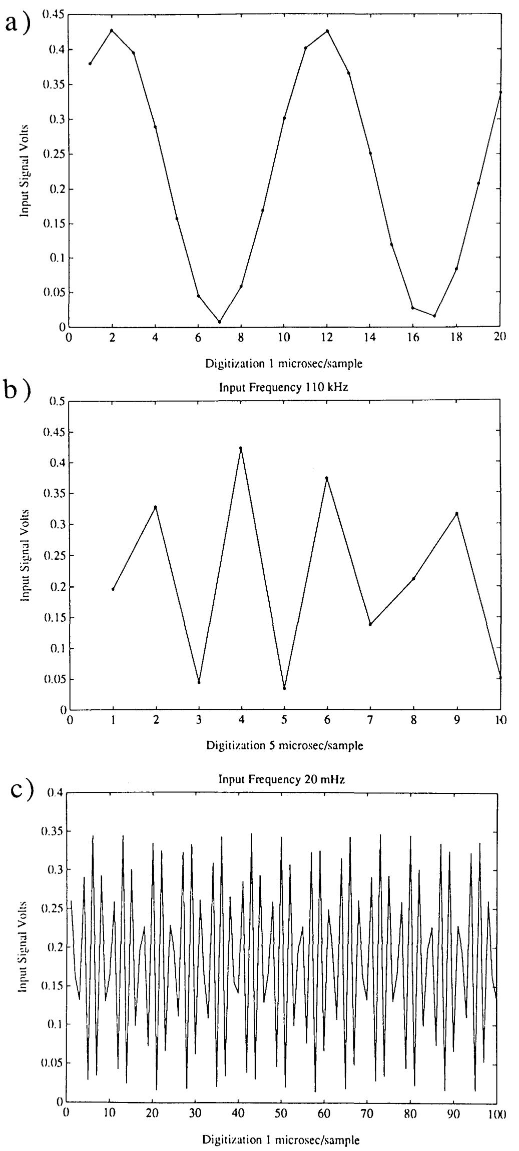

FIG. 5. (a) A 110-kHz signal digitized at 1 μs/sample. The dots on the curve are the digitized data and are connected by straight lines for clarity. The sine wave is choppy [unlike that of Fig. 4(a)] but easily recognizable. (b) The same signal digitized at 5 μs/sample, just above the Nyquist limit. This is truly a limit for the sine wave in (a) is not recognizable. The record shown is 50 μs in length. (c) The effect of undersampling. A 20-mHz signal is digitized at 1-μs intervals; a factor of 20 too slow. The time interval shown is 100 ms but a wave form of five oscillations is not visible.

4.3 Memory

Every analog-to-digital converter must be coupled to a memory. The digitizer performs a conversion of the input signal into a binary number which must then be read into a memory before the next conversion is attempted. In many cases this memory is closely coupled to the converter and is not the same as the memory of the computer which controls the process. When the digitizer's memory is full, its contents must be transferred to the host computer. The cost of an analog-to-digital converter depends upon how much resident memory it has, and how fast that memory must be addressed. Clearly, a digitizer which does one conversion per nanosecond must be matched to a memory fast enough to accept numbers at that rate.

5. HOW A DATA-ACQUISITION SYSTEM WORKS

As outlined above, there are many hardware variations within a DAS, but the process of acquiring data shares many common procedures. As an example of these common elements, we describe the features a software package should have for controlling the interaction between a digitizer (ADC) and a CAMAC-based DAS. When the DAS control software is initiated, the user decides which devices in the crates will participate in the experiment. The software generates a table containing which crate and slot the device occupies. If an experiment is to be repeated, these tables may be read from a file which defines the experiment.

5.1 Software

The software then issues an instruction to the crate controller, which in turn initiates the ADC. Before starting, the ADC must receive a LAM (look at me) enable instruction from the crate controller. In some crate controllers, an instruction to enable an interrupt of the processor when its data acquisition is complete must be issued also. Next, the crate receives a clear signal from the processor controlling it, all the device registers are cleared, and digitization begins. The ADC continually reads and converts data from its input signal. The digitized data are transferred into its local memory. When the memory is filled, the digitizer overwrites the start of memory and continues until a stop trigger is received from the control software. The trigger forces the ADC

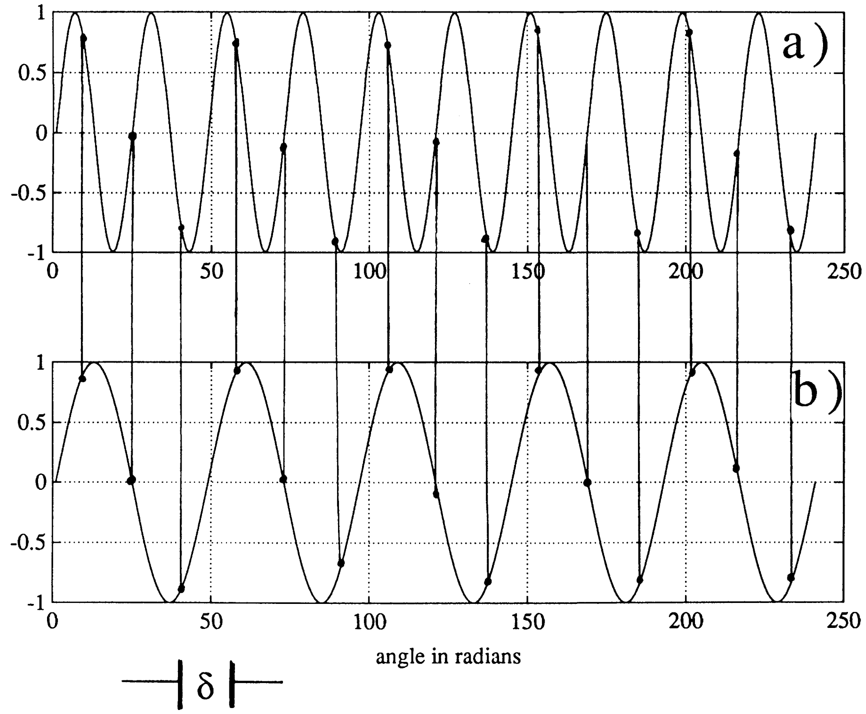

FIG. 6. Effect of undersampling a high-frequency wave form. A sine wave shown in (a) is sampled at an interval δ. Each sample time is denoted by a dot. If it is known that a sinusoidal wave form was input to the digitizer, an incorrectly reconstructed wave form, shown in (b), may result. Undersampling a high-frequency signal can therefore result in low-frequency *ghost* modes not present in the original one.

immediately to stop acquiring data and raise a LAM. When the crate processor detects a LAM, it immediately stops what it was doing and jumps to a location in its memory where it expects to find the starting address of an executable program. Such a program is called an interrupt handler.

5.1.1 Interrupt Handlers. These programs were formerly laboriously written in assembler language by data-acquisition programmers. If there was a programming error and the computer jumped to the wrong address, or there was nothing at the right address, the computer simply crashed. Now, however, companies which sell crate controllers also sell higher language subroutines (usually written in FORTRAN, PASCAL, or C) which activate handlers they have written. The handler is usually quite simple. For example, it might check to see that one of the devices authorized to participate in the experiment generated the interrupt. If an illegal device interrupted, that device could be ignored or the software could branch to an error-handling routine. If a legal device interrupted, the handler disables the LAM and branches off to another program which may be a user-written routine to read data. The interrupt handlers provide an interface between the software control package and internal crate operations.

There is another way to service the device without generating an interrupt. All the above steps are performed, but the device is not authorized to issue a processor interrupt. It does, however, issue a LAM. The software control package must enter a loop in which it looks at all the devices that could raise a LAM and waits for one.

5.2 Sample Program

A generic routine (in FORTRAN) might look like this:

```
       time = secnds(0.0)                      ! set clock to zero
       do i = 1,no_crates                      ! loop over crates
         if(status(crate(i),crate_stat).eq.0)  ! check for problem
           call error_message()                ! something wrong, print
         endif                                 ! an error message
10     if(crate_stat. eq. LAM_mask)then        ! we got a LAM
       {
                 .......do things like read data and turn off the LAM
                 }
       endif
       else                                    ! if we didn't get a LAM
         if (secnds(time).lt.timeout)then      ! continue to check
         goto 10
       else                                    ! we waited long enough
         goto 100                              ! leave the loop
       endif
       enddo                                   ! finish looping over valid modules
100    continue                                ! jump out of search for LAMs
```

Here, the crate controller has a word called crate_stat which it passes to the microprocessor. If the word is blank, there is a problem, and an error message is printed. Further action could be taken here as well. If the word returned from the crate controller equals the bit pattern (the correct sequence of zeros and ones) in the word LAM_mask, the *i*th device has raised a LAM and is then serviced. Finally, a timing routine must be included so that, if nothing happens for a while (timeout seconds), the computer can go on to do other things. Otherwise, it will be caught in an infinite loop!

5.3 Processor–Crate Communication

How do the crate controller (which is a microprocessor) and the master computer actually communicate with each other? This is done by sharing memory locations. Furthermore, the dataway lines previously discussed are directly mapped into these locations. This mapping is done by the hardware in the crate controller. Before the data-acquisition control software is run, the memory locations in the host computer permanently allocated for sharing with the crate controller must be assigned. For some small computers directly housed in the crate, this assignment can be done by setting dip switches in the back of the computer. For larger systems, a software *driver* must be loaded into memory when the computer is booted or turned on. This driver is a short program which permanently resides in memory with the computer's operating system and provides all these memory addresses. When the crate controller interrupts the computer, the driver takes over, finds the correct servicing program, and calls it. When you want to do something such as clear a LAM, the driver actually issues the instruction, which might be something like:

```
MOVB #10., @#164040.
```

This moves a byte, or 16-bit word, which contains the decimal number 10 (or 0 000 000 000 001 010), into memory location 164040, shared by both the controller and host computer. The crate controller then puts this number out onto the dataway, which has the effect of putting positive pulses on two of the signal lines, which in turn forces the hardware to turn off the LAM. Presently, the programmer who writes control software no longer needs to contend with these low-level instructions. Software that handles these processes may be purchased from the company that sells the crate controller.

Once the data is stored in the ADCs, the next step is transferring it to the host computer. In early crate controllers, this process was slow, since data could only be transferred word by word. A CAMAC command initiated the transfer and also passed the address of the data array in the host computer. Each time a word was transferred, the controller also set standard CAMAC bits (the Q and X bit) indicating that all went well. The user could check these bits with the main data-acquisition program. Later models of crate controllers allow for block transfers of data. Blocks of up to 32K (32 767) 24-bit words can be transferred all at once. This procedure saves time as there is considerable overhead in getting the host computer and crate controller to start the transfer (a memory region must be allocated and other parameters initialized). Actual transfer rates are hardware specific, but for a MicroVax (μVAX) running the VAXELN operating system (which is a Digital Equipment Corp. real-time operating system), the first word transfer takes about 700 μs and each additional word 2.3 μs (Antone *et al.*, 1989).

6. SPEED AND RESPONSE OF DATA-ACQUISITION SYSTEMS

6.1 Transfer Rate to Host Computer

The response required of a DAS is entirely dictated by the experimental situation. The relevant parameters are the repetition rate of the experiment (if indeed it is repetitive; a nuclear explosion is not!), the number of data channels and digitizers, and the amount of memory each digitizer must eventually transfer to another computer. The TFTR (Tokomak fusion test reactor) at Princeton is an experiment that lasts for several seconds and has a repetition rate of about 8 min. It can produce 24 MB of data in each shot (Randerson *et al.*, 1986), or about 2.4 GB per day. The experiment utilizes 280 CAMAC crates which contain over 5000 modules (Rauch, 1986). Because there is a fairly long time between shots in the TFTR experiment, the main problem is getting all the data out of the digitizers into storage. Real-time processing is not a great issue. The crates are connected to computers through eight separate serial highways. The CAMAC services a number of Gould SEL computers which gather the data. Data are then transferred to several VAX computers where it is written to disk. Some of it is immediately plotted to give the scientists an idea of what happened on the shot. After a day or two, the data are transferred to magnetic tape where it is archived. One obstacle the TFTR DAS overcame was that no fast digitizer has enough memory to store several seconds worth of data. The problem was solved by designing the system to generate preprogrammed timing pulses to start and stop digitizing. Fortunately, there are modules for CAMAC that can do this.

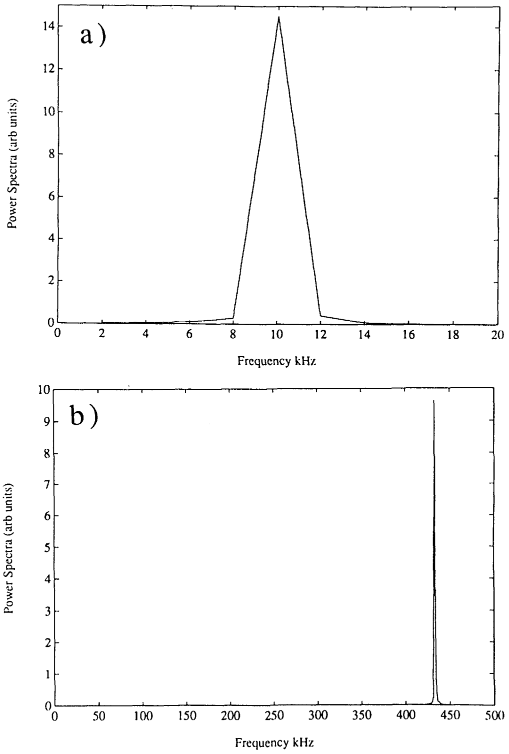

FIG. 7. (a) The power spectrum of a properly digitized 10-kHz signal. There is a peak at the appropriate frequency. The zero-frequency peak has been suppressed. (b) The power spectrum of an improperly digitized wave form. Here a 20-MHz signal is digitized at a 1-MHz sampling rate. Because of the Nyquist limit on the 1-MHz sampling the spectrum extends from 0 to 0.5 MHz. A peak at 440 kHz not present in the original signal is evident.

6.2 Real-Time Analysis

There are other cases where collection of all the data from the modules and storage for subsequent processing is not possible. This occurs in the LEP electron-positron collider at CERN in Geneva (Rüden, 1989). The detector there has several hundred thousand channels and produces 500 MB of data per second. It must be processed in real time and compressed to about 100 kB per second. Each channel, however, may or may not generate

FIG. 8. A large data-acquisition system used in a high-energy physics experiment at CERN. The symbols denote FASTBUS crates each with its own processor. Various abbreviations are as follows: TPC, time projection chamber; SATR, BCAL, HCAL, LCAL, various calorimeters; ITC, inner track chamber; MVER, minivertex detector; ALOV**, VAX computers; HSC, high-speed channel, WS, workstation; TA90, high-speed magnetic tape drive. The system works in parallel to discard an enormous amount of uninteresting data from the 500 MB/s which are continuously acquired.

data depending upon whether a particle passed its detector. In fact, a great many of the channels are empty at any given time. A schematic of the setup is shown in Fig. 8. In this schematic, each shaded area on the top of the page refers to data acquisition associated with a different detector (such as TPC, time projection chamber detector) or monitoring of the machine operation itself. The lower shaded area encloses the group of computers used to acquire, store, and analyze the data. The larger VAX computers are named AL0V** and are networked to each other, the tape drives, and the workstations. Data reduction is accomplished in several stages by use of distributed processing. In the first stage of processing, analog hardware compares signal levels against a threshold and rejects signals that are too small. Meaningful data, properly scaled by the 32-bit FASTBUS crate computers, is next transferred from the crates to a series of DEC KA800 computers through a network. These computers, which are not shown in this diagram, are placed directly on the bus of a larger DEC computer (a VAX 8700 denoted AL0VOL) and rapidly process the event and make a final decision as to whether it is worth saving. If the answer is yes, it is transferred to the memory of the VAX 8700. Final processing of the data is done on a cluster of MicroVAX workstations (Jost, 1989).

6.3 Choice of Operating System

Another issue regarding performance is the choice of computer operating systems. These can be broadly classified into two types, real-time and multitasking. A real-time operating system is stripped down for action. It is geared to serving one process only, the data-acquisition program. These operating systems were first available on single-user microcomputers and occupied very little memory. Real-time operating systems are designed to handle device interrupts quickly. When an interrupt occurs, they can stop the current process and initiate the interrupt handler within several microseconds. These small microprocessors are still extremely popular in DAS's. A multiuser operating system, such as UNIX or VMS, has a large built-in overhead since these systems are continually switching between many processes. A response to an interrupt can take several milliseconds to service, so they cannot work in strictly real time. It is possible to optimize performance by assigning a high priority to the DAS program and carefully designing the software (Appalaraju and Cleary, 1989; Atac *et al.*, 1989). It is also possible to buy an operating system which is tailored for real-time applications, such as VAXELN.

7. AN EXAMPLE OF A DATA-ACQUISITION SYSTEM

Let us consider a specific example that has some of the requirements cited above, i.e., the need for speed and distributed processing, but is not overly complex. The experiment involves the study of magnetic fluctuations in a plasma (a partially ionized gas) embedded in a magnetic field (Gekelman and Stenzel, 1984). When an electrical current is passed through an initially quiescent plasma, large fluctuations in the magnetic field are observed. The strength of these fluctuations is a function of space and time. The experimental goal is to find the source of these fluctuations. They are thought to be due to the random generation of waves in the plasma, but which waves are responsible? Since the waves are chaotic, it is necessary to perform correlation measurements at a number of frequencies to determine the cross spectral function (CSF) of the magnetic-field fluctuations (Bendat and Piersol, 1971). The data-acquisition procedure involves digitizing and storing three signals (B_x, B_y, B_z) that measure the three components of the fluctuating vector magnetic field. The signals from each of two probes are measured at 1024 time steps for an ensemble of 80 shots at 300 spatial positions on several planes. There is insufficient disk space to store all this data, so the CSF is evaluated at each position after the ensemble of data is acquired. The DAS used is shown in Fig. 9. The ADC's reside in CAMAC crates. The crates have a controller as well as an LSI 11/23 computer in them (Gekelman and Xu, 1986). The LSI runs a real-time operating system (RT-11) which rapidly responds to LAMs in the crates and services them. All of the software controlling the devices in the crates and reading data from them resides in the LSI. The LSI in turn is networked to a VAX computer with Ethernet hardware. The VAX has an array processor, which is a very fast calculating engine

FIG. 9. A small data-acquisition system in a university physics laboratory. A series of CAMAC crates are interfaced via a microcomputer and network to a minicomputer. The array processor in the minicomputer allows for real-time data analysis such as digital filtering. This combines elements found in Figs. 3(a), 3(d), and 3(e).

capable of directly accessing its memory through a DMA interface. The main data-acquisition program runs on the VAX. The system is configured to make the LSI microcomputer appear as a disk to the VAX. Whenever a command is sent to the LSI, a write statement to a certain device number is issued which activates a device driver setting up a dialog through the network to the LSI. Whenever the LSI sends data to the VAX, the reverse happens. The pseudodisks the two computers read from and write to are divided into logical areas. One area is reserved for instructions and, when data appear, those data are interpreted as a command. Another much larger area is reserved for the actual data. The system can throughput about 250 kB of data per second between the CAMAC crate and the VAX. As soon as data appear in the VAX, a DMA transfer is initiated to the array processor. After 80 shots, the array processor takes the data and calculates four components of the cross spectral tensor. This calculation takes a few seconds, and then the results are sent back to the VAX for storage. In this mode of operation, only 4K real (32-bit) numbers need to be stored for each probe position instead of 480K.

Technology is changing so rapidly that, as far as computing is concerned, systems can become obsolete a year after purchase. In the four years since the above system was designed, extremely powerful workstations have become available, some of them with vector processors. They make attached array processors obsolete. Fast crate controllers networked to these workstations allow for a direct interface to the host computer, making the separate LSI crate computers unnecessary. However, in some other applications, such as the system at CERN, distributed computing is still necessary. This progress is welcome since programming is simpler because it can generally be done entirely in a higher-level language.

8. DATA MANAGEMENT AND VISUALIZATION

The growth of powerful data-acquisition systems has enabled vast amounts of data to be collected in relatively short periods of time. Experimentalists are then faced with trying to analyze enormous data sets. In a situation with many investigators, there may be many separate channels of data, with each scientist chiefly interested in his or her own data. The requirement here is to organize and archive the data to make it simple to retrieve for subsequent analysis. This may involve data compression and migration of data to secondary computers or tapes as it ages. One way to deal with large data sets is to use commercially available database-management software. This has been done on a fusion mirror machine experiment (Stewart *et al.*, 1986), the TEXT Tokomak experiment (Wiley *et al.*, 1989), the Doublet experiment at General Atomics (McHarg, 1989), and others. The key to understanding complex multidimensional data sets is the ability to visualize them. Until recently, this was a difficult process. Data were generally displayed as a series of contour maps or surface plots for separate planes in whatever space (position, momentum, etc.) was of interest. Trying to understand volumetric data involved comparing many of these plots; information was inevitably lost or obscured in the procedure. Recently, a number of vendors have come out with extremely powerful three-dimensional graphics workstations. It is possible to transfer data to one of these and make a full color rendering of volume data as a set of nested isosurfaces of differing transparency, or as voxels, which are color pixel representations. By using appropriate display filters, such as changing the way colors represent key features in the data, many subtle features can be brought out. In addition, the data may be magnified, translated, or rotated in real time. Interfaces to video equipment and computer-controlled slide- and print-making equipment are also available and becoming reasonably priced. Finally, there have been some startling advances in software such that expertise in graphics programming is not required. There are several new commercially available software packages which are menu driven and do all of the above as well as instantly creating vector fields, streamlines, and cut slices through data sets with any number of dimensions. Presently, they run only on powerful graphics computers which are rather costly. However, it is anticipated that the price of these workstations will plummet, and someday they will be as affordable as personal computers. This will herald a new age of discovery of subtle and complex phenomena which now are buried in huge data sets.

9. FUTURE TRENDS

9.1 Communication

From the tone of the preceding text, it is not hard to predict the evolution of DAS's for the next five years. The emphasis on the high end will be speed. This will entail the use of multiprocessors, as mentioned previously, but the old way of connecting them via a bus may change radically. The basic limitation in signal transfer is the speed of light which will not allow an arbitrary number of information packets, each addressed to a different processor, to share one data path effectively. One possible solution is the CSI, coherent scalable interface (Gustavson, 1989), which is basically a point-to-point datapath between processors. It will be designed for GB/s processor-to-processor communication. The CSI is now in a standardization process phase before the IEEE.

9.2 Computer Farms

There is a great deal of experimentation with high-speed DAS's at the large accelerator laboratories. A team at the Fermi National Accelerator Laboratory (Atac *et al.*, 1989) has designed and built a system which links devices from both FASTBUS and VME crates to a farm of computers using a very fast crossbar switch manufactured by Texas Instruments. The switch can make eight simultaneous connections out of a possible 28, each connection having a 20-MB/s bandwidth for a total speed of 160 MB/s. Each connection can be between a crate and a group of parallel processors which receive the data and preprocess it before sending it to storage. As soon as a group of processors have data to work with, the switch changes position and connects more data channels to other free processors. Another approach was used in a nuclear physics experiment in Heidelberg (Männer and Stucky, 1990) in which a multiple 32-bit bus system is used instead of a switch to connect FASTBUS crates to an array of 30 processors. In this experiment, data flows in at a rate of 10^6 events per second, with up to 10^3 parameters per event. The processor farm filters this down to 10^5 numbers per second which actually must be stored, a data reduction of 4 orders of magnitude. Efforts such as the two described here are large because they involve the construction of the hardware and writing of the software to support it. They are, however, the precursors of what may be commercially available systems utilizing very rapid communication technologies between data channels and multiple processors.

9.3 Parallel Processors

One of the recent advances in high-end computation is the introduction of highly parallel processors (see PARALLEL COMPUTING). These computers contain from 64 to 16 384 individual processors. There are various schemes for interprocessor communication and use of memory, but the basic idea is that, if a problem can be broken up into many parallel segments which run independently, significant increase in speed may be attained using processors running in parallel. Although several companies manufacture these systems, they are still largely in the experimental stage since compilers which can generate efficient code for parallel CPUs have yet to be developed. In the future, one could consider the development of a DAS in which one CPU is dedicated to each input data channel. Interprocessor communication would make it possible to compare data from neighboring probes instantly to determine what should be stored, or to do mathematical operations such as the instantaneous evaluation of the curl of vector fields. This will be some time in coming, however, since these multiprocessor machines do not easily interface to any of the standard data-acquisition gear such as FASTBUS or CAMAC. Thus far, the only parallelizing is in the type of system at CERN described earlier, where many FASTBUS crates, each with its own processor, are brought to bear on the problem.

9.4 Inexpensive, Simple Systems

On the other end of the DAS spectrum, we see a trend in development of easy-to-use, off-the-shelf DAS's for small laboratories. A number of digital instruments, such as oscilloscopes and wave-form generators, have GPIB outputs and can be controlled by software running on a PC. Setting them up to acquire, store, and plot data on digital X-Y recorders can take several hours. The most expensive piece of equipment is usually the measurement instrument, not the DAS. As time goes on, these systems will continue to drop in price and become as easy to use as digital voltmeters.

10. SUMMARY

Fifteen years ago, data acquisition was in its infancy. Data were taken in an analog fashion using Polaroid photographs of oscilloscope traces or read off of plots on *X-Y* recorders. No detailed experiment could be performed on a complex multiparameter system. The introduction of data-acquisition standards and microcomputers has radically changed this. Experiments now routinely collect and process billions of numbers from a large variety of detectors. As the price of computers and high-speed instrumentation tumbles, and the ease of implementing them improves, this technology will become available to any research group that needs it.

ACKNOWLEDGMENTS

Writing this made me recall the many hours I spent writing data-acquisition software with Tim Mc Fadden and Lingyu Xu. I have enjoyed working with them and am indebted for all they have taught me. I would like to thank Dr. R.T. Cleary for contributing Fig. 3 and Dr. Wolfgang von Rüden for Fig. 8. I am also indebted to Dr. James Maggs and Marilyn Pagnusat for proofreading.

GLOSSARY

Byte: 8 bits, where a bit is a zero or a one.

CAMAC: Computer automated measurement and control; standardized (IEEE 583) modular data handling system, 1-MHz 24-bit wide data path.

CERN: Center for European Nuclear Research.

CSI: Coherent scalable interface.

DAS: Data-acquisition system.

DMA: Direct memory access; a device which can take over a computer bus and access its memory.

Ethernet: A local-area network with hardware which can sense and correct for collisions between data from different computers; limited to 10 megabits per second.

FASTBUS: Fastest high-density data-acquisition standard available; 32-bit, 40 MB/s (IEEE standard 960-1986).

FDDI: Fiber distributed data interface; fiber-optics–based high-speed network with a token ring topology.

Gigabyte: One billion bytes or 8 billion bits.

GPIB: General purpose instrument bus; most popular instrument bus today; serial transfers limit it to 400 kB/s.

LAM: Look at me; signal generated by device wishing to be serviced by a processor.

LAN: Local-area network; a data communications system for moderately high-speed traffic, usually limited to a building or group of buildings.

LSI: Large-scale integrated circuit.

Megabyte: One million bytes or 8 million bits.

MIPS: Millions of instructions per second.

VOXELS: Representation of volumetric data as colored spots.

21.1
Introduction

21.1.1
The Task of Particle Detectors

In many areas of experimental physics (solid-state, nuclear, and particle physics), kinematical properties of particles or quanta of radiation need to be determined. The momentum **p** and the energy E, or equivalently the particle's velocity **v** and its mass m [$\mathbf{p} = m\beta\gamma$, $E = m\gamma c^2$, $\boldsymbol{\beta} = \mathbf{v}/c$, and $\gamma = (1 - \beta^2)^{-1/2}$], or momentum **p** and velocity **v** (Fernow, 1986) have to be measured.

A host of different particle detectors has been developed, frequently with very specialized functions. The momentum of charged particles is determined in magnetic spectrometers: particles with momentum p (GeV c^{-1}) in a field B (Tesla) describe a circular trajectory with radius r (meter), such that $p = 0.2998Br$. Position detectors trace the trajectories. The methods used for the velocity measurement depend on the β-range to be covered. The flight time of particles traversing a known distance (time-of-flight (TOF) method) is clocked with sensors sensitive to the arrival time; accuracies of better than 100 picoseconds (10^{-10} seconds) are achieved quite routinely. This method is applicable for particle velocities up to $\beta \leq 0.98$. For even more relativistic particles, the velocity dependence of the electromagnetic interaction of the charged particle in the medium is exploited. If the particle velocity v is larger than the velocity of light c/n in the medium, n being the index of refraction, the medium radiates photons at a characteristic angle $\theta =$ arccos $(1/\beta n)$, called *Cherenkov radiation*. Measuring the angle of the emitted photons provides useful velocity determination up to $\beta \leq 0.9999$ and hence particle identification up to ≈100 GeV c^{-1}. Momentum and velocity measurements have found numerous and diverse applications despite two major shortcomings: (i) the method is limited only to charged particles and (ii) the relative accuracy scales as $\Delta p/p \sim p$; huge engineering efforts are required to employ very large (superconducting) magnets and position detectors comprising typically 10^6 or more position sensors, to achieve adequate momentum resolution at the 100 GeV c^{-1} scale.

For the measurement of neutral and very energetic particles, a further technique is required – calorimetry.

21.1.2
Energy Measurement with Calorimeters

The measurement of the particle's energy E relies on "total absorption" in the detector occurring within a few tens of nanoseconds through a cascade of interactions producing increasingly lower-energy particles. The kinetic energy of the particle is initially transformed into excitation or ionization energy of the absorber atoms. After approximately 10 microseconds, all energy appears in thermal form, hence the name *calorimeter*. Calorimeters are instrumented blocks of mostly dense absorbers with sensors embedded to detect these atomic excitations, which reflect the strength of the particle cascade and provide a measure related to the energy of the absorbed particle.

Calorimeters are widely used in experimental particle physics for several reasons:

1. They are sensitive to both charged (e.g., protons, pions, kaons, electrons) and neutral (e.g., neutrons, neutral pions, photons) particles.
2. The absorption process is statistical, so that in well-designed instruments the relative accuracy of energy measurements improves with the energy E, in principle, as $\sigma(E)/E \sim E^{-1/2}$.
3. The total depth D necessary to fully absorb (or "contain") the particle increases slowly with energy as $D \sim \ln E$, an important practical advantage.
4. The fundamental constituents of matter (called *quarks*) manifest themselves as tightly collimated groups of charged and neutral particles, whose total energy can only be measured with calorimeters.

In nuclear physics, the energy of particles (protons, nuclear fragments, electrons) or γ-quanta is typically in the mega electronvolts range; relatively small volumes of absorber (a few tens of cubic centimeters) are sufficient (Section 21.2).

In particle or high-energy physics (Sections 21.3–21.5), energies range from 100 MeV (0.1 GeV) to several 10^6 MeV (1 TeV). Total absorption proceeds, depending on the type of particle, via high-energy electromagnetic, strong, or even weak interactions.

Astroparticle physics (Section 21.6) has spawned the most original and diverse developments covering the widest spectrum of particles – known and unknown – as well as the largest energy range, from milli electronvolts to exa electronvolts (10^{19} eV).

The layout of a generic particle physics experiment is shown in Figure 21.1. The momentum of charged particles is derived from the track curvature in a magnetic field using position detectors, which barely affect the particle momentum. Calorimeters measure the energy of particles, charged or neutral. Photons, electrons, and positrons require relatively little mass to be absorbed. Hadrons, interacting predominantly through the strong interaction, require considerably more material for total absorption. The destructive nature of the calorimetric energy measurement imposes the spatial sequence of the measurement tasks and hence fixes the layout of experiments.

21.2
Calorimetry Methods in Nuclear Physics

21.2.1
Total Absorption and Range of Particles

In nuclear physics, the energy measurement of charged (protons, αs, nuclei, fission fragments, electrons, positrons) and neutral particles (neutral pions and, in particular, neutrons) is frequently required. Precision energy measurements of photons emitted from excited nuclear states are also important. The energies range typically from 100 keV to 100 MeV. In this energy range, the absorption of charged particles proceeds essentially through the electromagnetic (em) interaction.

The "mean energy loss per unit path length x" or "stopping power" is given to a good approximation by the Bethe–Bloch equation (Yao *et al.*, 2006):

$$\left[\frac{dE}{dx}\right]_{\text{inc}} = \frac{CZ_{\text{med}}\rho_{\text{med}}}{A_{\text{med}}}\left[\frac{Z_{\text{inc}}}{\beta}\right]^2 \times\left[\text{In}\left(\frac{2m_e\gamma^2\beta^2c^2}{I}\right) - \beta^2 + \text{correction term}\right] \quad (1)$$

where $C = 0.307\,\text{MeV}\,\text{cm}^2\ \text{g}^{-1}$, $Z_{\text{med, inc}}$ is the charge of the absorbing medium and incident particle, respectively, m_{e} the electron mass, and I the effective ionization potential of the absorber. Owing to the $1/\beta^2$ dependence on the particle velocity, most of the energy loss occurs near the end of the path. The energy loss, when expressed in units of length × density (grams per square centimeter), that is, the number of atomic electrons or scattering centers encountered, is approximately independent of the material (Figure 21.2).

The depth at which half the initial particles are stopped or "ranged out" is called the *mean range* $R(E)$. It is related to the energy loss by

$$R(E) = \int_E^0 \frac{-dE}{\left(\frac{dE}{dx}\right)} \quad (2)$$

Typical values of the mean energy loss and the range of various particles (Yao *et al.*, 2006) are given in Figure 21.2 and can be used to estimate the required absorber depth to range out charged particles in this energy domain. As an example, a pion with a momentum of $100\,\text{MeV}\,c^{-1}$ has a range of approximately $10\,\text{g}\,\text{cm}^{-2}$ in lead, that is, 0.9 cm: a lead layer of ≈1 cm will absorb or range out such a particle.

Neutrons with mega electronvolt energies are detected through elastic scattering (via the strong force) off the detector nuclei. The scattering process transfers a fraction of the neutron kinetic energy to the target nucleus, usually hydrogen, deuterium, or helium, resulting in a recoil nucleus. The recoil nuclei, in turn, lose their energy through ionization of the detector medium. This process is repeated until, essentially, all of the kinetic energy of the neutron has been transferred to the detector nuclei.

Low-energy quanta in the electronvolt to kilo electronvolt range will ionize the atoms of the detector medium and produce detectable electrons (atomic photoeffect). At higher energies, pair production, the conversion into electron–positron pairs in the em field of the nucleus,

dominates. These processes are described in Section 21.3.

21.2.2
Principal Detection Techniques: Scintillators and Solid-State Detectors

Having described the absorption processes relevant for particles in the mega electron-volt region, we address the two principal techniques, scintillators and semiconductor detectors, used for measuring particles in this energy range.

In scintillators, the molecules are excited by the interaction of the charged particles, converting a small fraction into visible photon emission. Time constants are typically 10^{-9}–10^{-6} seconds. Both inorganic (crystals) and organic scintillators are used. The inorganic scintillators are usually grown with an admixture of dopants acting as recombination centers for ionization charge with subsequent excitation, followed by light emission. Certain inorganic scintillation crystals are compounds of heavy elements and hence have a large absorption coefficient and an excellent energy resolution for γ-rays (see Section 21.4). More recently, the scintillating properties of noble liquids, in particular liquid xenon, have been investigated. These liquids combine high γ-absorption cross sections with a very fast time response (Doke, 2005).

Only a relatively small fraction of the absorbed energy, typically a few percent, is converted into visible light that can be detected with photon detectors (e.g., photomultipliers). Nevertheless, the light output is quite sufficient; in "good" scintillators, there may be as many as 10^4 photons produced for 1 MeV of absorbed energy. This method is suitable because the average fraction of energy converted into light is constant and the light output is proportional, apart from saturation effects (Section 21.4) to the energy deposited.

The second category of detectors, also pioneered by nuclear physicists, uses the measurement of ionization in semiconductors (predominantly silicon and germanium). In these materials, the energy ε required to create the basic measurable excitations, electron–hole pairs, is approximately $\varepsilon \approx 3\,\text{eV}$, compared with typically 100 eV per photon needed in a scintillator. Therefore, for a given energy deposit, the statistical signal fluctuations σ are smaller and the energy resolution can be better. Experimentally, one finds $\sigma^2(E) = (FE/\varepsilon)\varepsilon^2$, and a "Fano" factor $F \approx 0.1$ for Si and Ge; the limit of energy resolution is therefore $\sigma \sim 500\,\text{eV}$ for 1-MeV energy deposit (Fabjan and Gianotti, 2003).

Semiconductor detectors work as ionization chambers in which the charge created by the energy deposit is collected under the influence of an externally applied electric field. Registration of this ionization charge is, however, only possible if it is not masked by free charges, generated thermally or due to the presence of impurities. Adequate suppression is possible through purification of the material or implementing a diode structure in the detector material, operated in reversed bias mode. For Ge, impurity levels as low as 10^9 atoms cm^{-3} have been achieved. Such ultrapure crystals are fabricated in sizes of hundreds of cubic centimeters, making them the detector of choice for γ-ray spectroscopy in the energy range of 10 keV to a few mega electronvolts. Silicon cannot yet be purified to this level, limiting the useful depth of Si detectors to a few millimeters. Such detectors are still well suited for the energy measurement of X-rays and heavy charged particles, such as protons, αs, and fission fragments.

21.3
Calorimetry Methods in Particle Physics: Photons, Leptons, and Hadrons

21.3.1
Absorption Mechanisms

In the "high-energy" domain ($E \geq 100$ MeV) of calorimetry, the incident particle is sufficiently energetic to initiate particle production. This provides a further mechanism for absorption in addition to those previously discussed (ionization, excitation, etc.). With increasing energy of the incident particle, the energy of the secondary particles may be sufficient for subsequent, that is, tertiary production, and so forth. The image of an "avalanche" or shower of particles appropriately describes this process of energy degradation. The particle multiplication continues until the energy of the last generation drops below the energy threshold for further production; at this point, the shower has reached the maximum number of particles – the shower maximum – after which further degradation continues via the low-energy processes described in Section 21.3.2.

There are two distinct types of particle showers. The first type is initiated by energetic electrons (positrons) and photons and propagates through the electromagnetic interaction with the atoms of the absorber. The second type of cascade is produced by particles strongly interacting with the absorber, that is, hadrons, such as pions, kaons, and protons. In both types of cascade, the relevant interaction cross sections reach values that are rather energy independent for particle energies $E \geq 1\,\mathrm{GeV}$. Therefore, the cascade dimensions are described by a mean free path λ between collisions with a specific value of λ for a given material, in general, different for the electromagnetic and hadronic cascades. The geometrical dimensions of a shower of given energy in different absorber materials will be similar, when expressed in the appropriate physics units of the mean free path (scaling in λ).

The principle of the calorimetric energy measurement of energetic particles may be formulated as follows: particle cascading (through the electromagnetic or strong interactions) degrades the energy over rather small geometrical distances. The charged component in the cascade is measured through its ionizing or excitation effect on the medium, which provides a signal approximately proportional to the energy of the incident particle (Fabjan and Gianotti, 2003).

21.3.2
Physics of the Electromagnetic Cascade

In spite of the apparently complex phenomenology of shower development in a material, electrons and photons interact with matter via a few well-understood QED processes, and the main shower features can be parametrized with simple empirical functions.

The average energy lost by electrons and the photon interaction cross section is shown in Figure 21.3 for a frequently used absorber material, lead, as a function of energy. Two main regimes can be identified. For energies larger than $\sim 10\,\mathrm{MeV}$, the main source of electron energy loss is bremsstrahlung. In this energy range, photon interactions produce mainly electron–positron pairs. Above $1\,\mathrm{GeV}$, both processes become roughly energy independent. At low energies, electrons lose their energy mainly through collisions with the atoms and molecules of the material, giving rise to ionization and thermal excitation; photons lose their energy through Compton scattering and the photoelectric effect.

Electrons and photons of sufficiently high energy ($\geq 1\,\mathrm{GeV}$) incident on a block of material produce secondary photons by bremsstrahlung, or secondary electrons and positrons by pair production. These secondary particles in turn produce other particles by the same mechanisms, thus giving rise to a cascade (shower) of particles with progressively degraded energies. The number of particles in the shower increases until the energy of the electron component falls below a critical energy ε, where energy is mainly dissipated by ionization and excitation and not in the generation of other particles.

The main features of electromagnetic showers (e.g., their longitudinal and lateral sizes) can be described in terms of one parameter, the radiation length X_0, which depends on the characteristics of the material (Yao *et al.*, 2006)

$$X_0\left(\mathrm{g/cm^2}\right) \approx \frac{716\,\mathrm{g\,cm^{-2}}A}{Z(Z+1)ln\left(\frac{287}{\sqrt{Z}}\right)} \tag{3}$$

where Z and A are the atomic number and weight of the material, respectively. The radiation length X_0 represents the average distance x that an electron needs to travel

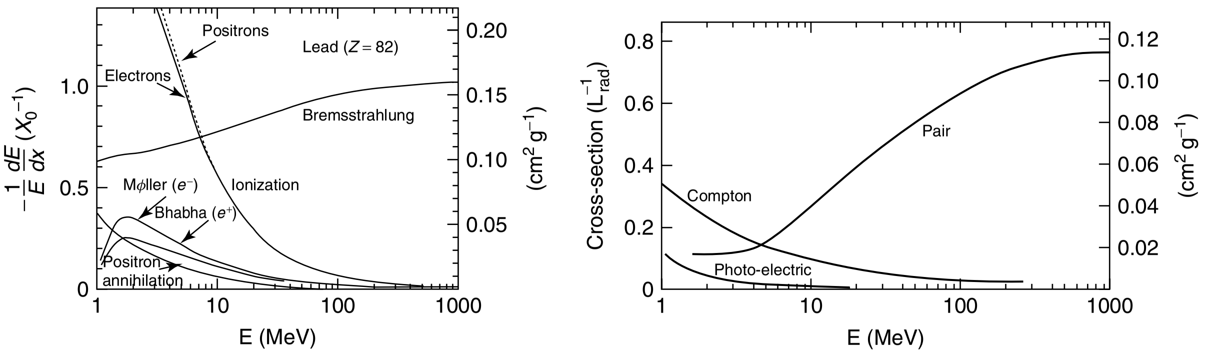

Fig. 21.3 (a) Fractional energy lost in lead by electron and positrons as a function of energy. (b) Photon interaction cross section in lead as a function of energy (Yao *et al.*, 2006).

in a material to reduce its energy to $1/e$ of its original energy E_0

$$\langle E(x)\rangle = E_0 \exp\left(-\frac{x}{X_0}\right) \tag{4}$$

Similarly, a photon beam of initial intensity I_0 traversing a block of material is absorbed mainly through pair production. After traveling a distance $x = 9/7X_0$ its intensity is reduced to $1/e$ of the original intensity

$$\langle I(x)\rangle = I_0 \exp\left(-\frac{7}{9}\frac{x}{X_0}\right) \tag{5}$$

These relations show that the physical scale over which a shower develops is similar for incident electrons and photons, and is independent of the material type if expressed in terms of X_0. Therefore, electromagnetic showers can be described in a universal way by using simple functions of the radiation length.

The shower maximum, that is, the depth at which the largest number of secondary particles is produced, is approximately located at $t_{\max} \approx \ln(E/\varepsilon) + t_0$, where $t_{\max}$ is measured in radiation lengths, E is the incident particle energy, and $t_0 = -0.5\,(+0.5)$ for electrons (photons). This formula shows the logarithmic dependence of the shower length, and therefore of the detector thickness needed to absorb a shower, on the incident particle energy. Longitudinal shower profiles for different energies of the incident particles are shown in Figure 21.4(a) and for electrons at 6 GeV in different material (Figure 21.4b). The calorimeter thickness containing 95% of the shower energy is approximately given by $t_{95\%} \approx t_{\max} + 0.08\,Z + 9.6$, where $t_{\max}$ and $t_{95\%}$ are measured in radiation lengths. As an example, in a calorimeter with thickness $\approx 25X_0$, the longitudinal shower leakage beyond the end of the active detector is less than 1% up to incident electron energies of $\sim$300 GeV. Therefore, even at the particle energies expected at the CERN Large Hadron Collider (LHC), of order about tera electronvolt, electromagnetic calorimeters (EMCs) are very compact devices: the ATLAS lead–liquid argon calorimeter (ATLAS Collaboration, 1996) and the CMS crystal calorimeter (CMS Collaboration, 1997) have thicknesses of $\approx$45 and $\approx$23 cm, respectively (the radiation lengths are $\approx$1.8 and $\approx$0.9 cm, respectively).

21.3.3
Physics of the Hadronic Cascade

Understanding the physics of the hadronic cascade is the basis for the construction of powerful, widely used instruments reaching performance limits imposed by the physics of the hadronic cascade.

By analogy with electromagnetic showers, the energy degradation of hadrons proceeds through an increasing number of mostly strong interactions with the calorimeter material.

In analogy to em cascades, a characteristic scaling length describes the longitudinal shower shape. This is the interaction length λ, defined as

$$\lambda = \frac{A}{N_{\mathrm{Av}}}\sigma_i\left(\mathrm{g\ cm^{-2}}\right) \approx 35A^{\frac{1}{3}}\ \mathrm{g\ cm^{-2}} \tag{6}$$

A being the mass number of the material, N_{Av} the Avogadro number, and σ_i the inelastic cross section. It describes the absorption of N hadrons in matter through the equation

$$\frac{dN}{dx} = \frac{-N}{\lambda} \tag{7}$$

For incident hadrons with sufficient energy to produce secondary hadrons ($E \geq 1$ GeV), a hadron shower is initiated. Typical

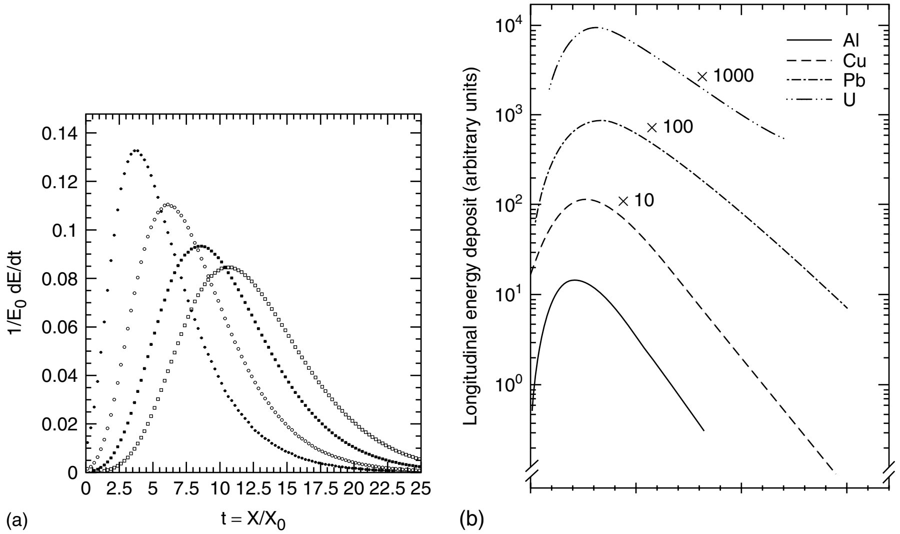

Fig. 21.4 (a) Simulated longitudinal shower profiles in $PbWO_4$ as a function of material thickness (expressed in radiation lengths), for incident electrons of energy (from left to right) 1, 10, 100, and 1000 GeV. (b) Longitudinal shower development of 6 GeV c^{-1} electrons in four very different materials, showing the approximate scaling in units of radiation lengths X_0.

longitudinal shower profiles in different absorbers are shown in Figure 21.5 and some useful features can be parametrized in approximate form as follows:

1. shower maximum $S_{\max}[\lambda] \approx 0.2 \ln E\,(\text{GeV}) + 0.7$;
2. longitudinal depth for 95% containment $L(0.95)\,[\lambda] \approx S_{\max} + 2.5E^{0.13}$ (GeV); and
3. transverse radius for 95% containment $R[\lambda] \approx 1[\lambda]$.

The hadronic interaction produces two classes of effects. Energetic secondary hadrons are produced with a mean free path (interaction length) λ between interactions; their momenta typically add up to a fair fraction of the primary hadron momentum, that is, at the giga electronvolt scale. Second, in the hadronic collisions with the absorber nuclei, a significant part of the hadron energy is consumed in nuclear processes such as excitation, nucleon evaporation, spallation, and so on, producing particles with characteristic nuclear energies at the mega electronvolt scale.

The fast, energetic hadronic component contains protons, neutrons, and charged and neutral pions. Owing to the charge independence of hadronic interactions, in each high-energy collision, on average, one-third of the pions produced will be π^0's, $F_{\pi 0} = 1/3$. This is the ''odd man'' in this group of energetic hadrons because these neutral pions will decay to two photons, $\pi^0 \rightarrow \gamma\gamma$, before having a chance to reinteract hadronically. These energetic photons will induce an electromagnetic cascade, proceeding along the laws of electromagnetic interactions (Section 21.3.2). This physics process acts like a ''one-way diode'', transferring energy

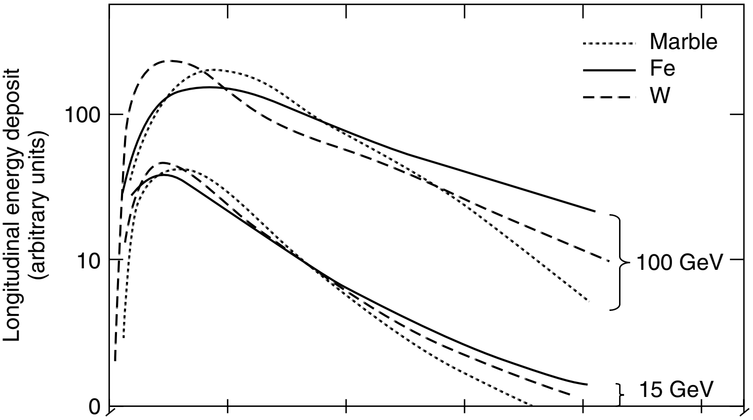

Fig. 21.5 Longitudinal shower development induced hadrons in different materials, showing approximate scaling in interaction length λ. The shower distributions are measured with respect to the face of the calorimeter (Fabjan and Ludlam, 1982; reproduced with permission of Annual Review of Nuclear and Particle Science).

from the hadronic part to the electromagnetic component, which will not contribute further to hadronic processes.

As the number of shower generations increases with increasing incident energy, so will the fraction of the electromagnetic cascade: there is an "identity change" of a predominantly hadron-rich cascade at low incident energy to a cascade developing into a mostly electromagnetic cascade at very high energies.

Second, contributions from nuclear interactions produce photons and neutrons in the few mega electronvolts range. The total energy carried by photons from nuclear reactions is substantial: only a fraction, however, will be recorded in practical instruments, as most of these photons are emitted with a considerable time delay ($\geq$1 microsecond). These nuclear effects, represented by delayed photons and soft neutrons, produce signals that are poorly or not at all detected in practical instruments. One part of the cascade particles is truly "invisible" or "missing", namely energy carried by escaping muons, neutrinos, or backscattered (albedo) particles. Let η_e be the efficiency for observing a signal E^e_meas (measurable energy) from an electromagnetic shower, that is, $E^e_\mathrm{meas} = \eta_e E$ (em); let η_h be the corresponding efficiency for purely hadronic energy to provide visible energy in an instrument. Therefore, for a pion-induced shower the visible energy E^π_meas is

$$E^\pi_\mathrm{meas} = \eta_\mathrm{e} F^0_\pi E + \eta_\mathrm{h} F_\mathrm{h} E \qquad (8)$$

where E is the incident pion energy. In Figure 21.6, the dependence of the various components as a function of the energy of the incident hadron is shown.

The ratio of observable signals induced by electromagnetic and hadronic showers, usually denoted by "e/π", is therefore

$$\frac{E^\pi_\mathrm{meas}}{E^e_\mathrm{meas}} = \left(\frac{e}{\pi}\right)^{-1} = 1 - \left(1 - \frac{\eta_h}{\eta_e}\right) F_h \qquad (9)$$

In general $\eta_h \neq \eta_\mathrm{e}$; therefore, the average response of a hadron calorimeter (HC) as

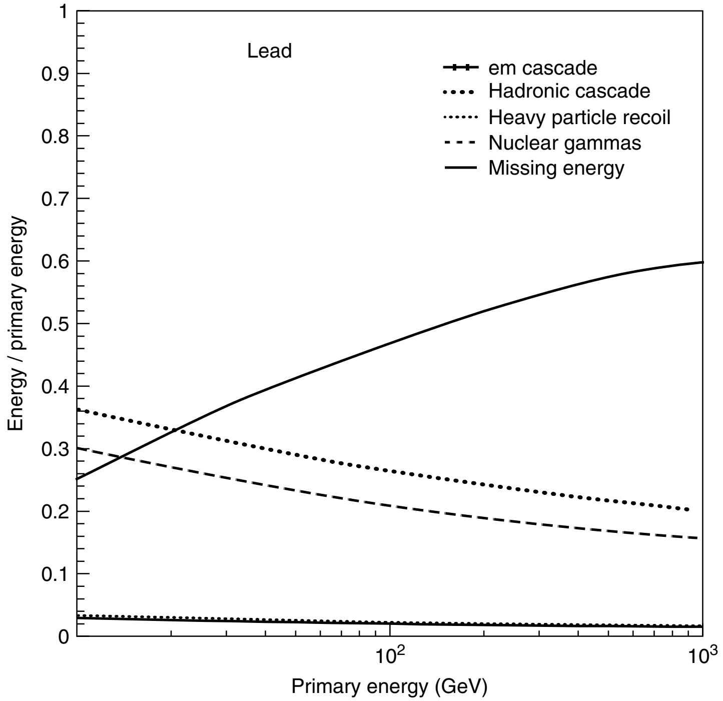

Fig. 21.6 Characteristic components of proton-initiated cascades in lead. With increasing primary energy, the em ($\pi^{0)}$) component increases. The component due to nuclear gammas is, in general, time-delayed and is detected with very low efficiency in practical instruments (Ferrari, 2001, *private communication*).

a function of energy will not be linear because F_{h} decreases with incident energy. More subtly, for $\eta_{\mathrm{h}} \neq \eta_{\mathrm{e}}$, we have to expect that event-by-event fluctuations in the F_{h} and F_{π}^{0} components will have an impact on the energy resolution of such instruments. The relative response "e/π" turns out to be the most important yardstick for gauging the performance of HCs (Wigmans, 1991).

21.4
Performance of Calorimeters

Suitably instrumented calorimeters measure not only the energy but also the time, direction, and impact point of the incident particle. The quality of the measurement (resolution) is driven by fluctuations in the measurement process, both intrinsic, due to the physics of particle absorption, but also due to a range of instrumental contributions.

With increasing energy, the particle content of the shower increases and therefore intrinsic fluctuations will scale as $1/\sqrt{(\text{number of particles})} \sim 1/\sqrt{E}$. Instrumental contributions may scale differently with energy. The conventional parametrization for the energy resolution is $\sigma(E)/E = a/\sqrt{E} \oplus b/E \oplus c$, a denoting the stochastic, b the "noise term", and c a constant term. Measurement of the shower

shape provides important information on the particle impact, its direction, and time of arrival. Furthermore, the shower shape encodes information about the particle type.

21.4.1
Energy Resolution in Homogeneous Electromagnetic Calorimeters

Homogeneous calorimeters are instruments in which the absorber serves also as the detecting medium. These fully sensitive instruments provide the most complete information about the shower cascade and hence the potentially best measurement performance. This type of instrument is particularly suitable for precision EMCs, for which crystals (Table 21.1) and liquefied noble gases (Table 21.2) are the most frequently used materials. At low (~1 MeV) energies, the achieved energy resolutions are at the 1–2% level. At these low energies, the measured energy resolution for crystals is quite consistent with counting statistics, based on the number of registered photons. For noble liquids, however, the measured low-energy resolution is a large factor (5–10) worse compared with the theoretical one based on the number of created ion pairs. Recombination and incomplete collection of the generated ion pairs are thought to be the origin of this discrepancy.

For particle physics applications at high energy – above 1 GeV – naïve $1/\sqrt{E}$ scaling from the 1 MeV energy domain is not observed. Such scaling would give resolutions at the 0.03% level at 1 GeV, far better than the measured resolutions, observed to be at the 1% level. This fact is generally attributed to the nonlinear response of the detector medium to the very low energy component (below 1 MeV) of the electromagnetic cascade, frequently parametrized with a cutoff value below which the detector medium effectively becomes insensitive. Neither detailed simulations with state-of-the-art Monte Carlo codes nor the low-energy results support this explanation. Plausibly, several effects conspire: a certain fraction ($\leq 0.5\%$) of the shower energy escapes through the front, resulting in $\sigma(E)/E \sim 0.3\%/\sqrt{E}$. In practical crystal calorimeters, inhomogeneous light production and transport also contribute at a comparable level as do counting statistics and electronics noise. Above 1 GeV, this $1/\sqrt{E}$ scaling is observed to hold to a very good approximation over a very wide energy range from one to several hundred giga electronvolts (CMS Collaboration, 1997; Lecoq *et al.*, 2006).

21.4.2
Instrumental Contributions to the Electromagnetic Energy Resolution

Sampling fluctuations arise in calorimeters that are not uniformly (homogeneously) sensitive, that is, in instruments having their signal sensors interspersed in the absorber (see discussion in Section 21.5.2). Such constructions are very common for EMCs, and almost exclusively used HCs. The shower profile is sampled, leading to incomplete signal information with increased signal fluctuations. The magnitude can be estimated by considering the variations in the number of charged particles N_{ch}, which cross the active layers and which produce the detectable signal. This number is proportional to

$$N_{\mathrm{ch}} \propto \frac{E_0}{\Delta E} \tag{10}$$

where ΔE is the energy loss in one ''unit cell'' (absorber plate + active layer). Assuming statistically independent crossings of the active layers, the ''sampling'' contribution to the energy resolution due to the fluctuation of N_{ch} are

$$\begin{aligned}\frac{\sigma}{E} \div \frac{1}{\sqrt{N_{\mathrm{ch}}}} \div \sqrt{\frac{\Delta E}{E_0(\mathrm{GeV})}} \\ = c\sqrt{\frac{\Delta E(\mathrm{MeV})}{E_0(\mathrm{GeV})}},\ c = 0.032\end{aligned} \tag{11}$$

In reality, the particles are not statistically independent and cross the gap on average under an angle different from normal, increasing ΔE. A coefficient $c \approx 0.05$ is consistent with measurements in many different sampling EMCs (Fabjan and Gianotti, 2003; Wigmans, 2000).

In practical sampling EMCs, the energy resolution is in the range of $5{-}20\%/\sqrt{E(\mathrm{GeV})}$. In well-designed instruments, it is below 1% for 100-GeV photons or electrons, consistent with the detection requirements for the physics discovery at the CERN LHC (ATLAS Collaboration, 1996).

There are several other instrumental contributions to the energy resolution that can be kept at a level below the intrinsic resolution of homogeneous calorimeters, well below the sampling contribution. Incomplete shower containment (transverse or longitudinal shower leakage) affects the performance, as do mechanical- or signal-collection nonuniformities. These instrumental contributions imply a lower limit to the resolution, usually parametrized with a constant term

c. At low energies electronic readout noise may contribute to the resolution, decreasing with energy as $1/E$. Achieving 1% energy resolution implies control of all these instrumental effects at a level well below: a major engineering challenge.

21.4.3
Time, Space, and Angular Resolution in EMCs

While the energy measurement is the principal task of calorimeters, such instruments also provide additional powerful information about the detected photons or electrons (positrons).

Pulse shape analysis of the detected signal can provide timing information on the arrival time of the particle. The performance depends – as always – on the signal/noise ratio and therefore scales – at least in principle – with $1/\sqrt{E}$. In modern instruments, the timing resolution is typically at a level of a few nanoseconds/$\sqrt{E}$ (giga electronvolt).

Space and angular resolution are achieved by appropriate subdivision of the detector in transverse and longitudinal directions. The scale for the subdivision is the radiation length X_0. Longitudinally cells typically have dimensions of a few X_0, while transversely the subdivisions are at the scale of 1 X_0. Such granularity in the readout allows a spatial resolution of the impact point of the particle at the level of $\sim 0.5\ X_0/\sqrt{E}$ (GeV) and an angular measurement of $\sim$50 mrad/$\sqrt{E}$ (GeV) (ATLAS Collaboration, 1996).

21.4.4
Energy Resolution of Hadron Calorimeters

The general analysis presented for EMCs is conceptually also applicable to HCs, albeit with significant quantitative differences due to the physics of the much more complex hadronic cascade.

Inevitably, hadronic cascades imply nuclear interactions with their correlated production of low-energy neutrons and photons, only partially detectable (invisible energy) (Section 21.3). On average, for particles with the same incident energy, the signal response of a calorimeter to hadrons (e.g., pions, π) will be lower than that to electrons, that is, $e/\pi > 1$. For hadrons, the visible energy will fluctuate, event by event, between two extremes: from fully electromagnetic, yielding the same signal as an electron to fully hadronic with a maximum of invisible energy, as shown conceptually in Figure 21.7.

This simple analysis already provides the following qualitative conclusions for HCs with $e/\pi \neq 1$:

- fluctuations in $F_{\pi 0}$ are a major contribution to the energy resolution;
- the average value $< F_{\pi 0} >$ is energy dependent and therefore calorimeters have a response to hadrons, which is nonlinear with energy;
- the above-mentioned fluctuations are non-Gaussian and therefore the energy resolution scales weaker than $1/\sqrt{E}$.

Empirically one finds that such instruments show typically an $e/\pi \approx 1.4$ and an energy resolution of $\sigma/E \geq 0.4/\sqrt{E}$ (GeV).

Understanding these effects suggests how to design instruments in which the response to this nuclear component is boosted or ‘‘compensated for’’, thereby achieving, on average, an equal response to electrons and pions, $e/\pi = 1$. Such instruments are referred to as *compensated calorimeters*.

Remarkably, it is possible to ‘‘tune’’ the e/π response of a calorimeter in the quest to achieve $e/\pi = 1$, and thus optimize the performance. This ‘‘tuning’’

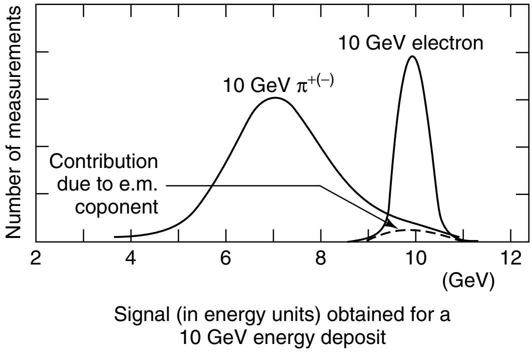

Fig. 21.7 Response function of calorimeters for electrons and hadrons. The curves are for an EMC with $\sigma/E = 0.1/\sqrt{E}$ and for a HC with $\sigma/E = 0.5$ and $e/\pi = 1.4$. A fraction of the hadron-induced cascade propagates almost completely electromagnetically, producing non-Gaussian tails and broadening of the response function.

is based on the fact that practical HCs are almost always built as sampling devices; the energy sampled in the active layers, E_{samp}, is typically a small fraction, a few percent or less, of the total incident energy.

The energetic hadrons lose relatively little energy ($\leq$10%) through ionization before being degraded to such low energies that nuclear processes dominate. Therefore, the response of the calorimeter will be strongly influenced by the response to neutrons (n/mip) and photons (γ/mip) relative to the signal produced by the fast (mip) hadrons (in both the absorber and the readout materials).

As an example, it is possible to influence the response to the abundant neutrons by choosing a readout material rich in hydrogen. The $n - p$ elastic cross section is large and, on average, half of the neutron kinetic energy is transferred to the recoil proton produced in the active material, contributing directly to the calorimeter signal: a 1-MeV proton has a range of ~20 μm in a scintillator and is not sampled unlike a fast hadron (mip). This difference in response between high-Z absorbers and hydrogen-containing readout materials is exploited in the "tuning".

The mip signal will be inversely proportional to the thickness of the absorber plates: increasing the thickness of the absorber plates will decrease E_{samp}, whereas the signal from proton recoils will not be affected and hence neutrons will contribute more significantly to e/π. Changing the sampling fraction changes e/π (Wigmans, 1991).

Having tuned the response to $e/\pi \sim 1$ results also in much improved energy resolution, as conceptually suggested in Figure 21.7, and qualitatively borne out by shower and signal simulations, confirmed by measurements (Fabjan and Gianotti, 2003). One observes a significant reduction in the fluctuations and an intrinsic hadronic energy resolution of $\sigma/E \sim 0.2\sqrt{E(\text{GeV})}$. In principle, tuning of e/π can be applied to all sampling calorimeters, opening the way to better performance. Note that this tuning can only be achieved in sampling calorimeters: a homogeneous calorimeter, for example, a BGO crystal calorimeter would show the typical response of an uncompensated device with a resolution of $\sim 0.4/\sqrt{E}$ (GeV).

Sampling fluctuations contribute, of course, to the energy resolution for which a similar empirical parametrization can be given as for EMCs:

$$\frac{\sigma_{\text{samp}}}{E} = c \cdot \left(\frac{\Delta E(\text{MeV})}{E(\text{GeV})}\right)^{1/2} \tag{12}$$

where ΔE is the energy lost in one sampling cell, with c (hadron) ≈ 0.09 for HCs (Fabjan and Gianotti, 2003).

For high-performance HCs, sampling fluctuations cannot usually be neglected.

We can summarize the principles of modern, optimized hadron calorimetry as follows:

- the key performance parameter is $e/\pi = 1$, which guarantees linearity, $E^{-1/2}$ scaling of the energy resolution, and best resolution;
- by proper choice of type and thickness of active and passive materials the response can be tuned to obtain $e/\pi \approx 1$;
- the intrinsic resolution in practical HCs can be as good as $(\sigma/E) \cdot \sqrt{E} \leq 0.2$;
- sampling fluctuations contribute at the level of $\sigma/E \approx 0.09(\Delta E\,(\mathrm{MeV})/E\,(\mathrm{GeV}))^{1/2}$.

21.5
Calorimeter Systems

The attractive detection properties of calorimeters – energy measurement of charged and neutral particles, improved performance with increasing energy – have made them essential components in modern nuclear and particle physics experiments. In the following we discuss the most important construction principles, frequently used instrumentation techniques, and calorimeter facilities at the LHC.

21.5.1
Calorimeter Construction Principles

A host of calorimeter techniques has been developed to optimize one or several of the following performance parameters:

1. linear response as a function of energy, covering a range from 100 MeV to >1000 GeV;
2. low instrumental noise of the sensors to avoid a degradation of the energy resolution;
3. high degree of readout segmentation is required for position resolution and discrimination between electrons (photons) and hadrons based on the differences in shower shape;
4. insensitivity to magnetic fields, temperature variations, or ionizing radiation on the sensors.

Given the very different properties of electromagnetic and hadronic showers, different optimization criteria apply to EMCs and HCs.

EMCs may be homogeneous or of the sampling type; HCs are essentially always sampling instruments. The calorimeters must also measure the topology (position, direction) of complex particle collisions requiring calorimeters of high lateral and longitudinal subdivision. Many experiments require precision at the 1% level over the full area of calorimeter facilities.

21.5.2
Instrumentation Techniques

All detectors, sensitive to charged particles in the shower cascade, can and are being used to obtain a recordable signal. Two categories are predominant: scintillators (crystals, plastic scintillators, liquefied noble gases) and charge-collecting detectors (liquefied noble gases, semiconductor detectors). A modern example of a homogeneous EMC, using crystals, is the CMS calorimeter, actually being installed at the CERN LHC, Figure 21.8. It uses approximately 76 000 $PbW0_4$ crystals (Table 21.1), surrounding the collision point almost ‘‘hermetically’’. This device has been developed to discover the putative Higgs particle via the decay channel $H \rightarrow \gamma\gamma$, requiring

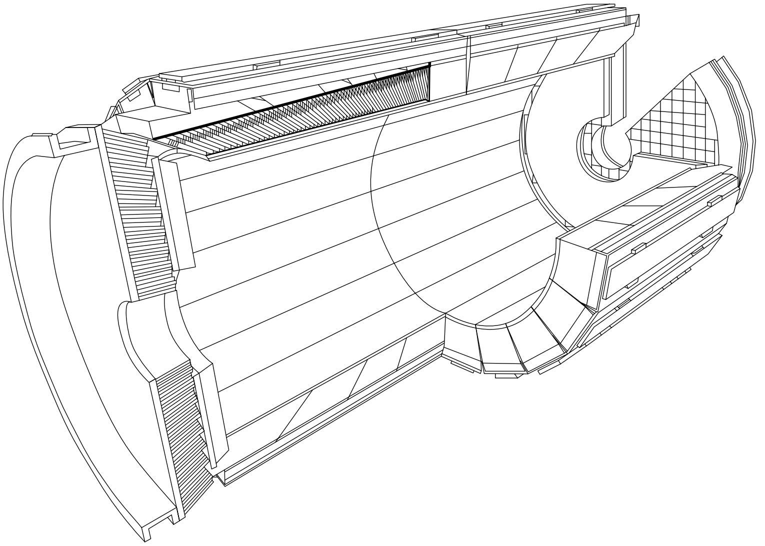

Fig. 21.8 Cutaway view of the CMS crystal EMC. The crystal points toward the collision point and is tapered for crackless coverage of the detection volume. The detector, consisting of 76 000 crystals, has a length of almost 8 m and a diameter of 3.6 m.

a precision of better than 1% at 100 GeV. $PbW0_4$ is the most recent example of a crystal being developed for particle physics by an international, 10-year long R&D effort with the aim to achieve the needed transparency and radiation hardness.

An example of a modern version of plastic scintillator readout is the ATLAS HC, installed at the LHC, Figure 21.9. It is doubly remarkable: the absorber plates, made from steel, are oriented longitudinally, along the direction of the incident hadron. This geometry works as well as the conventional, transverse orientation, because hadrons, after having traversed the preceding EMC, have developed a sufficiently broad shower to be insensitive to the precise orientation of the absorber plates. This geometry was chosen for ease of construction. Scintillation ''tiles'' are nested in slots; the light is transmitted to and absorbed in wavelength-shifting (WLS) fibers, running closely along two edges of the tile. The WLS fibers reemit the absorbed scintillation light at the larger wavelength, to which the fibers are transparent; a group of fibers from tiles covering a certain volume, a ''cell'', are routed to and read by a photomultiplier. The necessary subdivision of the calorimeter is naturally achieved.

Another novel use of scintillators is in the form of scintillating fibers, one to a few millimeters in diameter. Geometries with fibers perpendicular or along the direction of the incident particle have been used successfully (Fabjan and Gianotti, 2003).

Plastic scintillators are chosen for their potential to tune the e/π response (Section 21.4.4) and their relative facility in calorimeter construction. Systematic effects connected with light collection and material ageing need, however, to be very carefully handled, often requiring complex in situ calibration methods.

The second important instrumentation family is based on charge collection from

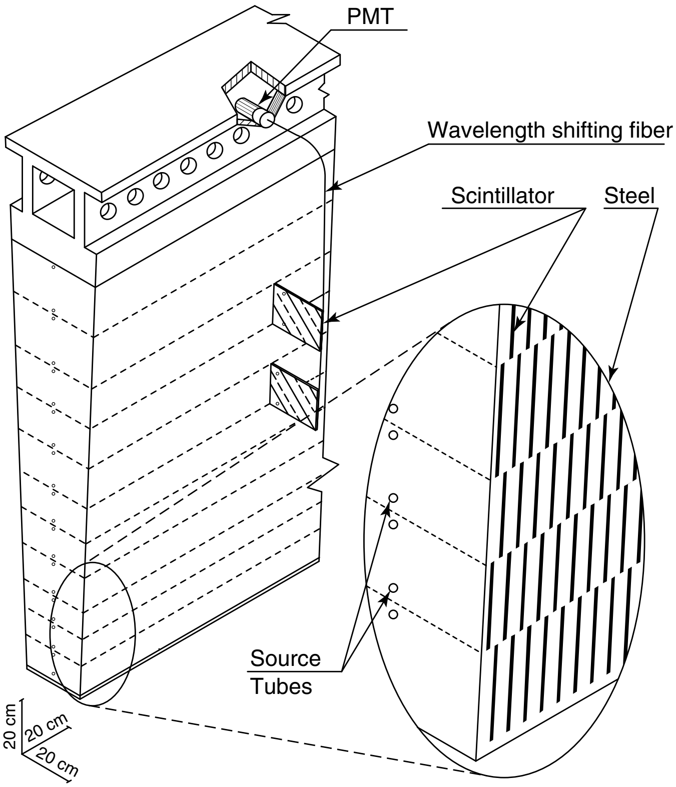

Fig. 21.9 View of one module of the central ATLAS hadronic calorimeter. Thirty-six such modules complete the cylindrical detector. Each of the longitudinally oriented scintillating tiles is read with two wavelength-shifting fibers.

liquid noble gases (Table 21.2). One recent example of a quasi-homogeneous liquid krypton EMC is shown in Figure 21.10. This instrument was built for a fixed target experiment at the CERN SPS to study CP violation, measuring the reaction $K^o_{s,l} \to \pi^0\pi^0$ and $K^o_{s,l} \to \pi + \pi -$. For this measurement, an EMC was needed with an energy resolution of $\sim 5\%/\sqrt{E}$ (GeV) and a position resolution of ~ 1 mm for 25 GeV photons (Fanti *et al.*, 2007). Liquid krypton was chosen as a compromise between the commonly used LAr, which has a quite large radiation length making a homogeneous detector quite bulky and the "ideal" noble liquid, LXe, which is prohibitively expensive for the volume needed. The use of LXe for precision photon and electron calorimetry is extremely attractive, the cost (and the necessary purity) however being a formidable obstacle. The largest LXe device to date is being prepared for a high-sensitivity search for the forbidden decay mode $\mu \to e\gamma$, in which a 53-MeV photon would be emitted. The MEG Collaboration has constructed a 900-l homogeneous LXe EMC with remarkable performance on energy resolution of $\sigma/E \leq 1\%$ at 100 MeV (a world record)

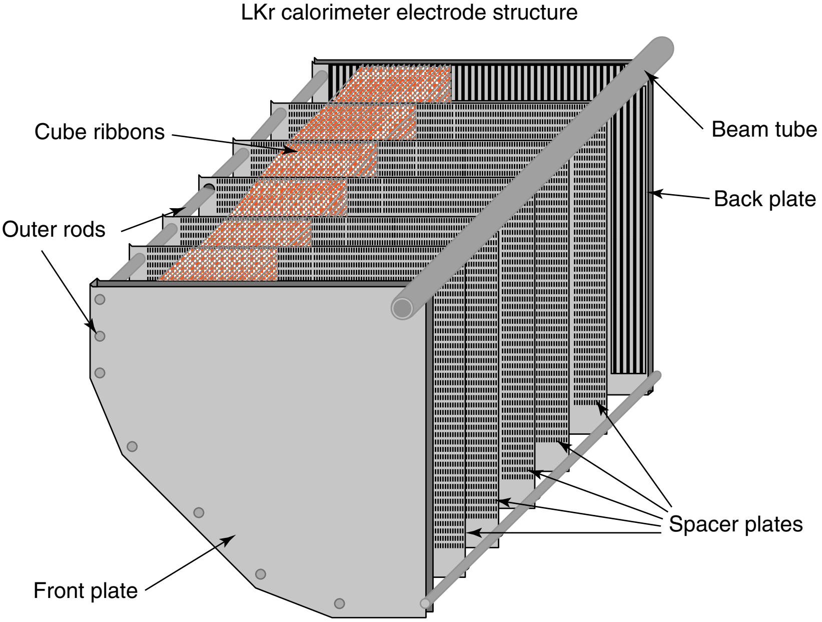

Fig. 21.10 Schematic view of a section of the NA48 liquid krypton electromagnetic calorimeter.

and a time resolution of ≈ 50 ps mm is reported (Sawada, 2007). It should be noted that only the scintillation light is recorded.

Liquid argon has been used for more than three decades as a readout medium: it is cheap, can be easily purchased at sufficient purity, and can be conveniently refrigerated with LN_2. The most advanced incarnation is the ATLAS EMC (Figure 21.11). It is a sampling calorimeter with again an unusual absorber structure in the form of "accordions" made of folded Pb-plates, covered with a stainless-steel skin. This geometry was chosen to achieve the following LHC requirements:

- uniform sensitivity to <1%;
- relatively fast readout;
- good transverse and longitudinal segmentation.

The geometry has allowed the construction of a cylindrical EMC without cracks or insensitive regions. Noble liquids are chosen for the advantages associated with charge collection and its superior control of systematic effects. Above 50 GeV, the ATLAS sampling EMC compares very well in performance with the crystal calorimeter of CMS.

21.5.3
Calorimeter Facilities

The physics and detector requirements for the LHC program have stimulated a major, worldwide R&D effort to meet the long list of conditions:

- *Fast response*: At the LHC design intensity, on average, 30 collisions will take place every 25 nanosecond. Most of these collisions will reflect "conventional" physics with relatively low-energy particles. With fast calorimeter response – 50–100 nanoseconds – the integration over

$\leq$100 events produces a "low-energy noise" in which the "new" physics signals are still well detectable.

- *Radiation hardness*: This is one of the severest technical requirements. At small angles to the collision axis radiation levels of $\sim 10^{17}$ neutrons cm^{-2} and $\sim 10^7$ Gy will be accumulated after 10 years of operation.
- *Construction methods that minimize nonsensitive areas*: Neutrinos, a frequent component of "new" physics, are recognized through an apparent "missing" energy. This method works, provided cracks do not simulate this signal.
- *Excellent electromagnetic energy resolution:* The "Holy Grail" of LHC physics is the search for the Higgs particle, which has an important decay channel of $H \rightarrow \gamma\gamma$. A resolution of 1% at 100 GeV is required, combined with an angular measurement of ~5 mrad for 100-GeV photons.
- *Large dynamic energy angle* for electrons, photons, and hadrons from a few giga electronvolts to few tera electronvolts.

In Figure 21.12, the calorimeter facility developed for the ATLAS experiment is shown. The very stringent requirements, combined with more mundane considerations, such as cost, have led to different choices for the EMC and HC; the radiation levels in the small-angle regions are so high that the very robust LAr technique was also chosen for the HC.

Hadronic LAr end cap calorimeters

Fig. 21.12 Partial cutaway view of the ATLAS calorimeter system (and the inner charged-particle tracker). The diameter is 8.5 m and the total length 13 m. The outer cylinder and the external end caps measure the hadrons; the inner (light gray) cylinders and end caps are the "Accordion" LAr EMCs. In principle, all particles are absorbed in this calorimeter system with the exception of neutrinos and muons, the latter being measured in the large muon spectrometer surrounding the calorimeters (not shown).

21.6
Calorimeters in Astroparticle Physics

This relatively new field addresses questions in cosmology and particle physics, which cannot be addressed with accelerator-based experimentation. At the energy frontier of 10^{20} eV are ultrahigh-energy cosmic rays, impinging on the Earth at a rate of one every few seconds. Another high-energy "cosmic" phenomenon is the study of sources of very high (hundreds of mega electronvolts to few tera electronvolts) photons. Not surprisingly, these studies are mostly based on extensions of the calorimetric principle. Given the rarity of these events, the calorimeter has to be gigantic. It turns out that the Earth's atmosphere is a most precious gift; at sea level, it represents approximately 28 radiations and 17 collisions length: an ideal, homogeneously sensitive calorimeter.

Ingenious approaches have been developed to instrument this homogeneous absorber. Relevant performance parameters are as follows (Hoffman, 1999; Pretzl, 2005):

- the energy threshold for particle detection;
- the systematic error on the energy scale;
- the energy resolution;
- their potential to discriminate between different particles.

One approach explores the Cherenkov light induced in the atmosphere by the relativistic component of a very high energy shower. This technique is tailored to explore the energy window between space-based detectors, rate limited to $E \leq 10\,\text{GeV}$, and ground-based systems, limited by signal to noise to $E \geq 300\,\text{GeV}$. The lateral distribution of the "Cherenkov shower" is narrowly concentrated around the shower axis and can be observed in a dark night sky. The Cherenkov light is collected with large mirrors and focused onto an array of light detectors, providing the energy, direction, and discrimination between photon- and hadron-induced showers. This technique allowed the recent observation of γ point sources (Hoffmann, 1999).

In another strategy, the fluorescence excited by the passage of the shower particle in the atmosphere provides the measure of the particle's energy. An array of telescopes is used to focus the light onto arrays of photo detectors. One observes a very large volume of the atmosphere, close to 10 000 km^2 sr in a fine grid of $1^0 * 1^0$. This technique measures the longitudinal shower profile and the shower maximum, sensitive to the composition of the cosmic rays. With its very high sensitivity, it has recorded some of the highest energy cosmic rays, to date.

The oldest of the three techniques has recently witnessed a remarkable renaissance. It uses ground-based detectors to record the tails of particle cascades initiated by sufficiently energetic primaries. The development of this technique (Cronin *et al.*, 1993) aims at the following:

- increased sensitivity towards higher energies;
- better understanding of the absolute energy scale;
- identification of the primary composition.

The most ambitious project is the Auger observatory, covering an area of 3000 km^2 with a variety of detectors: ground-based devices to measure the ratio between electromagnetic showers and muons, combined with detectors measuring the atmospheric fluorescence, providing complementary energy and particle type information. A spectacular proof of the power of this method has been the recent observation that ultrahigh-energy (close to 10^{20} eV) cosmic rays are emitted from extragalactic sources (Auger Collaboration, 2007).

Neutrino astronomy is another recent frontier requiring the most massive detectors: the water of the oceans and the Antarctic icecap has been instrumented to provide prototypes on the way to instrumenting one cubic kilometer (Learned, 2000).

While high-energy astrophysical applications use known calorimetric techniques in innovative ways, the detection of very low energy deposits in the milli electronvolt to electronvolt range requires totally new detection principles, opening the exploration of other fundamental physics questions, such as the following:

1. improved lower limits on the rest mass of neutrinos;
2. the search for weakly interacting massive particles (WIMPs), which may be responsible for the component of dark (invisible and not yet accounted for) matter in the Universe;

3. the search for magnetic monopoles, which may be relics of the Big Bang; and
4. the search for relic neutrinos from the Big Bang, which may have energies of $\sim$1 MeV.

The basic detection principle, registration of the interaction of the particle with the detector during the absorption process, is again calorimetry. However, the energies involved are below the atomic excitation levels, and different detection processes have to be invoked.

These calorimeters are characterized by operation at cryogenic temperatures, in the few millikelvins to $\sim$1 kelvin range. They exploit either some specific properties of the superconducting phase of matter or the reduction in the thermal noise of the detecting medium. Given the very low thresholds of the basic detection process, the number of elementary excitations can be considerably higher, and these detectors therefore hold the promise of much improved energy resolution.

Operation at cryogenic temperatures opens a number of detection channels:

1. Cooper pairs in superconductors have binding energies in the 10^{-6} to 10^{-3} eV range and may be broken into quasiparticles by phonon (lattice vibration) absorption.
2. The specific heat c for dielectric crystals decreases as $\sim \exp(-1/kT)$, resulting in a measurable, relatively fast temperature rise for very low energy absorption.
3. Energy absorption may induce a change in magnetization, latent heat release, or quasiparticle multiplication.

A powerful application of the detection in superconductors is being developed for dispersive spectroscopy in the wavelength region from 0.5 nm to 2 μm (Peacock, 1999). Arrays of superconducting tunneling junctions serve the dual function of absorber and detector. The number of excess carries N produced by the photon absorption as a function of the wavelength λ is

$N(\lambda) \approx 7 * 10^5/(\lambda\,(\mathrm{nm})\,\Delta\,(T/T_c)\,(\mathrm{meV}))$, Δ being the band gap.

Typical numbers of N are 10^6 at $\lambda \approx 1$ nm and the spectroscopic resolution is at a few percent level.

"Bolometric" detectors are an example of an application of concept 2, the true calorimeters, in which the temperature

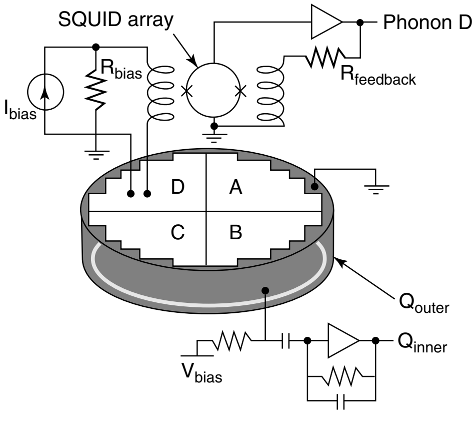

Fig. 21.13 Schematic diagram of a massive (few hundred grams) Ge detector for dark matter searches. Simultaneous measurements of phonons with transition-edge sensors and of the ionization charge provide the required background rejection (Cabrera, 2000).

rise due to the interaction of particles in an insulating crystal maintained at very low temperatures may be measured with a resistive thermometer. The energy resolution (neglecting noise in the readout electronics) is evaluated to be $\sigma(E) \sim T^{5/2}M^{1/2}$ (M being the mass of the bolometer); X-rays have been measured with 0.1% energy resolution (at 6 keV), superior to that obtained with conventional semiconductor detectors. An example is shown in Figure 21.13: using Ge allows simultaneous measurement of temperature and ionization providing powerful (and needed) discrimination between the putative WIMP and conventional background (Booth, 1996). Detectors with a mass between 100 and 1000 kg are being considered for sensitive dark-matter searches (Enns, 2005).

Glossary

Calorimetry: In its most general definition, a technique to measure the energy of a reaction or a process. Sometimes, the energy measurement is related to a temperature measurement, hence the name *calorimetry*. In particle physics, it is the name given to techniques that measure the energy of particles or quanta.

γ-Quanta: Energetic quanta of electromagnetic radiation. They may be emitted from the de-excitation of nuclei or created in very energetic interactions of elementary particles with matter.

Hadrons: Generic name for those elementary particles that are carriers of the ''strong interaction'' (e.g., protons, neutrons, and pions).

Leptons: Generic name for those elementary particles that do not participate in the strong interaction (e.g., electrons, muons, and their corresponding neutrinos).

Nucleon: Generic name for neutrons and protons, the constituents of the atomic nucleus.

Particle Detectors: Instruments to detect or measure properties of particles or radiation quanta. Here, particles designate the microscopic constituents of matter or elementary particles created in energetic collisions of matter. Typically, the trajectory, velocity, energy, or mass of such particles is detected.

Particle Physics: Branch of physics devoted to the study of elementary particles and forces between them. Frequently, very energetic accelerators are used to create or study such particles; this field is therefore often also called *high-energy physics*.

Scintillator: A group of materials that are widely used for particle detection; the material is excited by the passage of charged particles and emits photons (in the UV to visible range) in the de-excitation process. It has important applications outside particle physics.

Solid-State Detectors: Common class of particle detectors. Most frequently used are detectors based on very pure silicon, germanium, or gallium arsenide. The passage of a charged particle creates free charge carriers (''electron–hole'' pairs), which may be collected on suitably arranged electrodes. They are used for the precision measurement of the energy loss or the position of charged particles.

INTRODUCTION

In many areas of basic scientific research, as well as in a variety of applied fields, one wishes to detect the passage of radiation through matter. The fact that some materials emit light when struck by radiation has been known for many years, and this principle is the basis for the scintillation detector. For example, in 1911, Ernest Rutherford observed scintillation light produced by the interactions of α particles with a zinc sulfide screen in his pioneering scattering experiments which established the existence of the atomic nucleus. Since then, a large number of different scintillating materials have been developed for specific applications in the fields of physics, chemistry, and biology. This article describes the scintillation process and some of the uses of scintillation detectors in the laboratory and in industry.

Before describing the scintillation mechanism, it is useful to review briefly the processes by which radiation is absorbed by matter. For x rays and γ rays (high-energy photons) three processes are important: the photoelectric effect, Compton scattering, and pair production. In the photoelectric effect, the full energy of the photon is absorbed by a bound atomic electron. This ejects the electron from the atom with a kinetic energy equal to the photon energy minus the electron's original binding energy. In Compton scattering, the photon also interacts with an atomic electron, but only a fraction of its energy is transferred to the electron. The remaining energy is carried off by a secondary photon in an amount that depends on the angle of its emission relative to the direction of the primary photon. For photons with energies greater than twice the rest-mass energy of the electron ($2m_ec^2=1022$ keV) it is possible to convert into an electron-proton pair. The kinetic energy of the e^+e^- pair is then equal to the original photon energy minus 1022 keV.

When β particles (electrons) traverse matter, they produce atomic and molecular excitations and ionization through their collisions with atomic electrons. Heavy charged particles, such as protons, α particles (^{4}He nuclei), and nuclei of heavier atoms, also make inelastic collisions with atomic electrons that lead to atomic and molecular excitations as well as ionization. For neutrons, however, the situation is somewhat different. Since neutrons are electrically neutral, the primary way in which they lose energy in matter is through their nuclear interactions with atomic nuclei. They can be scattered off the nucleus or absorbed by it. In hydrogenous materials such as paraffin or polyethylene, neutrons scattering off hydrogen nuclei produce recoiling protons which then interact as described above. Some scintillation materials are doped with ^{6}Li, which has a large cross section for the $^6\mathrm{Li}(n,^3\mathrm{H})^4\mathrm{He}$ reaction. The recoiling triton and α particle then interact as described above.

1. PHYSICS OF SCINTILLATION DETECTORS

The mechanism by which energy deposited by radiation is converted into light within a scintillator is a fairly involved process and is

Copyright © WILEY-VCH Verlag GmbH & Co KGaA. All rights reserved.

somewhat different in inorganic and organic scintillators. In both types, however, the amount of light produced is proportional to the amount of energy deposited in the scintillator. Inorganic scintillators are made of crystals of materials such as NaI or CsI that are usually activated with an impurity such as Tl (thallium). It has been found that with an impurity concentration on the order of 1 part in 10^3 by number, there is a very efficient transfer of energy from the major constituent to the impurity. In NaI(Tl), for example, the result is that the capture of electrons and/or holes by the thallium impurity leads to excited states of the Tl^+ ion that decay by emitting the light which is observed from this scintillator. Through this process, approximately 12% of the incident energy is converted into Tl^+ light. Because the impurity concentration is so low, this type of scintillator is very transparent to its own light.

Liquid, plastic, and some kinds of crystal scintillators are composed of organic compounds known as aromatic hydrocarbons. These materials consist of molecules containing a benzene ring structure. Within these rings, not all of the electrons that bind the atoms together are strongly localized to individual atoms. These so-called valence electrons occupy the π molecular orbitals which extend above and below the plane of the molecule. Absorption of radiation by these electrons can produce excited states which decay to the ground state or other excited states by emitting light. If the decay proceeds to an excited state, then the photon that is emitted has too little energy to excite another molecule from its ground state to the appropriate excited state. Thus, such transitions produce light to which the scintillator is quite transparent.

Over the years, many different types of scintillators have been developed to meet a variety of radiation-detection needs. The physical properties of a number of different scintillation materials are listed in Table 1. Physical properties such as density, scintillation efficiency (i.e., a measure of the fraction of deposited energy that is converted into light), the wavelength at which the scintillation light appears, and the scintillation decay constant (i.e., the time interval over which light is emitted) vary widely among the different scintillators. These differences are used to decide which scintillator is used for a particular application. High-density materials containing elements with large atomic numbers have relatively high efficiencies for stopping γ rays. Thus, compounds such as NaI(Tl), BaF_2, or bismuth germanate (BGO) are used in such applications. Plastic scintillators have very short decay constants and thus are used in applications where there are needs for fast timing. Scintillators such as ^{6}LiI(Eu) contain nuclei that have high cross sections for neutron-induced reactions and thus are useful in neutron studies.

Table 1. Physical properties of various scintillator materials.

---

[a] Relative to NaI(Tl).

The process by which a complete scintillation detector system converts the energy deposited by the incident radiation into a usable signal involves several steps. Such a system is shown schematically in Fig. 1. As described above, the incident radiation ionizes and excites the scintillation material. Within the scintillator, a fraction of this energy is converted into light. This light travels through the scintillator and is then collected on a photosensitive surface. The resulting photoelectrons are multiplied and collected, thus producing a usable signal. Usually these functions are accomplished by coupling a scintillation material to a light pipe which guides the light to a photomultiplier tube. When photons strike the photocathode, electrons are ejected via the photoelectric effect. These electrons are then accelerated and focused onto a series of dynodes, where through collisions the number of electrons is greatly multiplied. By the time the signal reaches the collection anode, it may have been amplified by more than a factor of 10^6. This signal is usually then sent to an amplifier where further shaping and amplification of the pulse is done before it reaches the data-acquisition system. The size of this final signal provides a measure of the amount of energy deposited by the radiation in the scintillator.

An important characteristic of any type of energy-measuring device is its resolution. This is usually expressed as ΔE=the full width at half maximum (FWHM) of the peak observed from a source of monoenergetic particles. In the scintillation-detector system described above, the measure of the energy of the incident radiation is given by the amount of charge that comes out of the photomultiplier. However, as discussed by many authors (e.g., Rolfs and Rodney, 1988), at each step in the scintillation-detection process there are losses which contribute to the overall detector resolution. As discussed above, in NaI(Tl) detectors the efficiency, ϵ_1, of converting the incident energy into light is about 12%. The mean energy w of these photons is about 3 eV. Of these photons, only a fraction ϵ_2, of order 0.4, actually reaches the photocathode. Only another fraction ϵ_3, of order 0.2, causes the emission of a photoelectron. The fractional energy resolution $\Delta E/E$ of such detectors is limited by the statistical fluctuations in each of these processes and is given by the expression

$$\Delta E/E = 2.35(w/E\epsilon_1\epsilon_2\epsilon_3)^{1/2}.$$

This leads to an expected value of $\Delta E/E$ of approximately 4% for a 1.33-MeV γ ray. As will be shown below, in practice one usually observes slightly worse resolution than this because of imperfections in the detector crystal and/or electronics.

2. MANUFACTURE OF SCINTILLATION DETECTORS

Inorganic scintillators such as NaI(Tl) and CsI(Tl) can be produced as single-crystal ingots up to approximately 36 in. in diameter. To produce crystals of this size, grains or small chunks of the desired chemical are put into a large crucible. The crucible is heated to high enough temperature to melt the material. The crucible is then allowed to cool at a rate which is faster on the bottom than at the top.

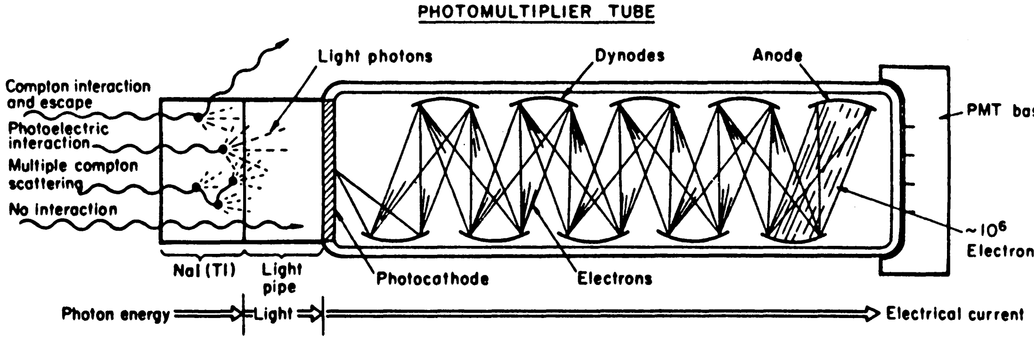

FIG. 1. Schematic view of a scintillation detector system. The interactions of photons in a NaI(Tl) scintillator are shown along with the transmission of the resulting optical photons through a light pipe to a photomultiplier where light is converted into an electrical signal. (Courtesy of S. E. Derenzo.)

Thus crystal growth begins at the bottom and proceeds upwards. In this way large single crystals can be grown. An example of this is shown in Fig. 2, where a large crystal of CsI has just been removed from the crucible in which it was grown. For more information on the production of crystals, see CRYSTAL GROWTH.

Plastic scintillators are usually manufactured in the form of cast sheets. However, these materials are also available in rods, fibers, or beads. They are produced by mixing together a suitable fluorescent organic compound with a polymer and allowing the mixture to solidify. Commonly used mixtures include *p*-terphenyl dissolved in either polystyrene or polyvinyltoluene. A typical plastic scintillator paddle with a light pipe attached is shown in Fig. 3.

Following the machining or forming process, the surfaces of a solid scintillator are polished. A highly reflective coating is usually applied to these surfaces to return the light to the crystal and thus aid in the transport of the scintillation light to the photomultiplier. Crystalline scintillators are normally packaged inside a metal canister so as to protect the scintillator from mechanical shocks. In the case of NaI such protection is also necessary because of the hygroscopic (i.e., moisture sensitive) nature of the material. Liquid scintillators are also often packaged in a metal container. In both cases, the can has a transparent window on one side on which the light pipe and then photomultiplier tube are mounted.

3. APPLICATIONS OF SCINTILLATION DETECTORS

In the areas of nuclear and particle physics research, scintillation detectors are used in a wide variety of experiments. In γ-ray-counting experiments, NaI(Tl) detectors are used in applications where high detection efficiency, good energy resolution, and reasonably good timing properties are needed. An example of low-energy γ rays observed in a small NaI(Tl) detector is shown in Fig. 4. A radioactive source of ^{60}Co, which emits a pair of coinci-

dent γ rays with energies of 1173 and 1332 keV, was counted with a 7.6-cm-diam × 7.6-cm-long NaI(Tl) detector. The full-energy (photo)peaks of these lines are clearly seen along with a well-defined "sum peak" which is produced when the full energies of both γ rays are absorbed at the same time by the detector. The counts in the region below the photopeaks and in the region between the photopeaks and the sum peak are due to events in which one or both of the γ rays underwent Compton scattering in the crystal or in its surroundings. The energy resolution for the photopeaks is just over 5% FWHM. In contrast, solid-state germanium detectors (described in the article DETECTORS, SEMICONDUCTOR) typically achieve resolutions of approximately 0.15% at this energy.

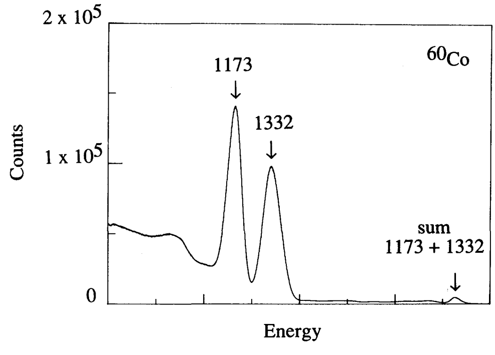

FIG. 4. γ-ray spectrum of ^{60}Co observed in a 7.6-cm-diam × 7.6-cm-long NaI(Tl) detector.

Another use of NaI(Tl) detectors is in nuclear reaction studies. In radiative capture reactions, the projectile fuses with the target nucleus and the resulting excitation energy is carried off by relatively high-energy ($\gtrsim 10$ MeV) γ rays. While solid-state germanium detectors would provide better energy resolution, their detection efficiency for such high-energy γ rays is too low for them to be useful. Therefore, in this type of research, NaI(Tl) detectors are often used. An example of a spectrum observed in the capture of protons by a target of ^{30}Si is shown in Fig. 5. The NaI(Tl) crystal used in this experiment is 25 cm in diameter and 28 cm thick. The proton bombarding energy is 25.5 MeV. The small peak near 32-MeV γ-ray energy corresponds to the case of leaving the resulting ^{31}P nucleus in its ground state; other peaks at lower γ-ray energy correspond to leaving the ^{31}P in one of its excited states.

Another application of scintillation detectors is in the area of Compton suppression. In a typical germanium detector, if a 1-MeV γ ray enters the detector, only about 20% of the recorded events will be in the full-energy peak (photopeak) and 80% will be in a continuous spectrum from zero up to the full γ-ray energy as a result of Compton scattering. These Comp-

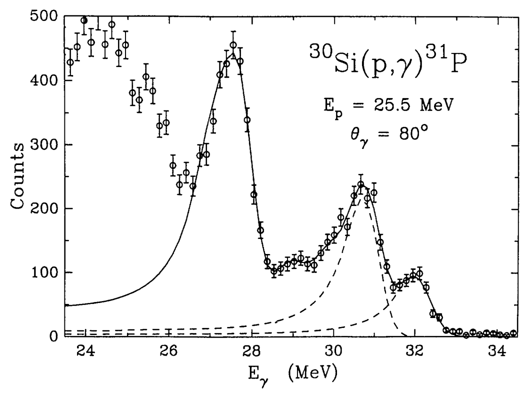

FIG. 5. γ-ray spectrum observed in a 25-cm-diam × 28-cm-long NaI(Tl) detector from the ^{30}Si(p,γ)^{31}P reaction at a proton bombarding energy of 25.5 MeV. (Courtesy of G. Feldman.)

ton events provide no useful information as to the original energy of the incident γ ray. Furthermore, they produce a background which can make it difficult to observe the often small full-energy peaks of interest. By surrounding a germanium detector with a suitable scintillator, one can look for events where both detectors fired simultaneously. Such events are produced by Compton scattering in the germanium detector into the scintillator and can be vetoed. An example of an annular NaI(Tl) scintillator acting as a Compton suppressor for a germanium detector is shown in Fig. 6. γ-ray spectra observed in the germanium detector in this system are shown in Fig. 7. A ^{54}Mn source, which emits monoenergetic γ rays at 835 keV, was counted with a 110-cm^3 germanium detector. The upper spectrum shows the response of the germanium detector without regard to what happened at the same time in the surrounding NaI(Tl) detector. One sees the 835-keV full-energy peak along with a Compton continuum. The lower spectrum is what is observed in the germanium detector when the NaI(Tl) did not observe an event in coincidence with the germanium detector. One can clearly see a reduction in the Compton continuum by a factor as large as 10 in some parts of the

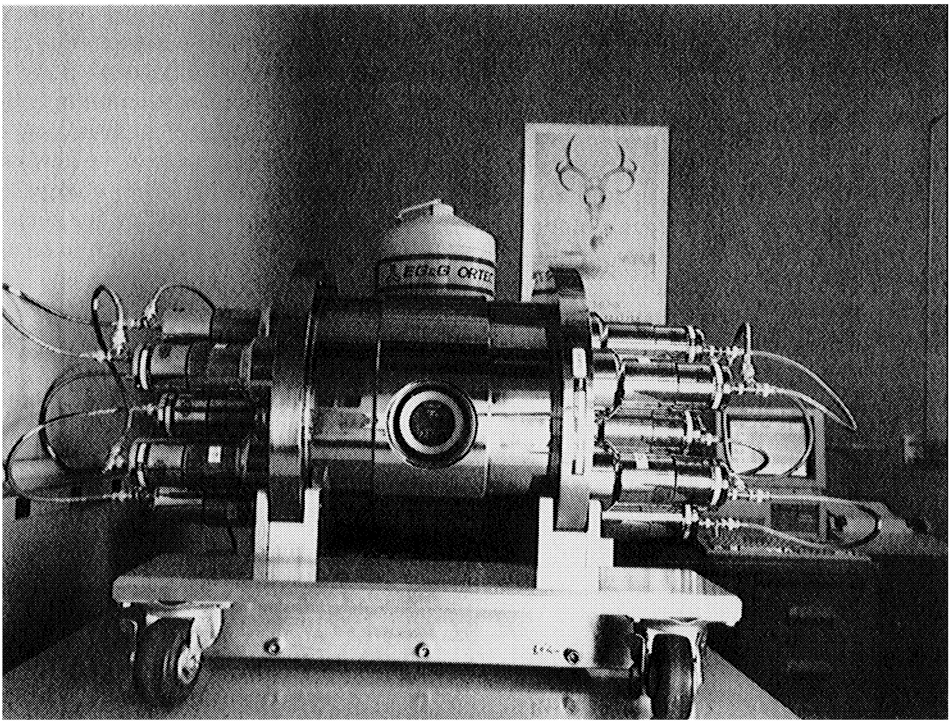

FIG. 6. A 30-cm-diameter × 30-cm-long annular NaI(Tl) detector system surrounding a 110-cm^3 germanium detector. The NaI(Tl) crystal is optically divided into two halves, each viewed by seven photomultiplier tubes. In this system, the NaI(Tl) detector is used to veto events in which a γ ray undergoes Compton scattering in the germanium detector and the scattered photon goes into the NaI(Tl) detector.

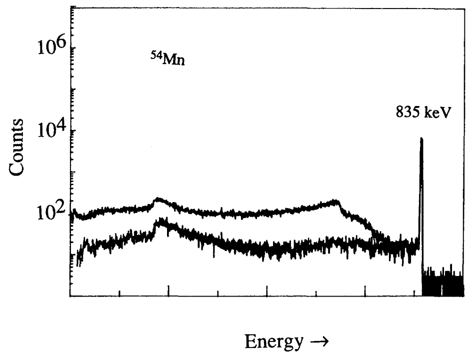

FIG. 7. γ-ray spectra observed in a 110-cm^3 germanium detector placed inside the NaI(Tl) annulus shown in Fig. 6. Data with (lower spectrum) and without (upper spectrum) the NaI(Tl) anticoincidence requirement are shown to illustrate the reduction of the continuum produced by Compton scattering.

spectrum. In a number of multielement germanium detector arrays, such as the High Energy Resolution Array (HERA) at Lawrence Berkeley Laboratory, TESSA at Daresbury Laboratory, and the soon-to-be-built GAMMASPHERE and EUROGAM arrays, BGO anti-Compton shields are used instead of NaI(Tl). The reason for this is that the large atomic number of Bi and the high density of BGO mean that a much smaller-sized scintillator is needed to provide the same amount of Compton suppression. This permits the germanium detectors to be packed together closely, and thus provides high efficiency for detecting the full-energy γ ray in a germanium detector.

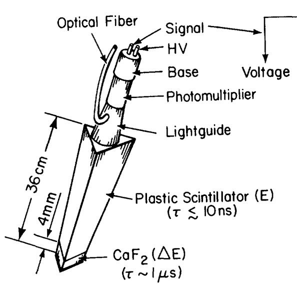

FIG. 8. Schematic view of a phoswich detector. Two scintillators with different decay constants are stacked one behind the other and are both viewed by a single photomultiplier tube. The resulting light signal then has two components which can be separated with appropriate electronics. (Baden *et al.*, 1982.)

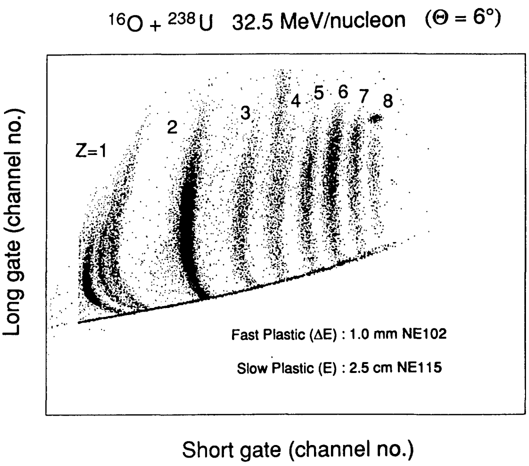

FIG. 9. An example of data obtained from an array of plastic phoswich detectors. By performing a fast integration of the photomultiplier signal, one obtains a measure of the light output from the thin front scintillator. A longer integration provides a measure of the energy deposited in the thicker and slower back scintillator. (Courtesy of Y. D. Chan.)

As can be seen in Table 1, the time dependence of the light output of scintillators varies widely. This variation has been put to practical use in what is called a phoswich detector. This consists of two different scintillators stacked one behind the other, both of which are viewed by one photomultiplier tube. An example of this type of detector is shown in Fig. 8. This detector consists of a thin crystal of CaF_2 mounted on the end of a long plastic scintillator. A charged particle which enters the CaF_2 and comes to rest in the plastic scintillator will produce scintillation light in both materials. Because of the difference in the decay time of the light output in these two materials, the photomultiplier output signal will have two components. There will be a fast component associated with the plastic scintillator and a slower one associated with the CaF_2. By appropriately integrating these signals, one can extract the individual signals from these two scintillators and obtain a measurement of both the energy lost in the front scintillator, ΔE, and the total energy of the charged particle, E. An example of the data resulting from a phoswich detector system is shown in Fig. 9. In this case the products of the fragmentation of an ^{16}O beam by a ^{238}U target were observed by an array of phoswich detectors consisting of two different types of plastic scintillator—one with a short decay time and one with a long decay time. From the "short" and "long" gates set on the photomultiplier output signals, one obtains

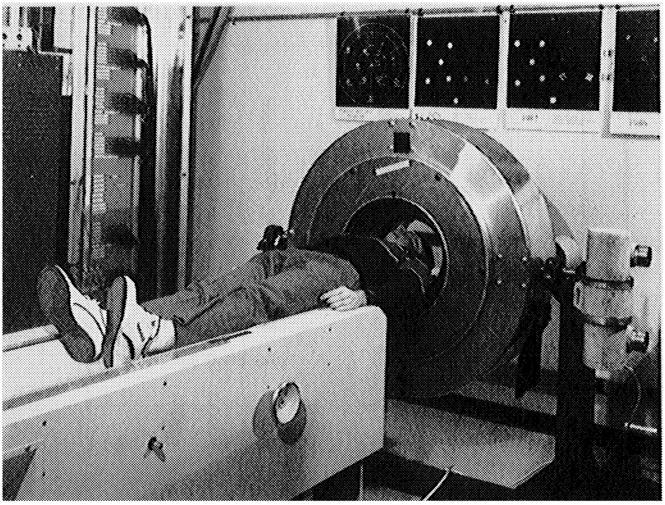

FIG. 10. A patient being examined with a positron-emission tomography system that consists of 280 NaI(Tl) crystals. (Courtesy of S. E. Derenzo.)

the ΔE and E parameters, respectively. The fact that, for a given kinetic energy, nuclei with different atomic numbers (Z) lose differing amounts of energy in the thin front scintillator gives rise to the various bands seen in this two-dimensional plot.

Scintillation detectors have also played a major role in astrophysical studies performed in space. For example, NaI(Tl) detectors on the Solar Maximum Mission detected nuclear γ rays at 847 and 1238 keV produced by the radioactive decay of ^{56}Co (half-life=77 days) coming from Supernova 1987A. This observation helped to confirm that the evolution of massive stars produces a core of iron which collapses and initiates the supernova explosion. This process had been suggested long ago, but the observation of these characteristic γ rays is one of the strongest pieces of experimental evidence that this type of nucleosynthesis actually occurs in supernovae.

In the field of medical physics, scintillation detectors have played major roles in a number of areas. Whole-body counters, which are used to determine the identities and quantities of radioisotopes contained in a person, often consist of large NaI(Tl) crystals. When housed in a low-background environment, such systems are capable of detecting very small (~nanocurie) amounts of γ-ray emitting radioisotopes.

Another area in which scintillators are now being widely used is positron-emission tomography, or PET scanning. In this procedure, a positron-emitting radioisotope, such as ^{18}F, is attached to a compound such as fluorodeoxyglucose and is then introduced into the subject's body. It is concentrated in an organ of

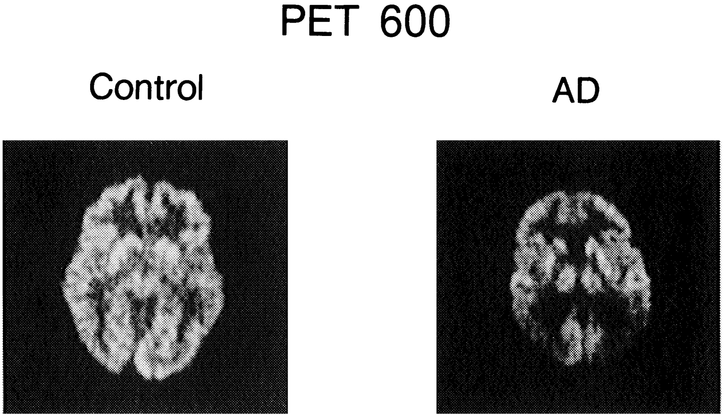

FIG. 11. An example of positron-emission tomography data taken with a PET system consisting of 600 scintillation detectors. Activity of the human brain is indicated by the white areas in the tomograph. A control patient is shown along with a patient suffering from Alzheimer's disease. (Valk *et al.*, 1990.)

interest where the positrons annihilate with electrons. The annihilation process produces two γ rays, each of 511 keV, which are emitted back-to-back. That is, they travel off in opposite directions from the point of annihilation. These annihilation photons are detected in coincidence in two diametrically opposed crystals. By surrounding the subject with a large number of detectors, and by finding the intersection point of all of the lines, one can determine the size and activity of the positron-emitting activity. By observing the time variations in such activity one can observe various body functions in progress. A subject being counted with a PET system of 280 bismuth germanate crystals is shown in Fig. 10. PET data showing activity of the human brain, taken with a system containing 600 individual crystals, are shown in Fig. 11.

In the area of geological exploration, scintillation detectors also play a major role. Measurement of natural radioactivity to locate deposits of uranium and thorium in the earth's crust is an activity in which scintillation detectors are widely used. Low-flying aircraft carrying large NaI(Tl) detectors make surveys of γ-ray activity searching for the characteristic γ rays emitted in the decay chains of ^{232}Th (2.6 MeV) and ^{238}U (1.76 MeV). Borehole measurements are performed in several different ways. Sometimes a scintillation detector is simply lowered down a hole and measurements are made of the local radioactivity. In other applications, sources of either neutrons or γ rays are also placed underground and the scintillation detector is used to measure the amount of scattered or induced activity.

In the area of nuclear safeguards, large plastic scintillators are often used in vehicle or personnel monitoring to look for unauthorized movements of radioactive materials. In such an installation, a vehicle or person drives or walks past the scintillation detector and the characteristic γ rays of ^{235}U or ^{239}Pu are sought for. Walk-through systems are now in place which can detect 0.02 g of ^{239}Pu or 1 g of ^{235}U.

In a number of industrial situations, one is interested in measuring the wearing away of material from an object as a result of its being used. This is the subject of tribology, and scintillation detectors are often used in this field. For example, in the automobile industry, engine wear can be determined by implanting a γ-ray-emitting radioisotope in the part of the engine of interest. A NaI(Tl) or BGO detector is then placed near this part and the γ-ray counting rate is monitored as a function of the engine use. As the part is worn away, one observes a decrease in the γ-ray activity. By taking an identically implanted part and measuring its γ-ray counting rate as one quantitatively removes material from the surface, one can calibrate the technique. Through such tests, it has been found that this method is sensitive to engine part wear as small as 0.00005 in.

Compton scattering of γ rays from an object can be used to determine the thickness and/or distribution of material within the object. This technique is often used in the area of quality control. For example, artillery shells coming off a production line have been irradiated with 662-keV γ rays from a ^{137}Cs source. By measuring the number of scattered γ rays and by comparing the result to that obtained from a standard, one can reject shells that contain voids or other imperfections. This method offers several advantages over more conventional schemes in that it is nondestructive and can be done very quickly.

4. CONCLUSIONS

The conversion of the energy deposited by radiation into light is the basis of the scintillation detector. Many different types of scintillators have been developed to meet a variety of needs in the field of radiation detection. Today scintillation detectors are used extensively in physics, chemistry, medicine, astrophysics, and in a number of industrial applications. With the ongoing development of new and improved scintillating materials, scintillation detectors will continue to play major roles in these fields for the foreseeable future.

22.1
Introduction

Radiation, light quanta, as well as energetic particles interact with semiconductor materials by liberating free charge carriers, negative electrons, as well as positive holes. In very pure silicon or germanium crystals, such charge carriers can move with a high mobility and a lifetime of milliseconds. They can move in an electrical field over distances of several millimeters on a nanosecond timescale, and induce electrical signals in the external contacts. Miniaturized electronic circuits then perform the charge signal processing; in this way, it has become possible to study various properties of the incoming radiation.

In the early years, 1950–1970, semiconductor detectors were primarily used as a ‘‘solid-state’’ ionization chamber. They offer the advantages of enhanced stopping power and compactness, compared with magnetic spectrometers or improved precision in the energy measurement compared with other solid-state detectors such as sodium iodide scintillating crystals. This chapter describes the development of semiconductor detector systems starting from about 1980, after a number of fundamental improvements were introduced in detector manufacturing and in systems architecture (Heijne, 2008). In particular, mastering of custom design of analog and mixed-mode integrated signal processing chips in commercial CMOS (Complementary Metal Oxide Semiconductor) technologies proved to be an essential boundary condition for the introduction of large-scale arrays. The properties of the semiconductor materials and the device technology are sufficiently complicated to justify an intensive effort in R&D, with thousands of technically oriented articles already dedicated to the study of these detectors. In exploiting these devices, a multitude of scientific and practical results have been obtained, often linked in a unique way to the innovation in these instruments.

The new applications of semiconductor detectors can be characterized as particle or photon radiation imaging. The detectors now consist of a regular structure of segmented sensor cells, usually diodes, each connected to a dedicated amplifier on an electronics readout chip. The amplifier circuit is matched to the characteristics of the sensor element. The measured positions of the radiation quanta are combined into a 2D or a 3D reconstruction of some object, process, or interaction of elementary particles. These imaging detectors use parallel processing of the signals from simultaneously incident ionizing particles, sometimes even at rates in excess of $10^{10}\,\mathrm{cm}^{-2}\,\mathrm{s}^{-1}$. Besides the hybrid detector

(a) (b)

Fig. 22.1 (a) People are shown assembling the Atlas silicon tracking detector SCT in a clean room at CERN. This detector system consists of a central barrel with several cylindrical layers and perpendicular forward discs on both sides. Fully assembled, it has been placed in the center of the Atlas experiment at the Large Hadron Collider (LHC). The evacuated beam pipe passes along the axis of the cilinder. The energetic proton beams collide around the midpoint of the barrel. Along this longitudinal axis the interactions take place, and particles originating from the vertex point fly in all directions. These will generally cross several planes of sensors and allow at least five space points to be determined. More details are discussed in Section 22.4. (Photo CERN.) (b) Part of a sector of the Atlas forward silicon detector. This module has been assembled at the NIKHEF particle physics laboratory, in Amsterdam, using boards tested in several labs around the world, and equipped with Si detectors that were manufactured by industrial suppliers, readout chips custom designed in a radhard, 0.25 µm CMOS technology, and components for powering, alignment and cooling. (Photo NIKHEF.)

systems, in which the sensors and the readout electronics are still distinct components, monolithic detectors in which all functions are integrated in the same piece of silicon are also being developed. In the hybrid approach, one can optimize functions in the separate parts, at the cost of complexity in interconnections, whereas the advantages of full integration come with loss of flexibility in the electronics design and manufacturing. However, the fully integrated devices profit from the rapid advances in silicon imagers for consumer applications.

In outer space and in elementary particle physics experiments, several large arrays have been constructed with a silicon sensitive area from approximately a few meters squared to over 200 m^2, consisting of thousands of modules with fairly large Si sensor chips and Si CMOS electronic readout chips. Such a large system is illustrated in Figure 22.1(a); Figure 22.1(b) provides a close-up of a detector module.

The turning point in elementary particle physics for abandoning photographic methods in favor of fully electronic experiments was around 1985. The ultimate, very large bubble chambers have been decommissioned and replaced by instruments that feature combinations of silicon vertex tracking detectors, gas-filled time-projection chambers, and heavy calorimeters that measure total particle energy. Large improvements in rate capability and in spatial precision have been achieved with this new equipment. A major driving force for the development and building of the large silicon detector arrays has been the need for improved precision in track reconstruction in physics experiments and the identification of short-lived charm and beauty particles. Applications in particle physics are discussed in some detail in Section 22.4.

A few other applications are mentioned in Section 22.5, such as space-based research and materials analysis with synchrotron light sources. Section 22.2 describes basic aspects of the semiconductor devices and technology and sensor designs are enumerated in Section 22.3.

The textbook *Semiconductor Detectors* by Bertolini and Coche (1968) describes principles and the developments until about 1965. A general, comprehensive book on detectors is *Radiation Detection and Measurement* by Knoll (2000). Recent books on silicon detectors have been written by Lutz (1999) and by Spieler (2005).

22.2
Basics of Silicon Detectors

The physics of semiconductor devices is described, for example, in the famous textbooks of Grove (1967) or Sze *et al.* (2007). Device properties are created by local modifications of electrical charge carrier concentrations at micrometer and recently even at nanometer scale, in an initially homogeneous piece of semiconductor. The extreme purity achieved in manufacturing silicon crystals, which can be less than one electrically active impurity atom on 10^{14}, has allowed reliable and reproducible silicon devices to be used for countless applications.

22.2.1
Device Structure

The p–n junction diode, treated by Sze (1981) in Chapter 3 of his book (Chapter 2 in the third edition by Sze and Ng, 2007), is the basic building block for a silicon detector. A schematic drawing is shown in Figure 22.2. The rectifying property of the diode is needed to limit the current in the sensing element, which at room temperature would flow when an electrical field is applied between ohmic contacts on Si. For many years, the metal-semiconductor Schottky diode gave the best achievable detector performance, but the recent imaging

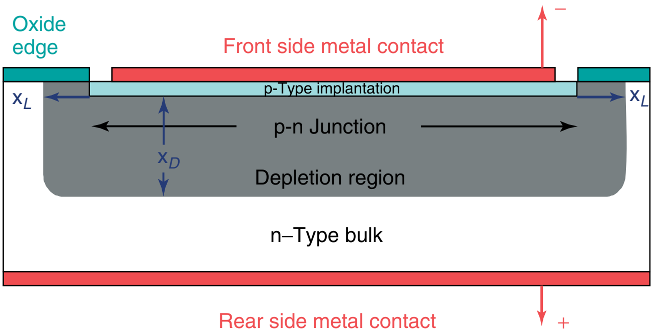

Fig. 22.2 Schematic drawing of a silicon p–n junction diode. The rectifying p–n junction can be obtained by controlled introduction of a p-type impurity such as ion implantation of boron into the bulk n-type silicon. The p–n diode junction area is defined by the opening that is etched in the surface oxide layer. The metal contacts usually are made with aluminum. The diode is reverse biased by applying a potential between the + and − contacts. For high resistivity n-type silicon, this is usually a voltage between 20 and 500 V. A depletion region extends a distance x_D into the n-type bulk as well as some lateral distance x_L under the surrounding oxide edge.

detector systems employ semiconductor–semiconductor p–n junctions obtained by local implantation of doping ions with a keV beam. In both approaches, a depletion layer is formed in which practically no mobile charge carriers exist, so that no current flows unless charges are created by incoming radiation. The concentration of free charge carriers in a semiconductor depends on the bandgap, the temperature, doping with impurity atoms, and crystal defects. A rectifying junction is not needed for semiconductor materials with a large bandgap, such as diamond, as long as the contacts are noninjecting.

Some unusual aspects of the diode structure for semiconductor nuclear particle detectors have to be briefly mentioned here. First of all, whereas most other devices use a surface layer of a few micrometers at most, a *thick sensitive volume* is needed for many of the detector applications and, ideally, the full wafer thickness of several hundred micrometers is exploited. The reasons for doing so may be to slow down and stop the incoming ionizing particle so that its total energy can be determined; a high efficiency may be needed for conversion of X-ray or γ-ray photons; for traversing, swift particles a sufficiently large signal charge is needed in comparison with noise fluctuations. For traversing particles, the signal is proportional to the energy deposition along the path length in the sensitive thickness of the device. Characteristics for energy loss are described later in this section. A second, related aspect is that the *rear-side contact* of the thick device wafer needs special attention, contrary to the usual situation for electronics chips, where the wafer acts simply as a mechanical support and grounded shield. For optimal functioning, only a *small reverse current* in the reverse-biased diode can be tolerated, to detect the randomly arriving, nonrepetitive signal charge above the noise background. The undesirable reverse diode current is increased by crystal or surface impurities that act as generation-recombination centers for free carriers, by injection from contacts, and by ambient factors such as temperature or light. Under optimal conditions, the generation current I_G is the main component, proportional to the sensitive volume: thickness w times area A, and is determined by the intrinsic equilibrium carrier concentration n_i and inversely proportional to the minority carrier lifetime τ:

$$I_{\mathrm{G}} = \left(\frac{n_i}{2\tau}\right) qwA \tag{1}$$

The electron unit charge is q ($q = 1.602 \times 10^{-19}$ C). In pure Si, $n_i = 10^{10}\,\mathrm{cm}^{-3}$ and with the years, the measured values tend to become a little lower as better silicon purity is achieved. By introducing n-type or p-type doping impurity atoms, one can increase the majority carrier concentration n or p over a large range, even close to $10^{20}\,\mathrm{cm}^{-3}$. The product of n and p remains a constant, equal to the value of n_i at the given temperature. The value of the intrinsic carrier concentration is a function of the semiconductor bandgap E_g, the absolute temperature T, and the effective densities of state in the valence band N_V and the conduction band N_C (see Table 22.1).

$$n_i{}^2 = np = N_C N_V \exp\left(\frac{-E_g}{kT}\right) \tag{2}$$

The bandgap E_g in silicon is 1.12 eV at room temperature. When the temperature is increased, the concentrations of electrons n and of holes p increase both and eventually become equal, at which temperature the material is again intrinsic and highly conductive. As the total number of charge carriers in a piece of semiconductor is

$n + p$, the minimum number of carriers is obtained when n and p are nearly equal, resulting in a low conductivity σ or reciprocally a high resistivity ρ. The resistivity (unit ohm centimeter – Ωcm) is also a function of the respective carrier mobilities μ_e and μ_h (unit centimeters squared per volt second – $\text{cm}^2\ \text{V}^{-1}\ \text{s}^{-1}$)

$$\rho = \frac{1}{\sigma} = \frac{1}{q(\mu_e n + \mu_h p)} \tag{3}$$

and for detectors, the values used are often in excess of 1 kΩcm, corresponding to $10^{11}\ \text{cm}^{-3}$ electrons in n-type Si. With such a low carrier concentration one can achieve low reverse current, and also obtain a thick depletion region x_D as shown in Figure 22.2. When the diode is heavily doped at the rectifying contact, the extension of the depletion layer is toward the lowly doped side of the diode, because of the equilibrium between the amounts of charge at either side of the p–n junction, as described by the Poisson equation (see Sze *et al.*, 2007). For a p^+n junction[1] one obtains

$$\begin{aligned} x_D &= \sqrt{\frac{2\varepsilon}{qn}(V_0 + V_B)} \\ &= \sqrt{2\varepsilon\mu_e\rho(V_0 + V_B)} \end{aligned} \tag{4}$$

where ε is the permittivity (for Si $1.054\ 10^{-12}\ \text{F cm}^{-1}$), V_B is the externally applied diode reverse bias voltage, and V_0 is the built-in voltage of the unbiased junction. A typically applied voltage is in the range 20–500 V, which can achieve several 100 μm of depletion layer thickness in kilo ohm centimeters Si. An essential feature is the *lateral extension* x_L of the depletion region under the surface oxide. The distance x_L might be equal to x_D, but can also be different, depending on the fixed charge that is present at the interface or in the oxide itself. As discussed later, the lateral extension allows the complete volume to be depleted in detectors with segmented diode contacts.

Such a diode detector presents, proportional to the surface area A of the device, a lower electrical capacitance C_D, the thicker the depletion region x_D.

$$C_D = \frac{\varepsilon A}{x_D} = A\sqrt{\frac{\varepsilon}{2\mu_e\rho(V_0 + V_B)}} \tag{5}$$

The capacitance of a detector is an important factor in the noise performance for small signals, which is discussed in Section 22.3.

A different situation arises in transistors in deep submicron CMOS technology, where the miniaturization implies very shallow junctions. These require a concentration approaching $10^{20}\ \text{cm}^{-3}$, which brings a large capacitance per unit of area. Yet, because of the nanovolume of such devices, the actual values in a device remain small and only ~1000 unit charges q may determine the function of a transistor. Fluctuations on such small numbers cause a significant spread in characteristics from one device to another. In heavily doped Si, the conductivity is not far from that caused by the $\sim 10^{23}$ free electrons cm^{-3} in metallic materials. The minority carrier concentration then becomes lower than 10 to $100\ \text{cm}^{-3}$ because under steady-state conditions the product *np* remains constant as mentioned above. In fact, this can be used to prevent minority carrier injection from an ohmic metal contact by creating such a heavily doped semiconductor layer between the metal and the lowly doped bulk part of the device.

---

[1] Adding + to the carrier concentration indicates which is the more highly doped side, it does not indicate the sign of the carriers.

Table 22.1 provides values for a number of properties of pure crystalline silicon. Some of these have a determining impact on detector characteristics, as mentioned in the text.

22.2.2
Detector Segmentation and Edges

An array of adjacent diodes, each with a separate contact, on a single piece of high-resistivity silicon presents several interesting features for use in physics experiments or radiation imaging applications. The positions of several simultaneously incident particles can be determined simply with reference to the positions of the responding cells in the array. The segmentation, moreover, leads to miniaturization of the elements, and this reduces their capacitance and noise, and also their leakage currents, even if the current per centimeter squared is high. With the use of high resistivity and a reverse bias voltage that achieves full depletion of the wafer thickness, one can avoid insensitive regions in the silicon volume, between the segments, except around the outer edges of the sensor chip. Currently, special techniques are being developed to increase the sensitive volume even quite close to the edges. This is important for elimination of dead areas in applications with multisensor arrays and when detection is needed of interaction products in proximity to a high-intensity beam, which itself should not pass through the detector.

By around 1960, the first segmented surface barrier silicon detectors had been made. However, the more recent development of custom-integrated circuits for signal processing and readout was needed to allow a large-scale use of such devices. It should be obvious that the characteristics and possibilities of the signal-processing chips basically determine the possibilities for different geometries and properties of the sensor matrix. The segments have to be connected to the signal amplifiers and further information processing circuits. Most often the rectifying side of the sensor is segmented, because the electrical field there is the strongest, but it is also possible to segment the side with the ohmic contact, when some precautions are taken. Finally, ‘‘double-sided’’ detectors can be made, in which both sides are segmented.

The sensor-manufacturing process imposes boundary conditions, such as needs for edge protection, maximum wafer size, and minimum achievable dark current. Also the irradiation of the sensors imposes requirements for the sensor architecture. Various designs of segmented sensors and the associated readout circuits are described and illustrated in Sections 22.3 and 22.4.

Segmentation of silicon detectors relies to a large extent on the unique properties of the silicon dioxide surface layer, which is created during very clean oxidation of a silicon wafer. Understanding the physics of the metal-oxide-semiconductor (MOS) system is useful for the design of segmented devices. The interface between the oxide and the silicon acts as one plate of the capacitor structure, and on the other side is a metal or polysilicon plate on top of the oxide layer. The classical book *MOS Physics and Technology* by Nicollian and Brews (1982) treats this in detail. The schematic, simplified drawing (Figure 22.3) for the case of n-type Si shows the accumulation, flat-band, depletion, and inversion states, depending on the external voltage applied to the top capacitor plate. When the swing of the external voltage is applied in a pulsed mode, the behavior depends on the pulse frequency, and above a megahertz the buildup of the inversion

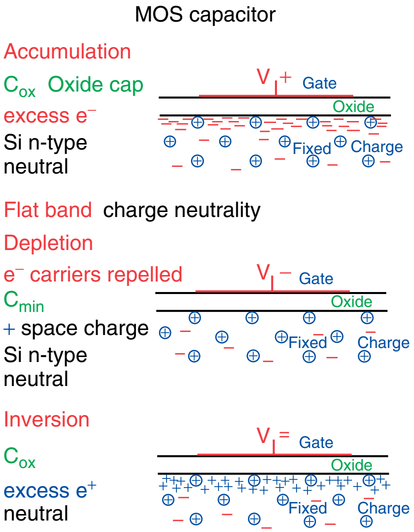

Fig. 22.3 Schematic drawing of the MOS capacitor structure on n-type Si with capacitance C_{ox}. in four different biasing conditions. From top to bottom are sketched the charge and carrier distributions at the oxide–silicon interface layer, for accumulation, flat band (no sketch), depletion, and inversion. Fixed unit charges are encircled, the mobile charges are not. The capacitor plate "gate" on top of the oxide can be a doped, conducting polysilicon or an aluminum metallic contact. The bulk volume, far from the interface, is electrically neutral n-type Si, with mobile carriers (electrons) compensating the positive fixed charges.

state cannot be achieved if the cycle time is shorter than the thermal generation time constant for the minority carriers that have to populate this inversion layer. Then the depletion state with a low capacitance value is maintained throughout the cycle.

The usual acceptor-type surface defects at the interface between the oxide and the silicon attract negative charges, which always provoke a thin depletion layer in the n-type Si. Therefore, an oxide on n-type Si naturally leads to a surface region with high resistance, while on p-type Si it provokes an accumulation layer that can conduct current between segments. To avoid such short-circuiting channels between diodes in p-type Si, special treatments or layouts must be introduced.

In the surface barrier technology, the separation between evaporated metallic gold or aluminum contacts depends on the quality of the native oxide layer of only some 3–4 nm, which is formed as soon as an Si surface is exposed to air. It was found that better stability can be obtained by oxidation in boiling water. The resistance of such a native oxide can be in mega ohms for 0.1 mm. Much better controlled and higher resistance, giga ohms instead of mega ohms, is achieved with modern oxidation technology.

In most segmentation schemes, the electrodes on one plane are all connected to the same potential, provided via the input contacts at the readout chip, so that there is no lateral electrical field between the contacts in the matrix. All field lines then end in a regularly distributed way on the segmented diode contacts.

22.2.3
Energy Deposition and Signal Generation in Silicon Detectors

Swift ionizing particles lose energy while traversing material. Various mechanisms are at work and an introductory description can be found for example, in *'Passage of particles through matter'* by Bichsel, Groom and Klein (2006). At low momentum, the energy loss in Si is some kilo electronvolts per micrometer, and when the momentum of the particle is much higher, ~0.5 GeV/c, the mean specific energy loss goes to a

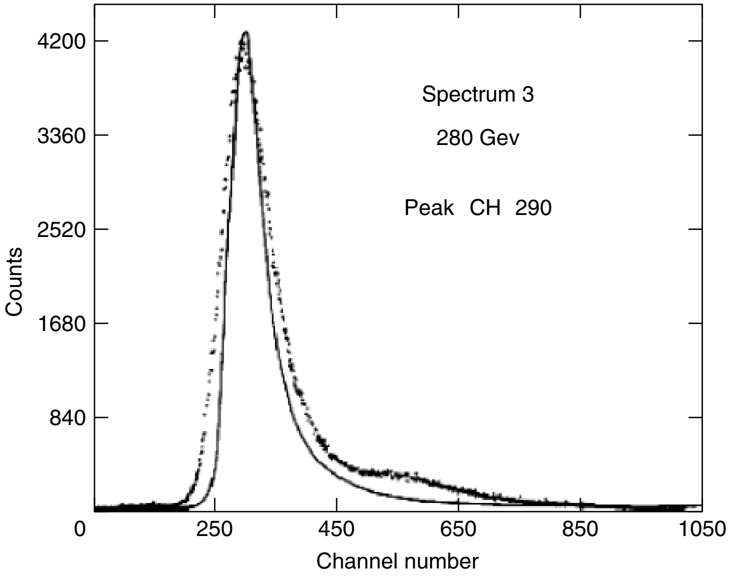

Fig. 22.4 Measured and calculated Landau energy loss distribution for 280 GeV muons traversing a 300 μm thick Si detector in air, from Heijne (1983). The most probable energy deposit is at the peak in channel 290, to which the calculation is normalized. One observes some accompanying secondary particles that give rise to an increased energy deposit probabilty at exactly twice the Landau peak.

minimum of 0.38 keV μm^{-1}. From that momentum range onward the particles are known as *minimum ionizing particles* (m.i.p. or mips). One has to distinguish the energy loss of the particle itself and the energy that is deposited in the absorbing medium. Some of the lost energy escapes from the medium in the form of energetic secondary radiation. Also, the actual energy deposit in a thin silicon layer varies for each particle and statistically it follows the so-called Landau energy distribution, shown in Figure 22.4. In practice, one must consider the "most probable energy deposition" for a particle that corresponds to the value at the peak of the Landau energy loss distribution. Occasionally, large fluctuations may occur, which are caused by close encounters with atomic electrons. Such electrons may receive a large energy transfer, and escape from the sensor volume as "δ-ray" electrons. The specific energy deposited in a thin silicon layer decreases with the layer thickness as shown in Figure 22.5. While for a thick silicon layer of several millimeters the peak of the distribution amounts to 0.36k eV μm^{-1}, the value becomes as low as 0.23 keV μm^{-1} for a layer of $\sim$50 μm thick. The actual value of the energy deposition also depends on the immediate surrounding of the sensitive sensor material.

In a semiconductor, on average about one-third of the deposited energy is spent on excitation of electrons out from the valence band into the conduction band, where carriers can move through the crystal. The remaining positive hole also becomes a mobile charge carrier. The average energy loss per generated e–h

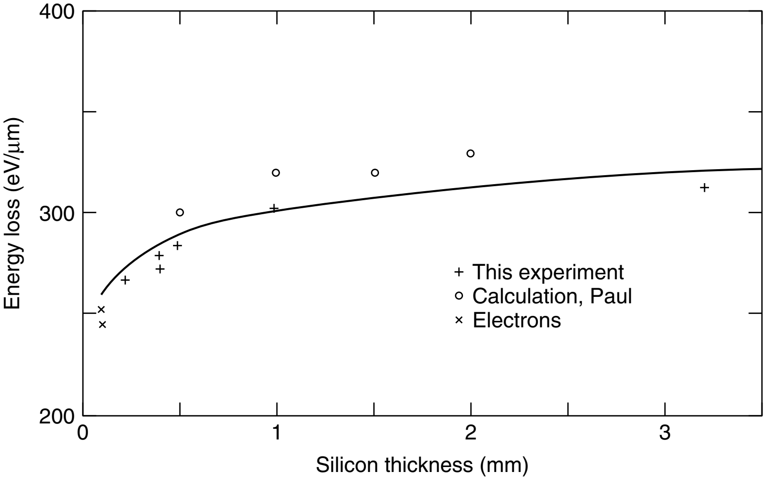

Fig. 22.5 Most probable energy deposition in silicon detectors of different thickness from 0.1 to 3.5 mm, that is, the values in electronvolts per micrometer for the peak of the Landau distributions. The curve is calculated for 200 GeV muons. The + are measured muon data, determined as shown in Figure 22.4, the × are electron data and the o are earlier calculations by Paul. Detailed explanations can be found in Bichsel, Groom and Klein (2006), and Heijne (1983).

pair is 3.62 eV. Of this, only 1.12 eV corresponds to the bandgap energy in Si, and the energy difference is dissipated as phonons and eventually as heat. In a detector of 300 μm thickness, an mip that traverses perpendicularly loses ~80 keV and generates ~22 000 electron–hole pairs. These free electrons (as well as the holes) move under the influence of an electrical field E, with a typical drift speed v, and a mobility μ_e depending on the temperature T:

$$v = \mu_e(T)E \tag{6}$$

The holes that are left in the valence band are mobile as well with mobility $\mu_h(T)$. Values for the mobilities in high purity Si have been measured by Jacoboni *et al.* (1977) and are 1500 V cm^{-2} s^{-1} for e$^-$ and 600 for h$^+$ at room temperature. There is a strong temperature dependence of the carrier mobilities in Si so that the transit time around room temperature varies ~1% for a 0.1° C temperature variation. The mobilities in Si increase with decreasing temperature and reach quite a high value at liquid N_2 temperature ~77 K. Also the thermal conductivity is an inverse function of temperature, and at 77 K, Si conducts actually better than Cu, although it cannot compete in thermal conductivity with diamond or modern diamond-like carbon materials.

The moving charge carriers represent a signal current in the diode and image charges are induced on the diode contacts during the movement as described by Ramo's theorem. The situation for a multielectrode geometry with arbitrary potentials was described by Gatti, Padovini, and Radeka (1982). The actual measured signal may be reduced by "ballistic deficit" if the integration time of the amplifier is shorter than the duration of the signal current, given by the charge transit time in the detector. In practice, for the usual Si detector thickness of 300 μm the hole transit time is <20 nanoseconds for typical bias voltages, and full charge integration can be achieved. In this situation, the integral on nearby electrodes is zero, because the initially induced charge is compensated when the moving carriers reach the collecting electrode(s).

22.2.4
Manufacturing of Semiconductor Detectors

Most of the large radiation imaging detectors currently in use have been made with relatively cheap, commercially manufactured, standard polished, thin silicon semiconductor wafers, sliced from industrial single-crystal ingots. Because of the immense effort in research and development of crystal manufacturing, the silicon industry has achieved extreme electrical and chemical purity and crystal homogeneity, even for a diameter of 300 mm. In some specific applications, different semiconductor materials may present advantages. However, with the exception of hyperpure germanium crystals, all other semiconductor materials have not yet been obtained with similar purity. Also, compound semiconductors such as CdTe often are not monocrystalline, but present a mosaic of subcrystals with different orientations.

The Si crystals are grown in ever-increasing dimensions, over 100-cm long and up to 45 cm diameter, most often along <100> direction, although high resistivity, >kΩcm, is traditionally grown along <111>. High-resistivity n-type or p-type wafers are sliced from float-zone purified crystals and they are available in diameters 2 or 3 in. and 100 mm, 125, 150 mm. The uniformity of resistivity is better in neutron-transmutation-doped (NTD), n-type silicon than in float-zone n-type silicon wafers, where circular striations of approximately millimeter periodicity are observed with tens of percents of resistivity variation. For recent, deep submicron CMOS processing with 90-, 65-, or 45-nm feature size one uses now mostly 300-mm diameter wafers, with resistivity approximately in ohm centimeters. The progress in silicon material is described in the series of four-yearly conference proceedings *'Semiconductor Silicon 19xx'*, ed. R. Huff *et al.* (Huff, Kriegler and Takeishi, 1981).

Standardization in materials and in processing equipment for the CMOS industry has led to much improved device quality and it has lowered production cost. Recent device-manufacturing technologies and parameters are treated in *Silicon VLSI Technology* by Plummer, Deal and Griffin (2000). This industrial development also has facilitated the manufacturing of silicon particle detectors, which started in 1980 with the introduction of "planar" processing by Kemmer (1980) and P. Burger as described in Heijne (2008).

In comparison with advanced CMOS technology, the processing of silicon particle detectors is relatively straightforward. However, special precautions have to be taken because of the unusual materials aspects such as the high resistivity and the need for a long minority carrier lifetime in the bulk silicon. Also the applied reverse bias to the diodes, of several hundred volts, impose a special approach, but which can be similar to that for power devices, as described in *Semiconductor Power Devices* by Ghandhi (1977) and Baliga (1996). The main breakthrough by Kemmer was the introduction of improved cleanliness during the first passivating oxidation step at ~1200 °C. This became possible by advances in MOS technology, but which had not yet been transferred to the detector-manufacturing environment. However, additional long exposures to high temperature, for example, the usual

1100 °C anneal step, still have to be avoided as these generally lead to the introduction and diffusion into the bulk volume of metallic impurity defects, which shorten the minority carrier lifetime and lead to an increase of dark reverse bias current.

Kemmer described schematically the basic manufacturing steps for silicon detectors, as shown in Figure 22.6. Some critical details have not been included, such as the profiling of the diode edges and the parameters of the cleaning steps. Commercial manufacturers, understandably, have been reluctant to publish such manufacturing details.

After thorough cleaning of the silicon wafers, the first processing step is the growth of a passivating oxide layer that completely covers the surface. Oxidation takes place in a quartz tube in a high-temperature furnace. The Si wafers are exposed to a homogeneous flow of oxygen or water vapor. At, for example, 1200 °C, a typical SiO$_2$ thickness of 25 nm is grown in 10 minutes. Often, HCl or, preferably, a Cl-containing compound is added in the gas flow, such as trichloroethylene, to prevent diffusion of metal atoms from the outside heating coils through the hot quartz tube into the Si wafers.

The definition of the diode pattern on the wafer is obtained by illuminating a light-sensitive photoresist, which after development presents a barrier layer of polymer material on the nonilluminated places and open windows where the light came through the mask (positive resist). The creation of diodes needs the implantation of doping atoms with an ion-implantation machine, which is, in fact, an ion accelerator with a high current beam that is swept over the wafer area. By chosing a low ion energy, for example, 15 keV, the penetration of the ions is only some tens of nanometers and a thin implanted thickness with high concentration of doping atoms is obtained. To be electrically active, the implanted ions have to be located on lattice positions and for this rearrangement, one needs an activation anneal at elevated temperature, usually above 1000 °C. Care has to be taken that during this step, the radiation damage from the implantation is repaired, and also that no diffusion of undesirable atoms such as Na or Fe takes place. Sometimes, special ''gettering'' structures are provided between the devices or on the back side of the wafer, which can catch such undesirable atoms.

After processing, the individual sensors on the wafer have to be separated. Traditionally, this is done with a wafer-saw that cuts an approximately 60-μm kerf in the ''dicing street'' between the chips. Recently, singulation has also been done with laser cutting or with plasma ion etching. These methods promise to bring less crystal damage along the edge of the cut, so that the insensitive edge width can be reduced.

The precision assembly of the sensors and the electrical, mechanical, and thermal contacts require careful design and construction. The position-sensitive devices aim at measurements with 2–10 μm accuracy. Manipulation and assembly are executed under dust-free conditions and at controlled temperature, in medium-quality clean rooms, as was already illustrated in Figure 22.1.

22.2.5
Degradation of Detectors

During operation, detectors may degrade for various reasons, such as a prolongated heat load that causes metal diffusion into the pure Si material, or humidity that short-circuits isolation layers in critical places of the device. Besides such accidental degradation, the changes induced by particles incident on the sensor material are a fundamental and unavoidable degradation mechanism. Radiation quanta generate free electrons by ionization of the semiconductor material, but at the same time a fraction of the energy deposition leads to dislocations of atoms from their original crystal lattice positions. The ejected atom is mobile as an interstitial; also, the created lattice vacancy can move around for a while, until it combines into a stable defect. The movement of atoms, vacancies, and complex defects is strongly dependent on the temperature and the concentrations of impurity atoms. Whereas in hyperpure Si, the concentration of electrically active impurities initially can be as low as $10^{12}\,\mathrm{cm}^{-3}$, there are usually chemical impurities such as C or O at a concentration of order $10^{15}\,\mathrm{cm}^{-3}$ and these play an important role in the stabilization of the radiation-induced defects. Many studies have been devoted to radiation effects in semiconductors, and Si, in particular (see Series of Conferences on *Defects in Semiconductors* (Oshiyama *et al.*, 2005)). The effects of radiation damage in high-resistivity Si did not receive a lot of attention until recent decades. Some defects that at first are stable at a certain temperature may gradually convert into a different type of defect complex, for example by combining with a diffused oxygen atom. Such a process, called *annealing*, is usually thermally activated, and often leads to reduction of the reverse bias current. When, on the contrary, the new defects lead to a continuing increase of dark current, it is referred to as *reverse annealing*.

Unfortunately, the defect complexes in Si that result from the irradiations, such as vacancy–vacancy, oxygen–vacancy, phosporus–vacancy, and so on, present a variety of electrically active energy levels in the semiconductor bandgap. Because the functioning of semiconductor detectors depends on a small concentration of electrical charges, typically $<10^{13}\,\mathrm{cm}^{-3}$, these devices are quite sensitive to changes in surface charge and to radiation-induced defects. It is found that active defects are introduced at a rate of $\sim 0.1\,\mathrm{cm}^{-3}$, per incident particle per centimeter squared. Therefore, it is not surprising that a fluence (integrated flux) of $\sim 10^{13}\,\mathrm{cm}^2$ particles leads to significant changes in the operation characteristics of a Si detector. It is found that many radiation-induced defects exhibit acceptor-type behavior, and compensate the donor characteristics of the traditional, n-type starting material for Si detectors. It was also found that an operating temperature well below $-10\,^\circ\mathrm{C}$ can prevent formation of the most agressive type of defect, which is believed to be a carbon-related complex. An excess of O in the starting Si seems also to lower the introduction rate of this agressive defect. Watts (1997) gave an overview of work on defects in the particle physics community.

Recently, studies have started on the use of silicon crystals that have been grown in a different way, such as epitaxially grown layers, or p-type instead of n-type material. The first results show that different types of stable defects are being obtained due to different background conditions, and that in some cases operation at $+15\,^\circ\mathrm{C}$ would be preferable above cold operation, owing to beneficial annealing.

22.3
Various Sensor Designs and the Associated Readout Electronics

The architecture of the readout electronics really determines the different sensor designs. Initially, a single amplifier with discrete components was used for each detecting unit. For position-sensitive devices it was possible to limit the number of readout channels to two, or to a maximum of four, by incorporating sophisticated, resistive charge division in the sensor construction, as reviewed by Laegsgaard (1979). In many nuclear physics measurements, such detectors with charge division are adequate, but they cannot handle a situation in which several particles are incident at the same moment, at different positions. Yet, already in 1970, it was possible to exploit detectors with tens to hundreds of segments using voluminous electronics, as in the BoL project in Amsterdam (Koerts *et al.*, 1971).

Using custom-designed integrated circuits, with 64, 128, 256 or even tens of thousands of amplifiers per chip, it has become much easier to apply parallel signal processing for a multitude of microscopic sensor elements. This alternative approach opened up applications in multiparticle experiments in particle physics, light detection, and space, with thousands of cells per sensor. Although there are no formal standards, one may distinguish sensor layouts following a classification of the cell dimensions, as shown in Table 22.2, with 1 mm as the distinguishing criterion for the naming convention.

A basic distinction exists between a hybrid detector system and a monolithic

Tab. 22.2 Segmented silicon detectors – naming convention based on cell dimensions.

Detector type	Coordinate	Long edge	Short edge	Associated chip
Pad detector	2D	≥1 mm	≥1 mm	16–64 channels
Microstrip detector	1D	≥1 mm	<1 mm	128 channels
Hybrid Pixel detector	2D	<1 mm	<1 mm	2048–65 536 channels
Monolithic pixel chip	2D	≤30 μm	≤30 μm	≥250 000 cells

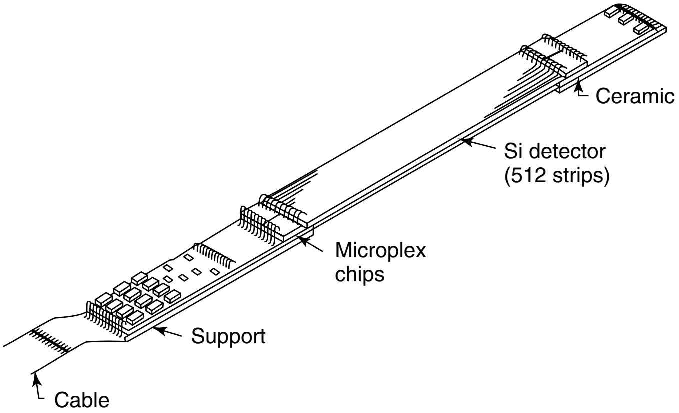

Fig. 22.7 Sketch of one of the first ladder assembly designs for a silicon detector module. This was made around 1987 for the silicon tracker in the MARKII experiment at SLAC. The module contains a single silicon microstrip detector with 512 strips. On both sides of the sensor, alternate strips are connected by wire bonding to the inputs on the two 128-channel Microplex readout chips, which are glued on a ceramic support that also carries the supply and filtering components, and the connector for the cable to the off-detector electronics. Reproduced from LaBarga *et al.* (1991).

detector system.[2] The first three rows in Table 22.2 refer to hybrid detector assemblies in which the sensor cells, manufactured on a separate silicon chip, are each separately connected to the first stages of the amplifier chains, located on another chip. A typical assembly is illustrated in Figure 22.7, which represents a so-called ladder, a module for a detector array in the form of a barrel. Pioneering work on module assembly and readout chip development was undertaken in a collaboration at SLAC, during the mid-1980s (LaBarga *et al.*, 1991).

22.3.1
Custom Design of Chips

Segmented silicon sensors such as microstrip detectors or hybrid pixel detectors need a large number of parallel amplifiers, and parallel-to-serial conversion of the signals in the chip circuit, so as to allow more economical sequential readout by the data acquisition system. At Stanford, Hyams, Parker, and Walker initiated the design of an NMOS chip, called *Microplex* (Walker *et al.*, 1984), which, with 128 amplifiers, was the first integrated design for silicon microstrip detector readout. Their design used a switched capacitor feedback amplifier and this evolved later, thanks to Kleinfelder *et al.* (1988) and Spieler (1994) and coworkers at the Lawrence Berkeley Laboratory, into a family of CMOS chips. These are used even now at Fermilab in the CDF and D0 Tevatron collider experiments. In Germany, a team at the Werner Heisenberg Laboratory, Max Planck Gesellschaft, Munich and the Microelectronics Institute in Duisburg, with Lutz and Buttler, together with Manfredi *et al.* at the University of Pavia, developed a 128-channel CMOS circuit with JFET front-end transistors (Lutz *et al.*, 1988). Later this chip was called *CAMEX* and was used in the electron collider experiment Aleph at CERN, from 1989 to 2001.

---

[2] Monolithic designates the situation that all elements are built on a single "stone" of silicon. A segmented sensor is also monolithic, but here we mean that the sensor as well as the amplifiers and other readout electronics are built on one chip.

An additional feature necessary with high-rate interactions in particle physics experiments is an on-chip temporary data-storage memory, from which selected data that belong to a precise timeframe with a positive trigger can be retrieved later. For the Large Hadron Collider (LHC) experiments, these memories usually operate at 40-MHz frequency and provide storage for the signal charge quantity that is measured every 25 nanoseconds in each of the sensor elements. The memory typically has a depth of 180 cells, which allows all data to be kept until ∼4 microseconds later a first level trigger has determined the data set that may be of interest.

Many of the front-end circuits use an amplifier with switching feedback and double-correlated sampling. A different line of devices, such as the 16-channel *AMPLEX* chip, was initiated by Jarron, as reported by Beuville *et al.* (1990). This family uses the more classical continuous feedback, which can be implemented in different ways. For example, in the first *AMPLEX* a long transistor is used as the feedback element, as shown in Figure 22.8 (Heijne and Jarron, 1988). This approach allows direct connection between sensor and amplifier input, with compensation of the effects of the sensor leakage current. A current up to 450 nA per segment can thus be compensated. The sensor dark current at the input modulates the effective resistance of the feedback so that the operational level

at the output can be maintained at the cost of a slight reduction of amplification. The chip was produced in 1987 in the 3-um CMOS technology of MIETEC in Belgium.

A variety of readout chips with a linear array of amplifiers has been designed since about 1990 for use with silicon microstrip detectors. The pitch of the diode elements on the sensor is not always identical to the pitch of the amplifier input pads on the readout chip. For reliable wire-bonding connections, it would be best to make pitch adaptation on the border of the sensor, using metal pads on a thick oxide in combination with a separate depletion region to make the border independent of the sensitive cells. In some systems, pitch adapters on a separate substrate such as quartz have been introduced, but then the number of connections would need to be doubled.

22.3.2
Imaging Matrix with Linear or 2D Sensor Geometry

Microstrip detectors provide a 1D projection of the particle positions. For 2D position measurement, a second detector is needed, with the strips orthogonal, or at a different angle. When several particles are simultaneously incident on such a sensor sandwich, ambiguities arise and a third sensor plane with another strip orientation is needed to resolve these. The use of a double-sided microstrip detector reduces the number of planes, but does not resolve ambiguities.

A true 2D device with a matrix of sensitive cells makes it possible to assign unambiguous positions to individual particles, even if there are many coincident on the same device. The first experiment that practically adopted this approach at full scale was NA11. Damerell *et al.* (1986) adapted standard charge coupled devices (CCDs) for use with mips. They showed that with true 2D detectors one can obtain a clean pattern recognition. The fully serial readout of the CCD makes it quite a slow detector, and increased parallelism is required for high-rate experiments. The integrated nature and the small pixel capacitance of the CCD result in low electronic noise, and a thin sensitive layer of $\sim 20\,\mu m$ of silicon delivers a sufficiently large signal.

While in a CCD the signal charge is transported from pixel to pixel, in a clocked parallel–serial operation, all over the matrix toward a single output node, a different charge transport mechanism can be implemented by the use of potential gradients in a homogeneous silicon volume. In the early 1970s, this approach had already been adopted for light-sensitive devices. It has been introduced for position-sensitive particle detection by Gatti and Rehak (1984). A lateral drift potential is superimposed on the voltage that depletes the silicon bulk volume. Signal charges are drifted by the potential gradient as well-defined packets toward the readout nodes, which form a linear matrix along one or two borders of the silicon chip, as in a microstrip detector. A drawing of a practical drift detector for the Alice experiment is shown in Figure 22.9, reproduced from a description by Nouais *et al.* (2003).

While the drift detector geometry has a linear, one-dimensional matrix of readout pads similar to that of a microstrip detector, it presents true 2D information on particle impact positions. The second coordinate can be derived from the drift time, if the timing of the impact is measured independently, for example, from a common pulse pickup at the detector backside or from the known bunch crossing time in a collider experiment. An important advantage of the drift detector is the very low capacitance of

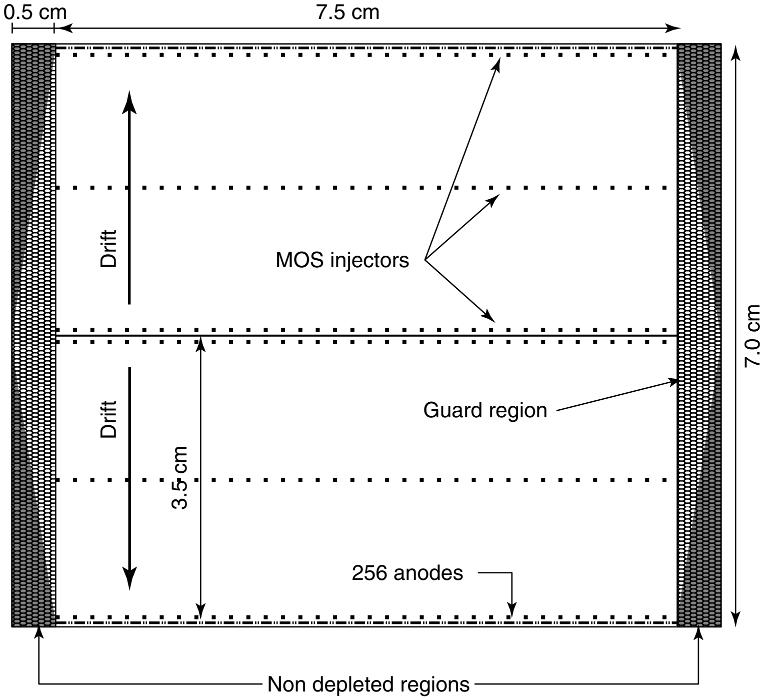

Fig. 22.9 Schematic drawing of a silicon drift detector for the Alice experiment (Nouais *et al.*, 2003), with 256 anode readout elements along the top and the bottom. The drift potential is vertical from the center, both to the top and to the bottom anodes. The drift potential is distributed along the sides, and a typical value is 2000 V over the 3.5-cm drift region. Several rows of MOS injection capacitors are indicated. These can be used to monitor the conditions for the drift velocity, which is strongly dependent on the silicon doping, radiation defects, and the ambient temperature.

the readout node, in comparison with a microstrip detector of similar dimensions. However, the sensitivity of the drift velocity on the uniformity of the devices and on the ambient temperature presents practical limitations that require continuous calibration procedures. Calibration is performed by charge injection via built-in capacitors.

For high-rate experiments, fully parallel hybrid pixel detectors have been developed, which consist of a silicon sensor chip and a matching chip with readout circuits, as illustrated in Figure 22.10. Each sensor cell is individually connected to a readout cell, using a microscopic solder connection, called *bump-bond*. The first such hybrid pixel detectors had ~1000 pixels of dimensions 75 μm × 500 μm, but the most recent one has a matrix of 256 × 256 pixels of 55 μm × 55 μm. Besides the need to register the positions of incident particles, one now aims also to incorporate a variety of additional functions in the pixel circuitry, such as local encoding of the timing and the signal amplitude. For example, a 100-MHz clock distribution has been implemented in the Timepix assembly (Llopart *et al.*, 2007). The schematic circuit diagram of the pixel electronics in this Timepix chip is reproduced in Figure 22.11. This drawing shows the complexity that can be achieved

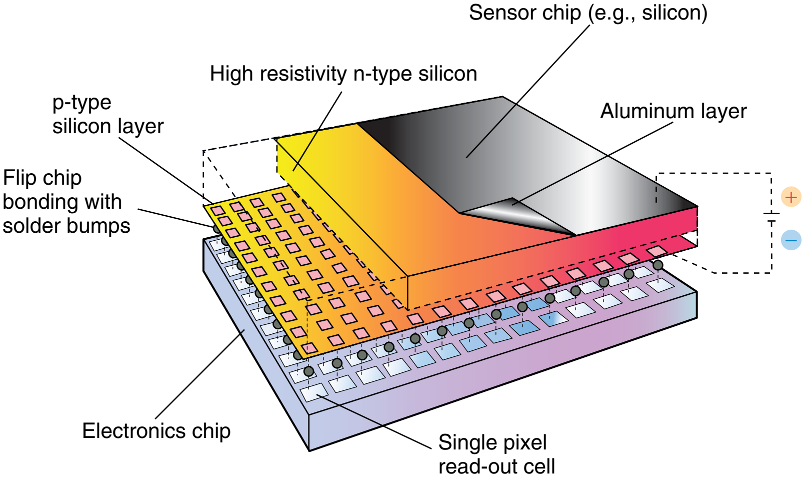

Fig. 22.10 Schematic drawing of a "flip-chip" hybrid silicon pixel detector showing a partially transparent sensor matrix chip and a matching CMOS electronics readout chip underneath. Solder bumps are indicated, which connect the individual sensor cells to the corresponding readout elements in a fully parallel fashion. The sensor is supposed to be a matrix of p–n junctions with a common ohmic rear-side contact covered with an aluminum metallization.

on a small, 55 μm × 55 μm area with recent submicron CMOS technologies.

22.3.3
Factors Affecting Signal/Noise

The signal amplitude in nuclear physics applications is mostly determined by the energy of the incoming particle, often several mega electron volts, provided that the particle comes to a complete stop inside the detector. In particle physics experiments, on the contrary, the ionizing particles generally traverse the silicon detector while undergoing only a fractional, small energy loss, typically of order 30 keV per 100 μm of Si thickness. The signal charge is practically independent of the particle energy, and only determined by the pathlength in the detector, and the thickness of the sensor chip. In order for such an mip particle to be detected with 100% efficiency, the noise of the signal-processing chain has to be sufficiently low. For readout electronics of particle detectors, the noise distribution is usually characterized by the standard deviation of the variance, expressed as the number of equivalent noise, given in units of electron charges (ENC) at the input of the chain, given in units of electron charges. For reliable discrimination of signals above a threshold from the noise distribution, it is desirable that the signal exceeds the noise baseline value by at least six standard deviations. For reliable detection of a swift particle in a segmented detector, one also has to take into account the signal charge division, when this is shared between adjacent segments.

The noise in the signal-processing chain has various sources, and optimization can be achieved in the sensor as well as in the front-end amplifier. The sensor capacitance, the signal shaping time, the power dissipation, and the dark current are prime objectives in the noise reduction. In the pixel detector, one can reduce

both capacitance and dark current for a single pixel, while the signal amplitude remains practically identical. Therefore, pixel detectors offer a very robust approach to detection with practically 100% efficiency for ionizing particles.

22.4
Typical Silicon Detector Arrays in a Particle Physics Experiment

During the recent decades, silicon detector arrays have become a standard feature of particle physics experiments, around fixed targets as well as in the collider experiments. Immediately after the first publications of test results in 1980, the first fixed target experiments to embrace this new technology were WA82 (in the Omega spectrometer), WA75 and NA11 at CERN, and the photoproduction experiment E691 at Fermilab. Around 1982, the CERN proton–antiproton collider experiments had not yet started using these devices, but in the final stage, 1986–1988, UA2 installed two layers of Si pad detectors to recognize leptons and to reject signals from photon conversions in the inner volume. These arrays had ∼1.1 m^2 area with 6000 sensing elements. The MARKII experiment at SLAC and the Fermilab collider experiments CDF and D0 then adopted, from the beginning, silicon microstrip detectors for their inner trackers, all with tens of thousands of amplifier channels. By the end of the 1980s, most Large Electron Positron collider (LEP) experiments at the CERN were preparing inner silicon detector barrel arrays, equipped with CMOS readout chips, as mentioned in the previous section. Also the BaBar experiment at SLAC and experiments at several other smaller accelerators incorporated silicon detector arrays. Now with the new generation of experiments at the LHC at CERN, the collaborations have installed silicon tracker arrays that are unprecedented in size and complexity. A few examples are mentioned, but already hundreds of pages have been published to provide details of the design, construction, system monitoring, and expected performance for all these silicon detector systems.

The design of the silicon tracker arrays is usually based on the physics goals for particle tracking near the interaction vertex. The precise measurement of the coordinates of the primary interaction point in particle physics experiments and those of possible secondary vertices became more important with the discovery of short-lived particles with a decay length of a few millimeters. A secondary vertex indicates the presence of a charm, beauty, or τ particle among the interaction products. Such a particle is a messenger for a potentially interesting, special reaction. A second goal of the silicon imaging detectors is the improvement on the momentum measurement of the outgoing particles. The precision needed to achieve a given momentum resolution is a function of the radius at which the detector plane is installed, and somewhat relaxed precision can be tolerated toward larger radii. This has led in several experiments to a multitude of different systems that enclose one another in the way of onion-shells. Practical experience will show if this is the optimal approach. Maintenance, replacement and extension operations, and cost may eventually lead to modified designs. It may be mentioned that the use of silicon tracking devices has led to order-of-magnitude improved precision compared to earlier employed gaseous detectors or scintillators, and this has allowed the overall volume of an experiment at a given energy to shrink significantly. The higher cost of the silicon-based systems in the center can be offset by the smaller volume of the magnet and other parts of the detector, including the outer muon chambers.

In recent studies about requirements for future electron collider experiments, the need for improved precision in the particle total energy measurement has become an issue. Some designs of a ‘‘silicon-based’’ calorimeter with tracking capability are being evaluated. In addition, the identification of original leptons from the primary or secondary interaction vertex may be improved by using radiation imaging arrays.

22.4.1
Tracking Detectors for Momentum Measurement

Silicon tracker detectors consist of several layers of silicon position-sensitive devices with associated readout chips. The layout for a typical example is shown in Figure 22.12, with the description of the device in the D0 experiment at Fermilab by Hanagaki (2004). The outer layers in this tracker barrel were supplemented at a later stage with layers 0A-B and 1A-B in the inner volume, very close to the beam pipe. Now being longer and carrying more sensors and readout chips, the modules in such a barrel geometry still continue to follow the original design that was developed for MARKII, as shown in Figure 22.7.

A photograph of part of the real silicon tracker for the CERN CMS collider experiment (Compact Muon Solenoid) is reproduced in Figure 22.13 before complete cabling and encapsulation. Here one can still see the silicon sensors and readout chips, arranged in a way very much similar to the schematic in Figure 22.12. Once all connections for power, signals and cooling have been installed, and thermal insulation is in place, not much of the devices remain visible. The CMS silicon tracker has been described in numerous publications, for example, by Pooth (2006),

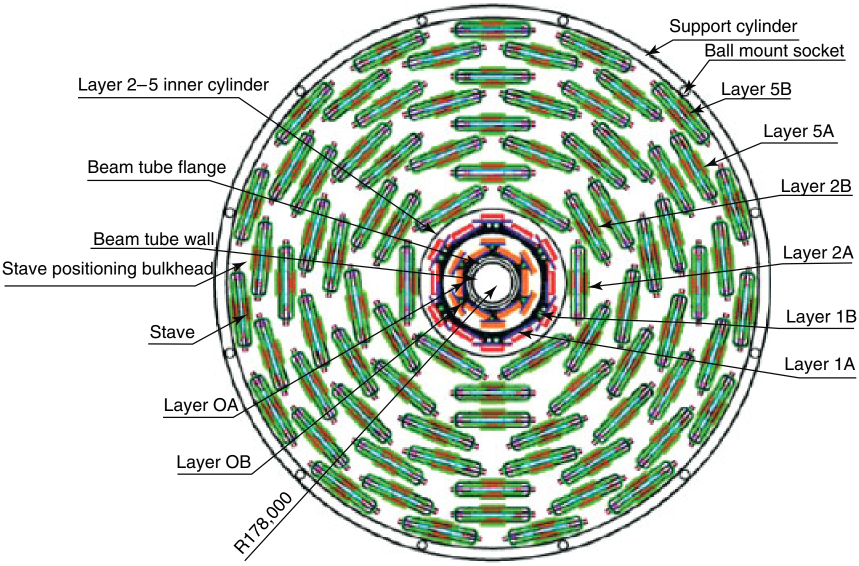

Fig. 22.12 Schematic drawing of the six silicon microstrip detector layers in the Fermilab D0 experiment. The tracker is divided in two groups, with the L0-1 layers in the center and the earlier installed layers 2–5 at radii between 53 and 164 mm. (from Hanagaki 2004).

and is the largest silicon array to date. The CMS tracker array has 10 cylindrical, overlapping layers in the barrel section with radius 20–120 cm, and three inner disks plus nine end-cap disks on either side of the barrel. The overall length is 5.6 m. It covers an active sensor area of 200 m^2, divided over more than 15 000 microstrip sensor units, with diode strip pitch between 100 and 200 μm, depending on the distance of the sensor from the interaction point. All sensors are read out using the 128-channel APV chip, of which ~80 000 have been installed next to the sensors. A critical aspect is the cooling of the instrument, which dissipates several tens of kilowatts, and which has to be maintained below −10 °C to preserve the quality of the high-resistivity silicon under irradiation.

The design of the CMS microstrip tracker allows 8–14 measurement points on each outgoing track, with position precision of the order 10–20 μm. This is complemented by about three points closer to the beampipe, measured in the pixel detector situated within the tracker barrel.

22.4.2
High-Precision Detectors for Interaction Vertexing

For high-precision vertex measurements, one now often uses pixel detector planes, which offer direct 2D space points with precision better than 10 μm. The first use of a pixelized matrix detector was the CCD in the NA11 experiment at CERN, already mentioned (Damerell *et al.*, 1986). Because of the shifting of the charge signals and serial readout via one or a few output nodes, the application of CCD is limited to some specific types of experiments. Some can tolerate low rates, or, as in NA11, the beam

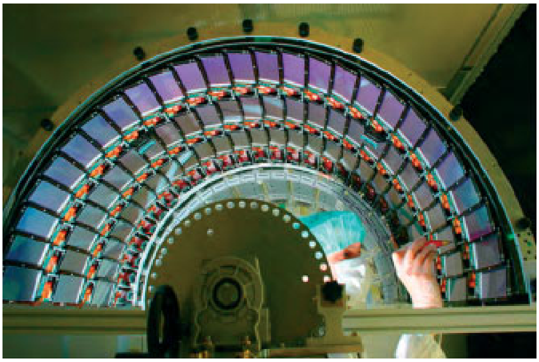

Fig. 22.13 Photograph of the Tracker-Inner-Barrel inside the CMS silicon microstrip detector at CERN, during construction in a clean room. Photo CERN, also published by Pooth (2006).

can be deflected after a positively triggered interaction so that the detectors are not flooded with additional, confusing signals.

In high-rate experiments one can use the hybrid pixel detectors described in Section 22.3. The first application was in the high-intensity environment of the CERN WA97 lead-ion beam, impinging on a lead target (Antinori *et al.*, 1995). A reconstruction of an event is shown in Figure 22.14. The resolving power compared to projective microstrip detectors as well as the low noise are clearly illustrated.

The pixel detector technology is a sophisticated integration of the sensor and the electronics readout function, and it is attractive to think of a full monolithic device, wherein all functions are implemented together. CMOS sensors for visible light now achieve this integration, and have become competitive with CCD in many applications. However, in nuclear and particle physics experiments the devices have to fulfill the need for single-quantum processing, where each particle is recorded with its time of incidence and other characteristics. Continued research is ongoing, in order to build such monolithic detectors for particle physics.

In the LHC collider experiments Alice, Atlas, and CMS at CERN, large arrays of hybrid pixel detectors have been constructed, with sensitive areas of 0.24, 1.7, and 1.2 m^2, respectively. A part of the Atlas pixel detector is shown during assembly in the clean room in Figure 22.15.

A comprehensive description of work on pixel detectors has been published as *Pixel Detectors, From fundamentals to applications* by Rossi *et al.* (2006).

22.4.3

Semiconductor Detectors for Particle Energy Measurement

The energy loss and the conversion into free electric charges in silicon is very reproducible and well understood. If an energetic particle can be made to stop in the detector volume, a constant fraction of its energy is converted into free electron–hole pairs, on average 3.62 eV per pair. For particles of much higher energy, so-called calorimeters have been built for the measurement of their total energy, and these may be more than a meter thick to stop the electromagnetic or the hadronic shower that develops when the particle comes to rest. A tedious calibration process is needed for the current calorimeter devices that employ alternating sheets of passive absorber (Fe, W) and active detector material such as light-emitting scintillator

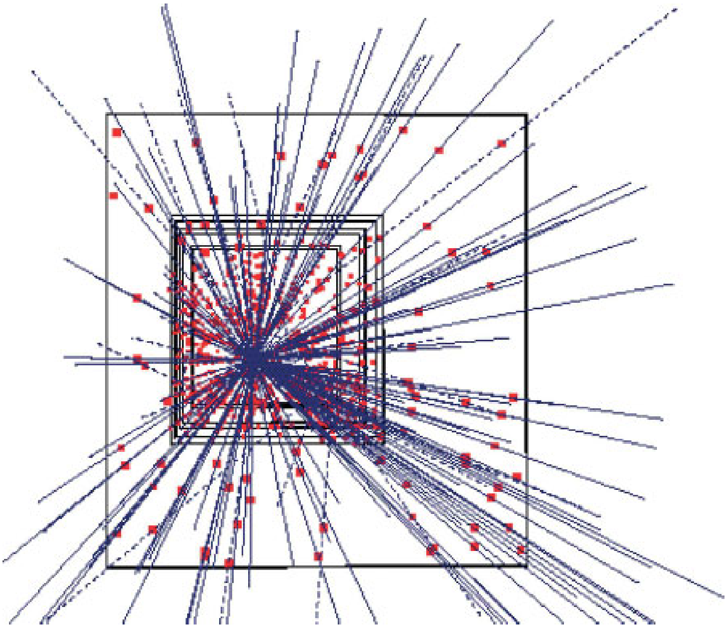

Fig. 22.14 Perspective view of the reconstruction of 153 tracks in a partial angular cone of a lead–lead interaction in the fixed target experiment WA97 (Antinori *et al.*, 1995), using seven planes of silicon hybrid pixel detectors. The registered hits in the planes are indicated by small squares, with smaller squares for the planes closer to the interaction vertex. Most tracks originate at this vertex, and are shown fully drawn. A few tracks cross only a subset of the planes and do not pass through this origin. These tracks are shown by a hatched line. In the analysis, it was found that all hits correspond to a physical particle track, and no uncorrelated noise hits have been observed. This is expected owing to the large noise margin in such a pixel detector. The magnetic field of the Omega spectrometer had been switched off when this interaction took place.

crystals or liquid argon, in which the ionizing secondaries generate mobile free electrons and slow-moving ions.

Simulations show that improved performance can be obtained if the sensor were made out of silicon semiconductor detectors. By about 1985, some prototypes had been tested, but the technology was practically abandoned in view of the high cost of silicon detectors. Since 2006, the development has been taken up again, and in the framework of the EUDET detector R&D for a future international linear collider (ILC), new prototypes are being evaluated (EUDET-Calice Collaboration). Besides the improved energy measurement, the increased calorimeter segmentation is an attractive feature; in addition, such a highly segmented device acts as a continuation of the inner tracker.

22.5
Other Applications of Semiconductor Detectors

The extensive efforts on silicon detector development in particle physics have paved the way for applications in other fields. A few space-borne projects are mentioned here, which have been initiated by particle physicists. In other applications,

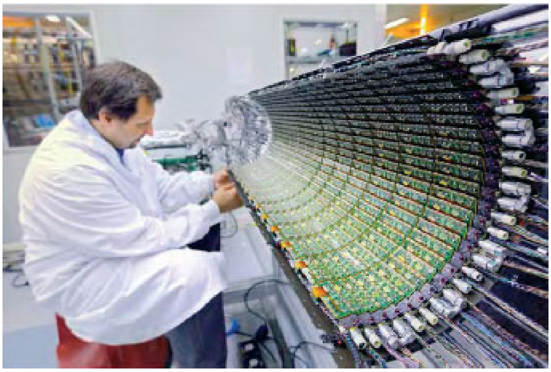

Fig. 22.15 The Atlas silicon pixel detector during assembly in the clean room. A half-shell of the barrel part can be seen. Ladders are supported on a lightweight but rigid carbon-fiber structure. On each ladder a number of through-connected modules can be distinguished. The white tubes are the connections for the cooling fluid (Photo CERN).

for example, protein diffraction with synchrotron light, or materials analysis, scientists from particle physics have been involved as well.

22.5.1
Satellite-Based Experiments

For a long time, silicon detectors have been used on-board satellites for intensity and energy measurement and identification of cosmic rays. There are numerous possibilities for physics exploration that are offered by the natural accelerators that exist far away in the universe. These generate particles with much higher energies than possible on earth, although the fluxes are very small when reaching the solar system. The particle imaging capabilities of multilayer silicon tracker arrays allow a much improved directional detection of these incoming particles, so that these may be correlated with a cosmic source. With this low flux, the sensitivity has to be increased by enlarging the sensitive area. In recent years, balloon experiments such as PAMELA (described by Straulino *et al.*, 2004), have used silicon detector arrays for the measurement and identification of cosmic particles. One of the PAMELA detector modules is shown in Figure 22.16.

The basic ladder structure is also maintained here, as it was adopted originally for the MARKII particle physics experiment at SLAC.

Between 1995 and 2008, two much larger experiments have been built for use in space, in which silicon detector arrays form the main component of the instrumentation. The Fermi Gamma Ray

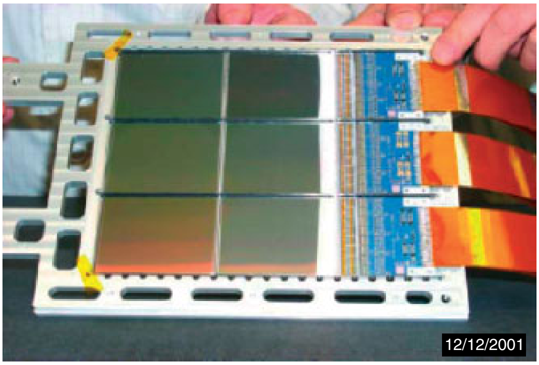

Fig. 22.16 Photograph of a silicon detector plane for the PAMELA experiment. Three ladders, each with two double-sided detectors, are mounted together on an aluminum frame. The diode strips are wire-bonded from sensor to sensor at the left and then bonded to the readout chips at the right. Flexible foils carry the amplified signals further (Straulino *et al.*, 2004).

Space Telescope (*www-glast.stanford.edu/*), formerly called *GLAST*, has a large area tracker (LAT) that consists of 87 m^2 of Si micostrip detectors, 20 000 sensors, and their associated readout chips. The instrument has been described by Sadrozinski (1998), and more recently by Tajima (2007). The total number of sensor readout channels is ~10 million, but the overall power budget is only ~250 W, which is provided by the solar panels. The GLAST/Fermi telescope was succesfully launched on June 13, 2008.

The Alpha Magnetic Spectrometer project is a two-step experiment, described, for example, by Viertel and Capell (1998), with AMS01 (3200 kg) and AMS02 (6000 kg). AMS02 is to be launched by the NASA shuttle and then to be operated at the International Space Station. The website (*http://ams-02project.jsc.nasa.gov/*) gives numerous details. The experiment searches for new physics phenomena in cosmic radiation. Inside a 0.8-T superconducting magnet there is an eight-layer ionizing particle tracker built from double-sided Si microstrip detectors. Some practical aspects of the Si tracker and the construction have been described in publications by Haas (2004) and by Ionica (2003). In this instrument, the total silicon sensor area is 7.2 m^2 and it contains 2286 Si detectors, placed on 192 ladders with a total of 196 608 sensing channels. For the readout, the VA-hdr chip (*http://www.ideas.no/*) is used with 32 channels per chip.

To give an impression of such a space-based instrument, the schematic drawing of AMS02 is shown in Figure 22.17. The distinctive feature is the superconducting, liquid He cooled magnet, that should allow charge determination and precise momentum analysis of the cosmic particles as they can be detected while still outside the earth's atmosphere. The instrument should be transported to the International Space Station by one of the space shuttle flights.

22.5.2
Detectors at Synchrotron Light Sources

Imaging of synchrotron light and X-ray diffraction operate often with photon signals that are similar to that of mips in silicon, in the range 5–100 keV. For the lower end of this range, the absorption of Si for X-rays is quite satisfactory, and the silicon devices that have been developed for particle physics experiments can serve well for different imaging applications at synchrotrons.

Medipix single photon processing detectors have been tested for low-intensity imaging and prove very efficient even for single quanta, as described by Tlustos (2005). A second imaging detector for high photon intensity, with storage capability for up to eight successive timeslots has been developed by Gruner and his team, as published in Rossi *et al.* (1999).

''Pilatus'' is the first large-area silicon array detector for protein crystallography with direct photon conversion, designed at the Swiss Light Source in the Paul Scherrer Institute in Villigen and now produced by Dectris AG (*http://www.dectris.com/*). The design is modular and an array can be composed of a certain number of basic pixel detector modules that each carries 16 readout chips on a Si detector with a matrix of pixels. The cell dimension in the most recent version is 172 μm ×172 μm for a 60 × 97 matrix on a readout chip of approximately 10 × 17 mm^2. The modular structure is illustrated in Figure 22.18.

Additional particle identification instruments are a time of flight (ToF) and a transition radiation detector (TRD) at the top (entrance side) and a ring imaging Cerenkov hodoscope (RICH), electromagnetic calorimeter Ecal and another ToF at the bottom (exit side). Reproduced from Haas (2004).

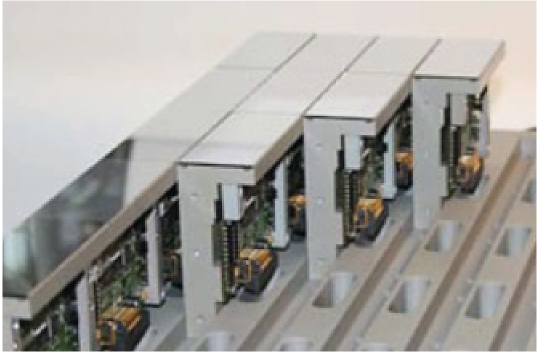

Fig. 22.18 Assembly of a number of "Pilatus" basic modules, which shows the structure that allows a large array to be constructed. A basic module carries a single sensor chip with 2 × 8 readout chips attached to it. The sensor faces the beam with the homogeneous rear side, while the segmented side is toward the readout chips. The dimensions of the sensor on top of the module on the rightmost rail are 84.5 mm × 33.5 mm (from *http://www.dectris.com/*).

22.5.3
Radiation Imaging Detectors in Industrial or Research Equipment

CCD have been in use for quite some time in research equipment and in medical and industrial X-ray imagers. Often the sensor is a scintillator with high-Z atomic number, in which the incident X-rays generate scintillation light. This light is transported and focused onto and detected by the CCD. It would be advantageous to replace such an indirect imaging by a sensor system that transforms the radiation directly into electrical signals. Silicon can be used for X-rays in the range 4–20 keV, and these quanta produce signals that are quite similar to those from mips. On the basis of the experience and advances in particle physics instrumentation, it is then even possible to implement X-ray imaging systems with single-quantum processing. Imaging with individual treatment of each photon still has to be studied in more detail to appreciate all the advantages. An early, striking example is the Medipix range of detectors, which is a spin-off from the Si pixel detector development for the Alice experiment at the LHC. This hybrid pixel assembly has a monolithic silicon sensor matrix of 256 × 256 cells of 55 μm × 55 μm, which is mated by solder bump bonding with a separate readout matrix in 0.25-μm CMOS technology. A sophisticated signal processing for individual, high-rate signals is incorporated in each pixel, such as was illustrated in Figure 22.11. In the most recent version Medipix3, now using 0.13-μm CMOS, one aims to acquire spectroscopic energy information on the individual photons while building up the X-ray image, as described by Ballabriga *et al.*, 2007. The previously mentioned Pilatus imager system is based also on this approach. For efficient absorption of energetic X-ray photons in the range 30–150 keV or even higher, it is needed to use different semiconductor materials such as CdTe.

A variety of applications can be thought of, including the use in visible light imaging with single-quantum photon detection. In this case, one uses a photocathode that produces a primary electron, which is then amplified in a gas-filled structure or in a vacuum tube with a microchannel plate or a kilovolt-accelerating field.

Glossary

Bias Voltage: The usual silicon particle sensor has the structure of a rectifying diode and needs a reverse bias voltage that depletes the sensor volume of free charge carriers.

CCD (Charge Coupled Device): Matrix of imaging cells consisting of capacitors with transparent polysilicon contact plates, so that light can enter the silicon and generate free charge carriers, proportional to the intensity.

Double-Sided Microstrip Detector: Semiconductor detector with a microstrip diode matrix on the rectifying front side, as well as on the ohmic rear side. Often the microstrip patterns make an angle of 90°. It may be useful to have a much smaller angle, such as 7°, which reduces the problem of ambiguities if several particles cross the detector matrix at the same time.

Drift Detector: Position-sensitive detector in which small readout electrodes are placed at the end of one or more carrier drift paths. These drift paths are defined by an electrode structure on the sensor surfaces, and on which a potential gradient is applied, typically $\sim 1\ \mathrm{V}\ \mu\mathrm{m}^{-1}$.

Efficiency: Detection efficiency is the percentage of particles or photon quanta that is detected in the instrument, as a fraction of the number of quanta that are incident on the sensitive detector area. This is equivalent to the probability that the signal charge generated by a particle in the detector volume can be distinguished above the noise charge.

Ion-Implanted Detector: Rectifying diode obtained by creating a p–n junction on a high-resistivity silicon slice, using an ion-implantation accelerator. Boron is often the species that is used to create the p-regions, and phosporous or arsenic is used to create the n+ ohmic rear contact of the detector diode.

Ladder: Linear assembly of two or more sensors on some substrate, often also including the signal readout circuits.

Leakage Current: Current that flows in a reverse-biased diode when no incident radiation is present.

Microstrip Detector: One-dimensional matrix of contiguous sensitive cells (strips) with long dimension above 1000 μm and short dimension (pitch) below 1000 μm.

Minimum Ionizing Particle (m.i.p. or mip): Swift particle with momentum at or above the value for which the specific energy loss reaches a minimum. The material surroundings of the detector modulate the actual value of the energy that is deposited in the sensitive volume. In a ''thin'' (<20-μ m) Si layer in vacuum the average specific energy deposit is $\sim 230\ \mathrm{eV}\ \mu\mathrm{m}^{-1}$, corresponding to an average generation of 63 electron–hole pairs. In an ''embedded, thick'' layer the values can be 360 eV and 99 e–h pairs on average.

Neutron-Transmutation-Doped (NTD) silicon: Under neutron irradiation, usually close to a nuclear reactor, silicon atoms can be converted into phosphorous atoms after neutron capture. This results in a very homogeneous n-type doping profile if the crystal is rotated in the neutron flux. The radiation defects have to be annealed and the doping atoms have to be electrically activated by a high-temperature treatment, usually above 1000 °C.

Noise Charge: The noise in the detector system is expressed as the equivalent noise charge (ENC) at the input of the amplifier in unit electron charges. The noise signal distribution is Gaussian and the width can be expressed by the rms. σ value or by the full width at half maximum (FWHM). The relation between these is $\mathrm{FWHM} = 2.35\sigma$.

Pad Detector: One-dimensional or two-dimensional matrix of contiguous sensitive cells with all lateral dimensions above 1000 μm.

Pixel Detector: Two-dimensional matrix of contiguous sensitive cells with dimensions below 1000 μm.

Surface Barrier Detector: Rectifying diode obtained by metal deposition on a high-resistivity silicon slice, which is used as particle detector.

Type Inversion: During prolonged irradiation of n-type silicon, the progressive introduction of acceptor-type radiation defects leads to effective compensation of the original type and the material exhibits properties of p-type silicon.

INTRODUCTION

Generalities

Dialysis is a process whereby solutes of differing molecular weights are separated according to their varying abilities to diffuse through a membrane. The driving force is the chemical gradient across the membrane for each solute, with no convective exchange or movement of solvent through the membrane. Diffusion is spontaneous and irreversible, leading to an increase in the entropy of the system, and requires no external source of thermal or chemical energy. Dialysis is used in the laboratory, in medicine, and in industry as a separation or concentration process.

The word was coined and the process described during the 1850s by the Scottish chemist Thomas Graham. Graham recognized that certain substances, which he termed "colloids"—probably largely proteins—diffused much more slowly across a parchment membrane than other smaller molecular weight solutes that he called "crystalloids." Using a simple device with a "dialytic septum" of albumin-coated parchment paper, he was able to separate the components of urine, recovering a crystalloid in the diffusate that proved to be primarily urea.

There is little standardization of terminology. The solution on the feed side, with retained macromolecules, may be termed retentate, while the product solution containing diffused solutes is called permeate or diffusate. The term dialysate has been used by different authors for solution on both sides of the membrane. In hemodialysis, however, which is the most widespread application of the process, the feed solution is blood and the

solution containing diffused solutes is always called dialysate.

The direct descendant of Graham's method is *equilibrium dialysis,* a laboratory procedure used primarily for purification of proteins, illustrated in Fig. 1. In this process, an aqueous solution containing both small molecules and macromolecules is placed in a collodion or cellophane bag, and the sealed bag placed in a large reservoir of buffer solution. The small molecules diffuse out of the bag along a concentration gradient, while the macromolecules are retained by the bag membrane. If the volume of buffer is large with respect to that of the bag—with, for example, continuous flux of fresh buffer—a relatively complete separation can be effected.

Applications

Industrial applications of dialysis include the recovery of caustic from hemicellulose in the production of rayon, salt removal in pharmaceuticals manufacture, and desalination of water, but the most extensive commercial use is for the medical treatment of end-stage renal disease. In patients with this condition, dialysis substitutes for the failed excretory function of the kidney, removing from the circulation the small [<1000 Da; 1 Da (dalton) $=1.007\,94$ u] and middle (~ 1000–5000 Da) molecular-weight metabolic end products that cause toxic symptoms if allowed to accumulate, while leaving behind proteins and other macromolecules. In 1988, over 110 000 patients received regular dialysis therapy in the United States alone, at a total cost of more than five billion dollars (United States Renal Data System, 1990).

Ion-Exchange Dialysis Methods

The retention of large solutes is ordinarily based on steric effects. The use of ion-selective membranes, which allow preferential passage of positively charged cations or negatively charged anions, has allowed the development of several specialized techniques. In *ion-exchange dialysis,* shown in Fig. 2(a), an anion-exchange membrane allows passage of anions, but excludes transfer of all cations except hydrogen ions. Thus if a solution of an acid and its metal salt is dialyzed against water, the anion diffuses along a concentration gradient and is accompanied by hydrogen ions to preserve electroneutrality. The net effect is separation of the acid from the metal salt, and the process is used for precisely this purpose in the recovery of metal ions in the electroplating industry.

Donnan dialysis, shown in Fig. 2(b), uses a cation-exchange membrane to concentrate a positive ion such as the cuprous ion shown in the figure. Hydrogen ions diffuse down a concentration gradient from the highly concentrated acid solution on the right side of the membrane. Since the membrane prevents diffusion of negative ions, the only way to maintain electroneutrality is to transfer the positive cuprous ion out of the left compartment against a concentration gradient, with resultant increase in concentration of the valuable metal ion by as much as one-hundredfold.

In *electrodialysis,* dialysis takes place in the presence of an electric field. The driving force for solute movement is the electrical attraction of anions to the positive anode and cations to the negative cathode. An array of alternating ion-selective membranes produces concentration and dilution of the ions in alternate cells of the dialyzer [Fig. 2(c)], and the process may be used to remove salts effectively from brackish water. Electrodialy-

Hemodialysis as a Paradigm

Therapeutic hemodialysis represents the most highly developed and by far the commonest and most economically important use of the procedure, and has been subjected to the most extensive mathematical analysis. Because of this, and since much of that analysis may be generalized to any dialysis procedure, the remainder of this article will use hemodialysis as a paradigm. After a discussion of the functions of the kidney that hemodialysis must replace, the mathematics of mass transfer and apparatus and techniques will be examined in depth.

1. FUNCTIONS OF THE KIDNEY: THE GOALS OF DIALYSIS THERAPY

Therapeutic dialysis is a "renal replacement therapy," intended to substitute for the normal functions of the kidney that are lost in end-stage renal failure. The dialyzer is thus often referred to as an "artificial kidney," although its simulation of kidney function is incomplete and relatively inefficient.

The physiological role of the kidney includes regulation of body water and electrolytes, excretion of metabolic wastes, and regulation of metabolism through the production of a number of hormones. The first two of these are separation processes, although not the functions of a passive filter. The anatomical unit that is responsible for the formation of urine and adjustment of its solute concentrations is the *nephron,* shown schematically in Fig. 3. Each human kidney contains $(0.8-1.2)\times 10^6$ of these structures, which consist of a tuft of blood capillaries, the *glomerulus,* in intimate contact with a long duct, the *tubule,* which is lined with epithelial cells. Ultrafiltration takes place across the glomerular basement membrane, which divides the capillary lumen from that of the tubule. This membrane is quite permeable to water and to solutes of molecular weight less than about 10,000 Da, but provides an effective barrier to passage of macromolecules over 50,000 Da, especially those that carry a net negative charge at the physiologic *p*H of 7.40.

The rate of glomerular ultrafiltration is determined by the hydrostatic pressure difference between the glomerular capillary and tubular lumina, $P_{GC}-P_T$, and by the osmotic gradient produced by the retained macromolecules, $\pi_{GC}-\pi_T$, where π is the colloid osmotic pressure. This relationship can be expressed as

$$\mathrm{SNGFR}=K_f[(P_{GC}-P_T)-(\pi_{GC}-\pi_T)], \qquad (1)$$

where SNGFR is the ultrafiltration rate of a single nephron and K_f is the glomerular ultrafiltration coefficient, in turn the product of membrane hydraulic permeability and surface area. Using data obtained from rat glomeruli, Dworkin and Brenner (1985) have calculated K_f to be 42.1 nL/(s·cm^2·mm Hg) (1 mm Hg = 133 Pa), a value that is one to two orders of magnitude greater than that of other capillaries. Glomerular filtration thus proceeds rapidly despite a relatively low hydro-

static driving force in the range of 5–10 mm Hg, reaching levels of 120–130 mL/min, or about 180 L/d.

The ultrafiltrate formed by the glomerulus is practically free of protein, but contains small-molecular-weight solutes in the same concentrations found in plasma. As this solution travels down the tubule, about 99% of the filtered water is reabsorbed into the circulation. Some filtered solutes, such as inulin, a 5200-Da polysaccharide used in the measurement of renal function, remain entirely within the tubule and become progressively more concentrated as water is removed. Other solutes, including sodium, potassium, phosphate, bicarbonate, small proteins, and essential nutrients such as glucose and amino acids, are themselves reabsorbed, so that less than 1% of the solute filtered by the glomerulus is ultimately excreted in the urine (that is, the *fractional solute excretion* is less than 0.01). Finally, potentially toxic organic acids and bases such as hippurate and creatinine are secreted into the tubular fluid, so that their fractional excretion may exceed 1.0. Sites along the nephron where typical solutes are reabsorbed or secreted are indicated in Fig. 3.

By varying the rates of reabsorption and secretion, the tubule adjusts solute excretion to the current needs of the organism. At extremely low levels of salt intake, for example, or in states of dehydration, when there is need to minimize sodium loss, the urine sodium concentration may be virtually unmeasurable. During heavy salt ingestion, however, as much as 4 or 5 g of sodium per day may appear in the urine.

The kidney's ability to excrete a solute x may be represented by the *clearance* of x (C_x), defined as the mass removal rate divided by the plasma concentration. Clearance may also be conceptualized as the volume of plasma required to supply the amount of x appearing in the urine in a given time, usually expressed in mL/min,

$$C_x = U_x \dot{V} / P_x, \tag{2}$$

where U_x and P_x are the concentrations of x in the urine and plasma and $\dot{V}$ is the urine flow rate. Since the rate of excretion of x is equal to $U_x \dot{V}$, and rate of filtration of x is equal to the product of P_x and the glomerular filtration rate (GFR), the fractional excretion of x (FE_x) is

$$\mathrm{FE}_x = U_x \dot{V} / (P_x \times \mathrm{GFR}) \tag{3}$$

and is equal to the ratio of C_x to GFR. Thus, if x is freely filtered at the glomerulus and is neither secreted nor reabsorbed, then its rate of filtration is equal to its rate of excretion, $\mathrm{FE}_x = 1.0$, and C_x is equal to GFR. In clinical practice, the clearance of *creatinine,* a product of muscle metabolism, is generally used as an estimate of GFR, despite the fact that some creatinine is secreted into the tubule and $\mathrm{FE}_{\mathrm{creatinine}}$ is slightly greater than 1.0.

2. HISTORY

In 1913, a little more than fifty years after Graham's first description of dialysis, *in vivo* dialysis was first performed at Johns Hopkins University, and the term "artificial kidney" entered the language. Abel, Rowntree, and Turner passed the blood of nephrectomized dogs through collodion tubes and demonstrated the removal of nonprotein nitrogen. In 1924 Georg Haas, in Germany, performed the first human dialysis, which lasted 15 min and demonstrated primarily that the procedure could be done without harm to the patient.

Two developments of the next decade had profound influence on the nascent hemodialysis. In 1928 the first practical anticoagulant—heparin—became available, making prevention of the coagulation of blood passing through the dialysis apparatus much more manageable. Secondly, cellophane membranes were developed and manufactured commercially, largely for sausage casings. This regenerated cellulose product was far more practical than the fragile collodion for the construction of dialyzers, and in slightly modified forms remains today the mainstay of hemodialyzer manufacture.

Clinical dialysis became a reality in the small town of Kampen, during the Second World War German occupation of the Netherlands. Using a large rotating drum wound with 2.5-in. cellophane sausage tubing and immersed in a 70-L tank of dialysate, Willem Kolff began in 1943 to dialyze patients suffering from uremia, and in 1945 succeeded in keeping a woman alive until her recovery from acute renal failure. After the war Kolff donated machines to clinics in Europe and the United States, and hemodialysis began slowly to grow. By the late 1950's it was an established therapy for acute renal failure, but long-term dialysis was not possible because of the extreme difficulty of repeated cannulation of a patient's arteries and veins.

The breakthrough came in 1960 with the development of the Quinton-Scribner shunt—a Teflon, and later Silastic, cannula that was implanted in an artery and vein in the arm and afforded permanent vascular access. This device was still fraught with problems of infection and coagulation of blood within its tubing, but it eliminated the need for repeated surgical cutdowns, and made chronic hemodialysis a possibility for the first time. Six years later Brescia, Cimino, and their colleagues in the Bronx surgically created an arteriovenous fistula in the wrist, and the resultant high flow and pressure in the draining cephalic vein caused it to dilate and its wall to become thickened. This dilated vein could then be accessed by venipuncture with a large needle, providing sufficient blood flow for effective dialysis. Routine intermittent access to the circulation became a reality, and the modern era of chronic dialysis was established.

Over the scant three decades of its existence as a practical treatment for kidney failure, dialysis has been a remarkable success. In the United States alone, well over 100 000 people receive regular dialysis treatment. The 1-yr mortality rate in industrialized countries is high, ranging from 7% to 23%, but many patients with renal failure, once doomed to a rapid demise from their disease, now continue to live independent and active lives for as much as 20 yr or more.

3. THE KINETICS OF DIALYSIS

Therapeutic dialysis replaces the filtration functions of the kidney—specifically, the establishment and maintenance of physiological solute concentrations and normal body water content. The basic elements, as illustrated in Fig. 4, are simple, with solution (blood) flowing on one side of a semipermeable membrane, and dialysate (an osmotically balanced electrolyte solution) flowing in a countercurrent direction on the other. Solutes diffuse down concentration gradients, and water removal is effected by ultrafiltration, driven by the hydrostatic pressure difference between solution (blood) and dialysate. A mathematical analysis of the process can be divided into several parts: mass transfer characteristics of the artificial kidney, or dialyzer; ultrafiltration; and the kinetics of solute removal from the body. The last of these will not be treated in this article.

3.1 Dialyzer Mass Transfer

Solute transfer across dialysis membranes occurs by diffusion, and is governed by Fick's law

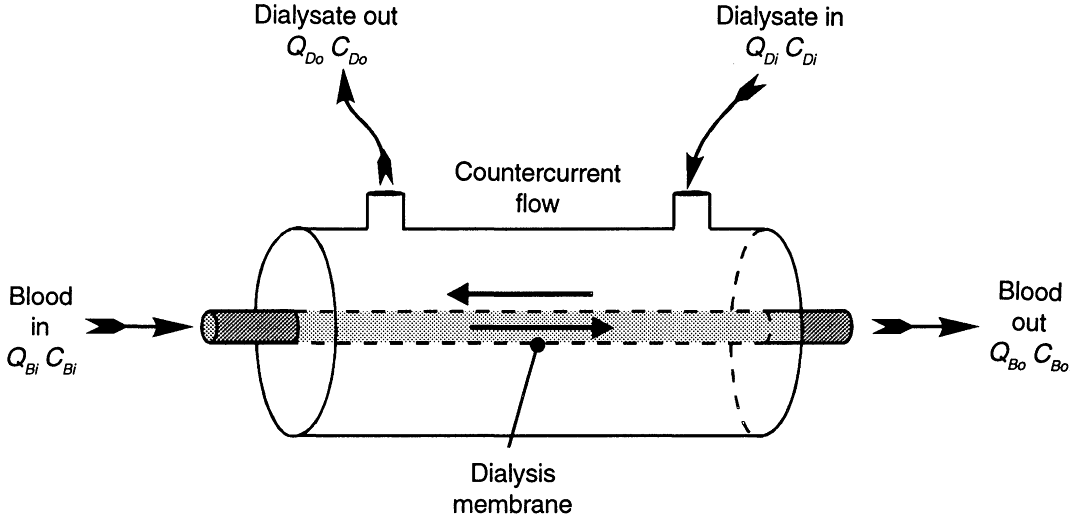

FIG. 4. Schematic representation of an artificial kidney. Blood and dialysate flow in opposite, or countercurrent, direction. Q=flow, C=concentration, Bi=blood inlet, Bo=blood outlet, Di=dialysate inlet, Do=dialysate outlet.

$$J_x = -D_x A \frac{dc}{dx} \qquad (4)$$

or in integrated form

$$J_x = -(D_x A/L)(c_B - c_D), \qquad (5)$$

which states that flux of solute x—J_x (mol/cm^2/s)—proceeds over the distance L at a rate proportional to the concentration difference from solution (blood) to dialysate, $c_B - c_D$, the surface area of the diffusing front, A, and the diffusivity, D_x, which is a constant property of the solute-solvent system at a given temperature. In a dialyzer D_x is constant for a given temperature and solute, and L is determined by membrane thickness and dialyzer geometry and is also constant, so that for a specified solute D_x and L may be combined in the overall mass transfer coefficient, k_0:

$$J_x = -k_0 A (c_B - c_D)_{\text{avg}}. \qquad (6)$$

k_0 is a complex coefficient with components that depend on transport in solution (blood), membrane, and dialysate. Each of these phases has an associated mass transfer coefficient and reciprocal mass transfer resistance, R, related by

$$1/k_0 = R_0 = R_B + R_M + R_D, \qquad (7)$$

$$1/k_0 = 1/k_B + 1/P_M + 1/k_D, \qquad (8)$$

where the subscripts B, M, and D refer to blood, membrane, and dialysate, and P_M is membrane permeability. In some early hemodialyzers, thick and poorly distributed blood and dialysate boundary layers contributed as much as 75–80% of the total resistance to solute transfer. With modern dialyzer design techniques, this figure has fallen to less than 25% (Colton and Lowne, 1981).

Strictly speaking, k_0 is a local property of a point on the dialysis membrane, since k_B and k_D may vary as concentrations change with position along the dialyzer. In practice another value, K_0, is used, defined as the length-averaged value of k_0, and considered constant throughout the dialyzer. The product of K_0 and the membrane surface area, K_0A, is a fixed property of a dialyzer for a given solute (assuming aqueous solution and a fixed temperature, usually 37 °C), and expresses the dialyzer's intrinsic ability to filter that solute.

3.2 Dialysance

Potential dialyzer performance may be expressed by K_0, but in practice it is necessary to quantify the actual amount of filtration of specific solutes taking place under clinical conditions, that is, at known blood and dialysate flow rates. Diffusive dialysance D, the rate constant used to characterize dialyzer solute removal, was defined by Wolff (1951) as "the minute rate of net exchange of a substance between blood and bath fluid per unit blood-bath concentration gradient," or

$$D = \frac{\text{Rate of solute transfer}}{\text{Unit concentration driving force}}. \qquad (9)$$

The concentration driving force appears in Eq. (6) as $(c_B - c_D)_{\text{avg}}$. The correct average concentration difference is the logarithmic mean of the inlet and outlet concentrations:

$$(c_B - c_D)_{lm} = \frac{(c_B - c_D)_1 - (c_B - c_D)_2}{\ln[(c_B - c_D)_1/(c_B - c_D)_2]}, \qquad (10)$$

where 1 and 2 are the two ends of the dialyzer. Nevertheless, because of the inconvenience of measuring inlet and outlet concentrations in both dialysate and blood, in the clinical setting the driving force is approximated by the maximum concentration difference, $c_{Bi} - c_{Di}$, using the terminology of Fig. 4.

The mass transfer rate N, in moles per unit time, is given by the difference between incoming and outgoing solute mass (either in blood or in dialysate):

$$N = Q_{Bi} c_{Bi} - Q_{Bo} c_{Bo} = Q_{Do} c_{Do} - Q_{Di} c_{Di}. \qquad (11)$$

Since in the absence of ultrafiltration $Q_{Bi} = Q_{Bo}$ and $Q_{Di} = Q_{Do}$, dialysance may be written as

$$D_B = \frac{Q_B(c_{Bi} - c_{Bo})}{c_{Bi} - c_{Di}} = \frac{Q_D(c_{Do} - c_{Di})}{c_{Bi} - c_{Di}}. \qquad (12)$$

In modern hemodialyzers, blood and dialysate flows are always countercurrent, and for solutes like urea, creatinine, and phosphate, concentrations in the entering dialysate are 0. In this case, the denominator of Eq. (12) simplifies further to c_{Bi}, and the equation becomes the equivalent of Eq. (2), the definition of clearance for the natural kidney. By this analogy, the rate constant for transfer of solutes not present in entering dialysate is known as dialyzer clearance (K):

$$K = \frac{Q_B(c_{Bi} - c_{Bo})}{c_{Bi}} = \frac{Q_D(c_{Do} - c_{Di})}{c_{Bi}}. \qquad (13)$$

Both dialysance and clearance may be calculated using either blood- or dialysate-side flow rates and concentrations, although in clinical practice the former is more common.

Dialysance is dependent on momentary conditions, that is, blood and dialysate flow rates, while K_0A is a fixed property of a dialyzer for each solute examined. The relationship between K_0A and dialysance is thus an important and useful one, necessary for prediction of dialyzer performance under changing conditions of flow. Equating J as defined in Eqs. (6) and (11), assuming countercurrent blood-dialysate flow and no net ultrafiltration, and substituting with Eqs. (10) and (12), yields

$$D = \frac{e^{-z} - 1}{e^{-z}/Q_B - 1/Q_D}, \qquad (14)$$

where

$$z = \frac{K_0A(1 - Q_B/Q_D)}{Q_B}.$$

Equation (14) is plotted in Fig. 5 for a range of K_0A that varies from 50—a typical value for a large-molecular-weight solute such as vitamin B_{12}—to 900 mL/min, which is about the highest value of K_0A for the small molecule urea obtainable with modern high-performance dialyzers. Examination of this graph—which is calculated for a fixed dialysate flow of 800 mL/min—reveals the boundary conditions for dialysance. When K_0A/Q_B is large, as for small solutes at low blood flow rates, then $D \approx Q_B$. Conversely, when K_0A/Q_B is small, either because the solute is large and poorly diffusible or when blood flows are very high, then the limiting value is $D \approx K_0A$. Clinically attainable blood flows range from 200 to 600 mL/min; in this range small-molecular-weight solute dialysance is flow dependent with most dialyzers. For molecules larger than about 500 Da, increasing blood flow beyond 200 mL/min has little effect on dialysance in conventional cellulose dialyzers. Thus, to increase removal from the circulation of high-molecular-weight solutes, it is necessary to enlarge the surface area of the dialyzer or lengthen the treatment. The situation may, however, be different when newer, more highly permeable membranes, which have higher K_0A's for larger molecules, are used.

3.3 Ultrafiltration

Besides removal of waste solutes, therapeutic dialysis also has the task of removing excess water accumulated by ingestion and by

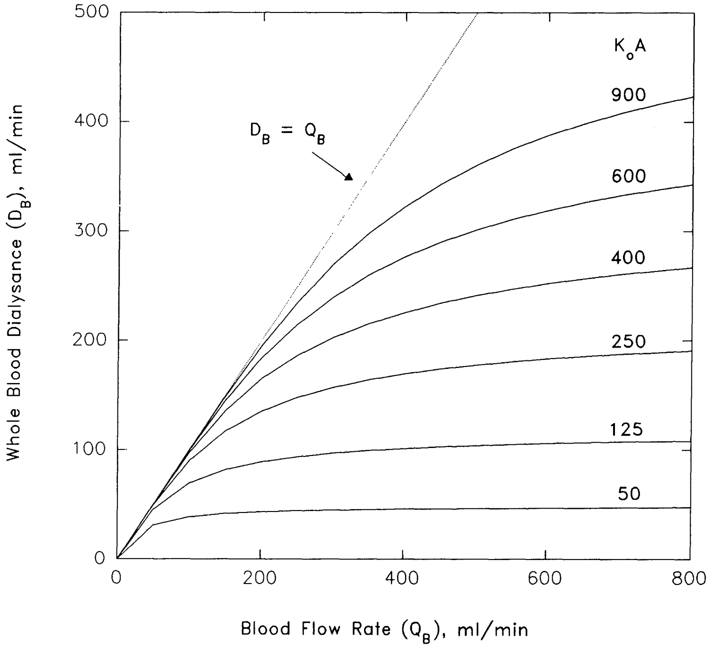

FIG. 5. Dependence of dialysance on blood flow rate, plotted for different values of K_0A.

metabolic formation, often as much as 1–2 L/d. This is accomplished by ultrafiltration across the dialysis membrane, a process described by

$$J_F = \frac{Q_F}{A} = \frac{L_p(\Delta P - \Delta\pi)}{\mu}, \tag{16}$$

where J_F is the water flux (mL/cm^2/min), Q_F is the ultrafiltrate flow rate, A the membrane surface area, L_p the membrane hydraulic permeability coefficient, and μ the filtrate viscosity. The driving force is the sum of the hydrostatic and osmotic pressure gradients. In hemodialysis the transmembrane hydrostatic pressure (TMP) from blood to dialysate varies from 100 to 500 mm Hg, and almost invariably markedly exceeds the osmotic pressure generated by large molecules on the blood side. In clinical practice, an empirically defined ultrafiltration coefficient, K_{UF} [mL/(mm Hg)h], is used to describe dialyzer performance:

$$K_{UF} = \frac{\text{Water flux (mL/h)}}{\text{Transmembrane pressure (mm Hg)}} = Q_F/(P_B - P_D). \tag{17}$$

Table 1 includes approximate ultrafiltration coefficients for a number of membrane materials, with kidney glomerular basement membrane added for comparison.

3.3.1 Convective Clearance. Frictional interaction between water and solute molecules—so-called solvent drag—results in transport of solute across the dialysis membrane with the ultrafiltrate. The restraining action of the membrane to this convective solute movement is expressed as the sieving coefficient S of a membrane for a given solute:

$$S = c_F/c_B. \tag{18}$$

When $S=1$, there is no resistance to solute movement, and the concentration in the filtrate will be unchanged from that of blood. With cuprophane membranes, there is a rapid falloff in permeability with increasing molecular weight, but more "open" membranes such as sulfonated polyacrylonitrile (AN69) have sieving coefficients close to unity for molecules as large as 1500 Da (Table 2) (Green *et al.*, 1976). Since diffusive clearance of these larger molecules is low, convection plays a relatively important part in the transfer of these substances across open membranes.

When ultrafiltration is occurring,

$$Q_{Bo} = Q_{Bi} - Q_F \tag{19}$$

and

$$Q_{Do}=Q_{Di}+Q_F, \tag{20}$$

and Eq. (11) is thus no longer an accurate expression of solute transfer. Substitution of Eqs. (19) and (20) yields a new expression for dialysance:

$$D=\frac{Q_{Bi}(c_{Bi}-c_{Bo})}{c_{Bi}-c_{Di}}+\frac{Q_F\, c_{Bo}}{c_{Bi}-c_{Di}} \tag{21}$$

$$=\frac{Q_{Di}(c_{Do}-c_{Di})}{c_{Bi}-c_{Di}}+\frac{Q_F\, c_{Do}}{c_{Bi}-c_{Di}}, \tag{22}$$

which now consists of a diffusive term and a term containing Q_F, which represents the convective portion of dialysance. The equation for clearance can be similarly corrected, yielding the convective clearance term $Q_F\, c_{Bo}/c_{Bi}$, which cannot exceed the value of Q_F. Ultrafiltration rates in hemodialysis are rarely greater than 30 mL/min, a value that would range between 10% and 20% of the diffusive clearance for urea, but might account for the majority of removal of solutes with molecular weights over 1500.

3.3.2 Backfiltration. When no net ultrafiltration is occurring ($Q_{Do}=Q_{Di}$), the total net TMP is 0; nevertheless, at single points along the membrane this may not be the case. In fact, dialysate-side pressure is maximal at the blood outlet end of the dialyzer, where blood-side pressure is at a minimum. In the example shown in Fig. 6, net driving pressure on the blood side of the membrane varies from 42 mm Hg at the blood inlet to −16 mm Hg at the outlet. As a result, there is movement of ultrafiltrate out of blood at one end of the dialyzer, and an equivalent movement back from dialysate to blood at the other end, with total net ultrafiltration being 0.

With cellulose membranes, long the mainstay of hemodialysis, ultrafiltration coefficients range from 2 to about 4 mL/(mm Hg)h. Thus the maximum backfiltration rate at any point on the membrane at the pressures in Fig. 6 would be about 1.1 mL/min, probably not a clinically significant effect, especially since negative pressure applied to the dialysate side to produce net ultrafiltration further reduces the potential for backfiltration. With newer membranes, however, K_{UF} may be as high as 80–90 mL/(mm Hg)h, leading to a potential rate of back filtration as high as 24 mL/min at the blood outlet end if net Q_F is 0. At high backfiltration rates, contaminants in the dialysate, which is usually not sterilized, might be convectively transported into the blood by the back-filtrate. Endotoxin, a polymeric product of gram-negative bacteria, or its fragments, is a particularly feared contaminant, since exposure to even trace amounts could cause serious anaphylactic reactions.

4. COMPONENTS OF THE DIALYSIS SYSTEM

The dialysis system consists of a number of discrete components, each with characteristics that influence the process and that may vary considerably. The actual solute exchange takes place within one of several kinds of "artificial kidney," or dialyzer, among which membrane materials, geometry, and flow patterns may differ. Blood has chemical and rheological properties that strongly affect diffusion. The solutes contained in the dialysate determine concentration driving forces for diffusion of numerous small molecules, and the choice of dialysate buffer used to adjust *p*H may have profound effects on the patient. Finally, there is a variety of apparatus used to deliver blood and dialysate to the dialyzer and to control and monitor temperature, pressure, flow rates, and dialysate composition.

4.1 The Dialyzer

Early dialysis was performed with multiple-use devices that generally consisted of a large-surface-area blood-filled cellophane compartment suspended in an open dialysate bath. The ensuing three decades have seen the

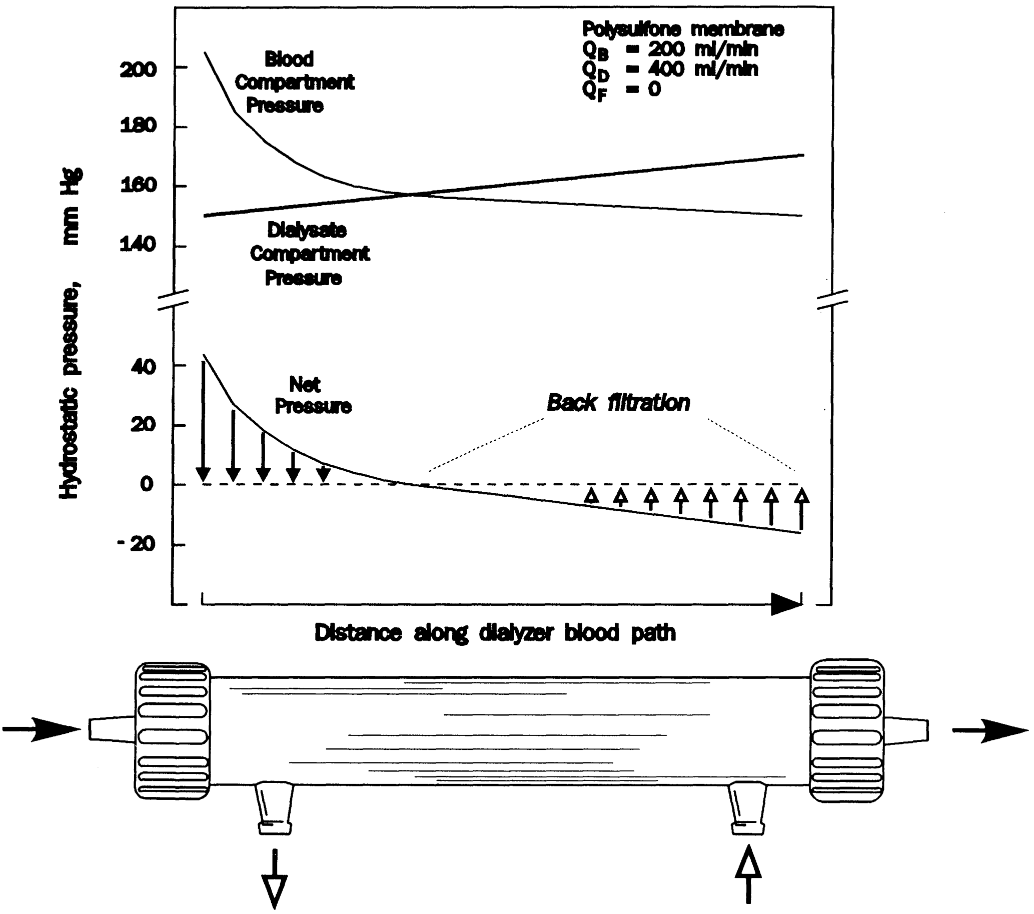

FIG. 6. Backfiltration. With no net ultrafiltration, blood-side hydrostatic pressure exceeds that on the dialysate side over about the first 40% of the blood path, and there is movement of ultrafiltrate out of blood. Over the last 60% of the blood path, the pressure relationships reverse and an equivalent amount of fluid moves from dialysate to blood. Filled arrows, blood compartment; open arrows, dialysate compartment. [Data from Streicher and Schneider (1985).]

development of disposable hemodialyzers, in which all transport processes take place within a self-contained small-volume unit. Cellulosic membranes remain the mainstay of therapeutic dialysis, but a number of new synthetic membrane materials have appeared that have distinctly different properties with respect to mass transfer and to biocompatibility.

4.1.1 Dialyzer Geometry. Hemodialyzers have been produced in several different dialyzer designs, with varying geometrical relationships between blood, membrane, and dialysate. The coil dialyzer dominated the 1950s and early 1960s, when it was succeeded by the parallel plate design. During the 1980s hollow-fiber dialyzers almost completely replaced the earlier designs in clinical use.

4.1.1.1 Coil Dialyzers. The first clinically viable dialyzer constructed consisted of a long cellophane sausage tubing wrapped around a cylindrical drum support. The tube was perfused with the patient's blood, and the entire apparatus was rotated in a tank of dialysis fluid. From this design descended the "twin coil" artificial kidney, introduced in 1956, which was small, efficient (capable of a $K_{D\,\text{urea}}$ of 140 mL/min), inexpensive, and disposable. The dialyzer was placed on end in a canister in an open 100-L tank, and dialysate was pumped crosswise through the supporting mesh. The twin coil was widely used throughout the 1950s and 1960s, and smaller, improved coils were used in many hospitals well into the 1980s, but by 1985 only 1–2% of dialyses in Europe, where the most complete data are available, were performed with this type of dialyzer (Hoenich *et al.*, 1989).

4.1.1.2 The Parallel Plate. The coil dialyzer has now been almost completely replaced by two other designs: parallel-plate and hollow-fiber dialyzers. Parallel-plate devices have evolved from the two-layer 40×14×3-in. Kiil dialyzer of the early 1960s, which was reassembled and fitted with new cellophane membranes before each dialysis. Current versions are small, sterile, disposable devices like the one shown in Fig. 7(a). Blood flows in flat chambers between sheets of membrane with dialysate moving in a countercurrent direction, as illustrated in Fig. 7(b). Modern flat-plate design innovations include precision membrane assembly that allows as many as 17 blood and 34 dialysate layers, and the formation of wavelike microchannels [Fig. 7(c)] in the blood and dialysate chambers to promote turbulent flow. The turbulence en-

sures active mixing, impeding the formation of large stagnant boundary layers, and thereby minimizes mass transfer resistance within the blood and dialysate phases. Parallel plates are probably used in about 20% of dialyses worldwide.

4.1.1.3 Hollow-Fiber Dialyzers. The most widely used design today is the capillary or hollow-fiber dialyzer (Fig. 8), first introduced by Cordis-Dow in the early 1970s. A typical hollow-fiber design consists of a bundle of 6000 to 20 000 capillary tubes, each with an internal diameter of approximately 200 μm and a wall thickness of 8–15 μm for cellulose and up to 40–50 μm for synthetic hydrophobic membranes. The fiber bundle is supported at each end by a "tube sheet" of potting compound, usually polyurethane [Fig. 8(c)]. Hollow-fiber dialyzers have several marked advantages over parallel-plate designs. The ratio of membrane surface area to device volume is greater, leading to a lighter, more compact dialyzer. The fibers are self-supporting, so that effective surface area is not lost through contact with an external rigid framework. Finally, the fibers are less compliant than the parallel-plate blood chambers, so that there is less expansion of the blood compartment during dialysis treatment and consequent decreased pooling of blood outside the body. This is important in minimizing the tendency toward falls in blood pressure in the patient undergoing treatment.

A disadvantage of the hollow-fiber design is its greater vulnerability to plugging of the fibers by particulate matter, making these dialyzers more susceptible to the effects of clot formation in the blood compartment. Severe anaphylactic reactions occasionally occur at the onset of dialysis, which are thought to be largely caused by allergy to residual ethylene oxide gas contained in the dialyzer (Daugirdas and Ing, 1988). This gas, used as a sterilant, is absorbed and slowly released by the polyurethane potting compound, which is not used in parallel-plate devices (Lee *et al.*, 1985); reactions occur over 10 times more commonly with hollow-fiber devices (Villarroel and Ciarkowski, 1985). Nevertheless, hollow-fiber dialyzers now account for up to 80% of dialysis treatments.

4.1.2 Membranes. Dialysis is, after all, a membrane separation process, and the characteristics of the membrane itself strongly affect the nature and efficiency of the dialysis treatment. A number of membranes are in use today, which differ in their structures, their transport properties, and their tendency to interact with blood components.

4.1.2.1 Classification. Dialysis membranes may be conveniently categorized in three groups: cellulose, modified cellulose, and synthetics, with the synthetic membranes further classified as hydrophilic or hydrophobic (Lysaght, 1988). All are natural or synthetic polymers, and are listed along with several properties in Table 1.

Cellulose Membranes. For the first 20 yr of chronic dialysis, there was really only one membrane material—regenerated cellulose. Reconstituted by the cuprammonium process or by saponification of heat-spun cellulose acetate, cellulose is prepared as flat-sheet or hollow-fiber membranes, and still is used in the large majority of dialysis treatments, principally because of its low cost. The structure of cellulose confers particular properties on a hemodialysis membrane. The density of hydroxyl groups on the cellobiose dimer (see Fig. 9) leads to a high polarity, high degree of intramolecular hydrogen bonding, and large affinity for water. The membranes swell markedly when wet, and form a *hydrogel,* a homogeneous single phase containing both water and polymer. Finally, the free hydroxyl groups readily participate in chemical reactions, and probably account for the high interactivity of cellulose membranes with blood cells and proteins.

Modified Cellulose Membranes. To reduce the chemical reactivity of cellulose, blocking groups may be used to replace some or all of the hydroxyl hydrogen atoms (Fig. 9). The most common membrane material of this type is cellulose acetate, in which 60–80% of the available hydrogen has been replaced by acetate radicals. The resultant membrane is less bioactive (see below) and somewhat less hydrophilic, forming a more "open" hydrogel with higher water permeability. The newer cellulose triacetate, with all hydroxyl groups bound to acetate, is so altered that its behavior is more similar to the synthetic hydrophobic materials than to native cellulose. Hemophan is cellulose with about 5% of hydroxyl hydrogen replaced by the diethylaminoethyl moiety, and has properties similar to cellulose acetate.

FIG. 9. Structure of cellulose and its derivatives.

Hydrophilic Synthetic Polymers. Polycarbonate-polyether (PC-PE) and poly-ethylvinyl alcohol (EVAL) are synthetic membranes with chemical and physical similarities to cellulose. PC-PE has many polar carbonyl groups, and EVAL has unsubstituted hydroxyls; thus both membranes are quite hydrophilic, and form hydrogels. Unlike cellulose, however, PC-PE does not swell when wet.

Hydrophobic Synthetic Polymers. These are nonpolar, resonance-stabilized polymers with low energy of interaction with water, listed in Table 1. Membranes are produced from these materials by a phase inversion process, in which the polymer is dissolved in a solvent and pumped through a spinning jet. As the polymer solution emerges from the jet, it is immersed in a nonsolvent precipitant (often water) that replaces the solvent and converts the solution into a two-phase system, the solid phase forming the rigid membrane structure and the liquid, polymer-poor phase forming pores. Membranes formed in this way have chemical and physical properties quite different from cuprophane and other hydrophilic materials. Their overall structure is that of an anisotropic foam. The inner, blood-contacting surface of a hollow fiber made from these materials is a thin skin, usually about 1 μm in thickness. This relatively dense skin determines the transport characteristics of the membrane. The surrounding open foam-like layer has very little flow resistance and functions mainly as mechanical support. The precise morphology of the membrane may be varied by changes in the polymer concentration, solvent, precipitant, or temperature of the phase inversion.

4.1.2.2 Transport Characteristics. The structural differences among these membranes lead to differences in transport capabilities. In general, clearances of small–molecular-weight solutes such as urea are similar for similar conditions of blood and dialysate flow rate, although individual dialyzer design and varying membrane thickness account for about a 40% difference between the highest and lowest urea clearance in the group CA > PS > PMMA > PAN > Cuprophane (Petersen *et al.*, 1987). Examination of Table 1, however, reveals a marked difference between hydrophilic and hydrophobic membranes in water permeability: K_{UF} for the hydrophobic synthetics is as much as 10 times higher than that of cuprophane. As a result, convective clearance is also higher with the hydrophobic group, and larger–molecular-weight solute removal is considerably more efficient. This marked advantage for control of uremic toxicity is partially offset by the problem of potentially excessive water loss, which necessitates the use of special volumetric ultrafiltration systems, by the increased risk of backfiltration (see Sec. 3.3.2), and by the generally much higher cost of the newer synthetic membranes.

4.1.2.3 Biocompatibility. Besides transport characteristics, there is another important property that determines the suitability of a membrane material for hemodialysis, and that is its propensity to interact, usually in deleterious ways, with components of the body. The term "biocompatibility" has come to be used in this context, defined in negative terms as the *absence* of (1) thrombogenic, toxic, allergic or inflammatory reaction, (2) destruction of formed elements of blood, (3) changes in plasma proteins and enzymes, (4) immunological reaction, (5) carcinogenic effect, and (6) deterioration of adjacent tissues (Klinkmann *et al.*, 1989). It is perhaps more accurate to speak of the occurrence of any of these reactions as "bioincompatibility."

Coagulation. Bioincompatibility of hemodialysis membranes occurs in several ways, primarily through interaction with the blood coagulation system, with the circulating inflammatory mediator proteins of the complement system, and with white blood cells. As occurs with almost any artificial surface, exposure of dialysis membranes to the circulation leads to rapid adsorption of a layer of plasma proteins and adhesion of platelets, the small formed elements in blood that initiate the formation of a "hemostatic plug." This is frequently followed by activation of the blood coagulation system and formation of a thrombus, necessitating the use of anticoagulants, usually heparin, during the dialysis treatment. Membranes differ in thrombogenicity, and although data are scarce, cellulose seems the most reactive, with a decrease in clotting tendency when derivatized to cellulose acetate or hemophan. The least reactivity is shown by the hydrophobic synthetic membranes.

Complement activation. The complement system is a group of more than 20 plasma proteins, normally inactive, which in response to appropriate stimuli may be enzymatically cleaved to yield a number of bioactive proteins and peptides that mediate host-defense and acute inflammatory reactions. Dialysis membranes may serve as the stimuli, and activation of complement to varying degrees is a well-established phenomenon in hemodialysis and a common measure of bioincompatibility. The effects of activated products include agglutination of white blood cells in the lung, leading to transient neutropenia and contributing to the hypoxemia associated with the first hour of dialysis. New, nonreprocessed cellulose membranes, with their exposed hydroxyl groups, are by far the strongest activators of complement, while the hydrophobic synthetics are the most biocompatible. Relative activities of various membranes are shown in Table 1.

Synthetic hydrophobic membranes seem to represent a step forward in hemodialysis technology, with improved transport properties and enhanced biocompatibility with respect to cellulosic membranes. There is also evidence that cellulose may induce the release into the circulation of β-2-microglobulin, a ubiquitous 11 800-Da cell-surface protein that accumulates in dialysis patients and may be deposited in bones and joints, leading to a painful and crippling arthropathy, while the synthetic membranes clear the molecule from the blood with varying effectiveness. Nevertheless, technical difficulties associated with high water permeability, and especially high cost, have greatly hindered acceptance of the synthetics, and in the United States cellulosic membranes are still used for 70–80% of hemodialysis treatments.

4.2 Blood

Much of the preceding analysis of diffusion phenomena in hemodialysis treats blood as a simple aqueous solution. The reality is a good deal more complex. Transport phenomena in blood are influenced by solute interactions with electrolytes, with suspended proteins, and with cellular elements—especially red blood cells—as well as by the particular rheological properties of blood.

4.2.1 Protein. The protein content of blood affects transport in several ways. First, small solutes may bind noncovalently to protein macromolecules, thereby becoming markedly less diffusible. In the extreme case, a small molecule may be almost completely unaffected by dialysis. The trivalent aluminum ion, for example, with a molecular weight of only 27, not only is not removed from the circulation by dialysis, but can actually be transported into the blood from contaminated water against an apparent concentration gradient. In fact, about 80% of blood-borne aluminum is bound to protein, and is therefore not available for diffusion, remaining entrapped in the intravascular space. A similar phenomenon occurs with some drugs, such as digoxin and glutethimide, which are highly protein-bound and not significantly removed by dialysis.

Hemodialysis membranes may themselves interact with plasma proteins, both specifically, as outlined in Sec. 4.1.2.3, and nonspecifically. The high hydraulic fluxes that are often attained with high permeability membranes carry along macromolecules, which accumulate in the immediate area of the membrane. This "concentration polarization," shown in Fig. 10, can lead to formation of a protein gel that may interfere with transport. In fact, perfusion of a polysulfone hollow fiber dialyzer with plasma may lead to a 60% reduction in K_{UF} compared to values obtained with saline perfusion (Bosch *et al.*, 1985).

4.2.2 Blood Cells. Blood is not, of course, a homogeneous liquid, but a suspension in which the dispersed phase—the blood cells—consists of liquid droplets each enclosed in a solid elastic envelope. Its resultant non-Newtonian rheological properties are complex, but probably not of major consequence to dialysis transport phenomena.

The distribution of solutes in the plasma and cell compartments, and the rate of transfer between them, however, have significant impact on the efficiency of dialysis. More urea is removed from aqueous solutions than from equimolar solutions in whole blood, partly because of the decreased volume fraction of free water in plasma and red cells (92% and 72%), and partly because of increased resistance to diffusion caused by plasma protein in the boundary layer. Equilibrium distribution coefficients ($c_{\text{red cells}}/c_{\text{plasma}}$) for various solutes are shown in Table 3. The average concentration in whole blood for most of these solutes, given by

$$\bar{c}=\phi c_{\text{red cells}}+(1-\phi)c_{\text{plasma}}, \tag{23}$$

where ϕ is the hematocrit, or volume fraction of cells, will be less than the concentration measured in plasma. Thus for most solutes the quantity passing through the dialyzer decreases as the hematocrit increases, and solute removal per unit time will correspondingly decrease.

Urea crosses cell membranes with great facility. During the 20 s or so that it takes for an erythrocyte to pass through the dialyzer, the urea concentration in its immediate environment falls by as much as 70–80%. Despite this drastic change in the cell's milieu, the

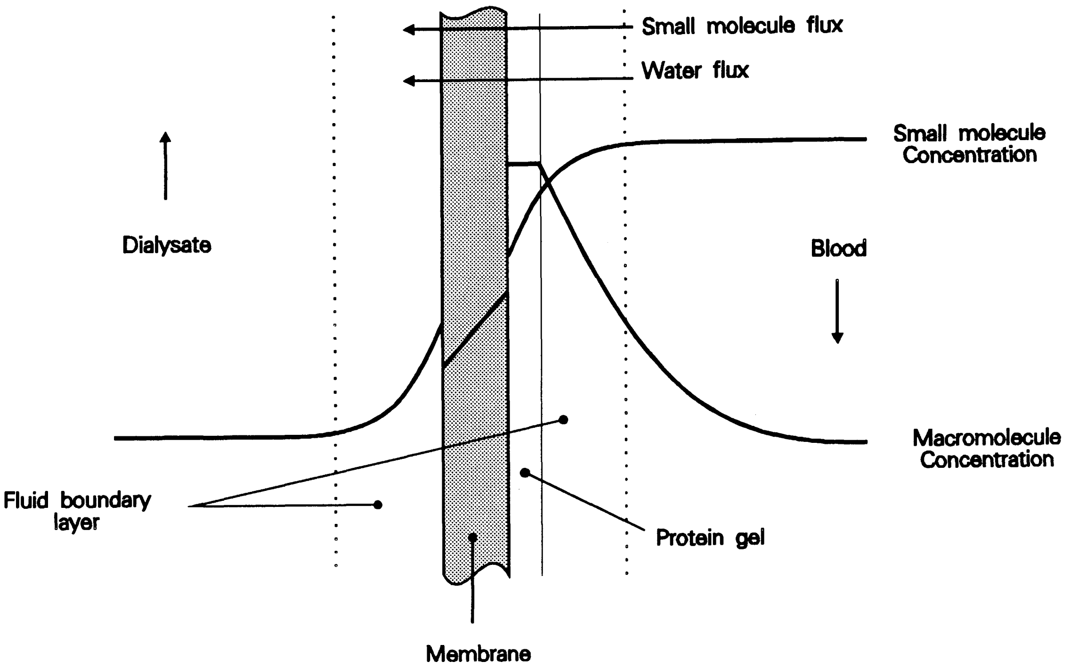

FIG. 10. Concentration polarization. Shown are concentration profiles for small molecules and macromolecules (protein) in the vicinity of a hemodialysis membrane. Water flux from blood to dialysate carries protein molecules to the membrane surface, where a gel may be formed that can interfere with transport of smaller solutes and water. Increasing blood flow rate increases shear forces which tend to limit gel formation.

ratio between intracellular and extracellular urea is virtually the same at the dialyzer blood inlet and outlet. Other substances, however, such as potassium and phosphate, diffuse more slowly across biological membranes, are retained within the red blood cell, and are relatively less available for removal by dialysis. Late equilibration between the intracellular and extracellular pools of these solutes after the dialysis treatment is finished contributes to a rebound rise in plasma concentration.

4.3 Dialysis Fluid

The driving force for transport of small molecules in dialysis is the transmembrane concentration gradient, which may be manipulated by altering the composition of the dialysis fluid.

4.3.1 Composition. Table 4 lists the composition of typical dialysate solution, with comparative values for serum. The presence of glucose in dialysate may be something of an anachronism. Its originally intended functions—stabilization of serum osmolality and osmotic extraction of water—have been rendered obsolete by high-sodium dialysate and by pressure- and volume-mediated ultrafiltration.

The need for an alkaline buffer to correct the accumulation of hydrogen ions in the patient with renal failure led to the early use of bicarbonate in dialysis solutions. Preparation of dialysate from concentrates, however, made the use of bicarbonate problematic. High concentrations of HCO_3^- are unstable in solution, as the high partial pressure of carbon dioxide leads to loss of the gas into the surrounding atmosphere and fall in HCO_3^- concentration. Further, the presence of calcium and magnesium ions in the dialysate causes precipitation of carbonates with these cations. During the 1960s, the problem was resolved by the use of acetate as the buffer anion. Once in the circulation, acetate is converted quickly and quantitatively to bicarbonate by normal metabolic pathways, and presents no problems of solubility or stability in dialysate solution.

As dialysis became more rapid and efficient, however, and transfer rates of acetate exceeded the rate of metabolic conversion, other problems arose. Acetate in the concentrations achieved in blood produced significant clinical toxicity, including hypotension, headaches, and vomiting. Patients differ in their sensitivity, but by now it is clear that there is a common and marked increase in

Table 4. Composition of serum and dialysate.

symptoms and hemodynamic instability associated with acetate use. The result has been a return to bicarbonate, but with more sophisticated dialysis delivery systems that allow mixing of two separate concentrates, one containing the buffer and the other the divalent cations Mg^{2+} and Ca^{2+}.

4.3.2 Water Preparation. In most modern dialysis systems the dialysate is prepared continuously by a proportioning system from concentrate and line water. During three 4-h hemodialysis treatments with 500-mL/min dialysate flow, a patient is exposed to 360 L of municipal water. This is roughly 25 times the average exposure by ingestion, and the transport of trace elements and toxins into the blood is far more direct. Moreover, dialysis patients are unable to clear toxins continuously by urinary excretion. Water that is suitable for drinking, therefore, requires further preparation for use in hemodialysis.

Most hemodialysis units use a serial water purification system with several components. After initial screening of particulate matter by a sediment filter, a water softener utilizes a cationic resin to exchange sodium ions for divalent cations, principally magnesium and calcium. An activated carbon filter is used to adsorb chlorine, chloramines, and dissolved organic material. Chlorine and chloramines are used extensively for bactericidal treatment of municipal water supplies, and in high dialysate concentrations can cause serious toxicity. A second sediment filter removes the small carbon particles released from the carbon filter.

For most water supplies, reverse osmosis (RO) is the method of choice for removal of solutes. Within the RO module, feedwater is in contact with a spirally wound or hollow-fiber semipermeable (often cellulose acetate) membrane, and a hydrostatic pressure is applied that exceeds the osmotic pressure generated by the dissolved solutes. As a result, water flows against the osmotic gradient, and a purified product is produced, even small ionic solutes having been removed by molecular sieving. Effectiveness of the device is monitored by measuring resistivity of feedwater and product water and calculating the percentage rejection of solutes, which ranges from 90% to 98% of monovalent and 95% to 99% of divalent ions. RO also effectively removes organic contaminants and bacteria, as well as particle matter; the combination of RO and pretreatment with water softener and carbon filter virtually always produces water pure enough for safe hemodialysis.

4.4 Dialysis Monitoring and Delivery Systems

Hemodialysis has evolved in 30 yr from a difficult and dangerous procedure, requiring constant supervision by a physician, to a routine treatment carried out with a minimum of technical intervention, even practicable in a patient's home. The dialysis apparatus has become more self-regulating, with the latest equipment capable of on-line automatic blood pressure recording and minute-to-minute variability in dialysate sodium concentration.

4.4.1 Functions. The delivery system, commonly referred to as the "dialysis machine," has four principal functions. First, it maintains flow through the blood chamber of the dialyzer, via the extracorporeal blood circuit. Second, it continuously prepares dialysate from line water and concentrate and keeps it flowing through the dialyzer. Third, it regulates ultrafiltration, usually by adjusting volume or hydrostatic pressure in the dialysate circuit. Fourth, it assures patient safety by monitoring and regulating temperature, pressures, and dialysate concentration, and detecting emergency situations like dialysis membrane ruptures or the presence of air in the blood returning to the circulation. A dialysis machine of the conventional "single-pass" type—in which dialysate flows in an uninterrupted path from line water to drain—is shown schematically in Fig. 11.

4.4.2 The Blood Circuit. In modern dialysis, blood is both withdrawn from and returned to the venous circulation; hence there is no pressure gradient to drive blood flow. The driving force for extracorporeal flow is therefore provided by a peristaltic roller pump in the blood circuit. This in turn necessitates a system of air traps and alarms to prevent air, which may be drawn into the system by the negative pressure created by the pump, from being returned to the patient's circulation.

An intermittent or continuous infusion of heparin is necessary to prevent coagulation of blood in the dialyzer or lines. A continuous pressure monitor on the returning ("venous")

blood line stops the blood pump if pressure exceeds or falls below preset limits. The dialyzer and all of the tubing that contacts blood are disposable. For economic reasons dialyzers are often reprocessed for repeated use by the same patient; the tubing is always discarded after one use.

4.4.3 The Dialysate Circuit. The dialysate is continuously prepared by a proportioning system from heated line water and bottled concentrate, usually mixing the two in a ratio of about 35 to 1. The solution is deaerated by subjection to negative pressure to prevent later spontaneous degassing, bubble formation, and "vapor lock" of blood channels in the dialyzer. The final composition is monitored by measuring the electrical conductivity of the solution; when the conductivity varies by more than 10% from the target value, an alarm condition results, and bypass valves are tripped that isolate the dialyzer from the dialysate path. A similar alarm system monitors temperature, and an optical sensor stops the blood pump if blood is detected in dialysate exiting from the dialyzer.

4.4.4 Ultrafiltration Systems. Control of the amount of fluid removed during a dialysis treatment requires special apparatus to regulate the hydrostatic pressure across the membrane. The earliest ultrafiltration control system, shown in Fig. 12(a), used with large open tanks of dialysate, consisted of a screw clamp (3) on the venous blood line. Increasing blood outflow resistance with the clamp raised the hydrostatic pressure in the dialyzer blood chamber (shown in figure as + signs) and increased the rate of ultrafiltration. The development of continuously proportioned single-pass delivery systems allowed regulation of the pressure on the dialysate side, and the system shown in Fig. 12(b) is now the most common method of ultrafiltration control. Raising inflow resistance with the throttle valve (4) causes the dialysate pump (5) to develop increasing negative pressure within

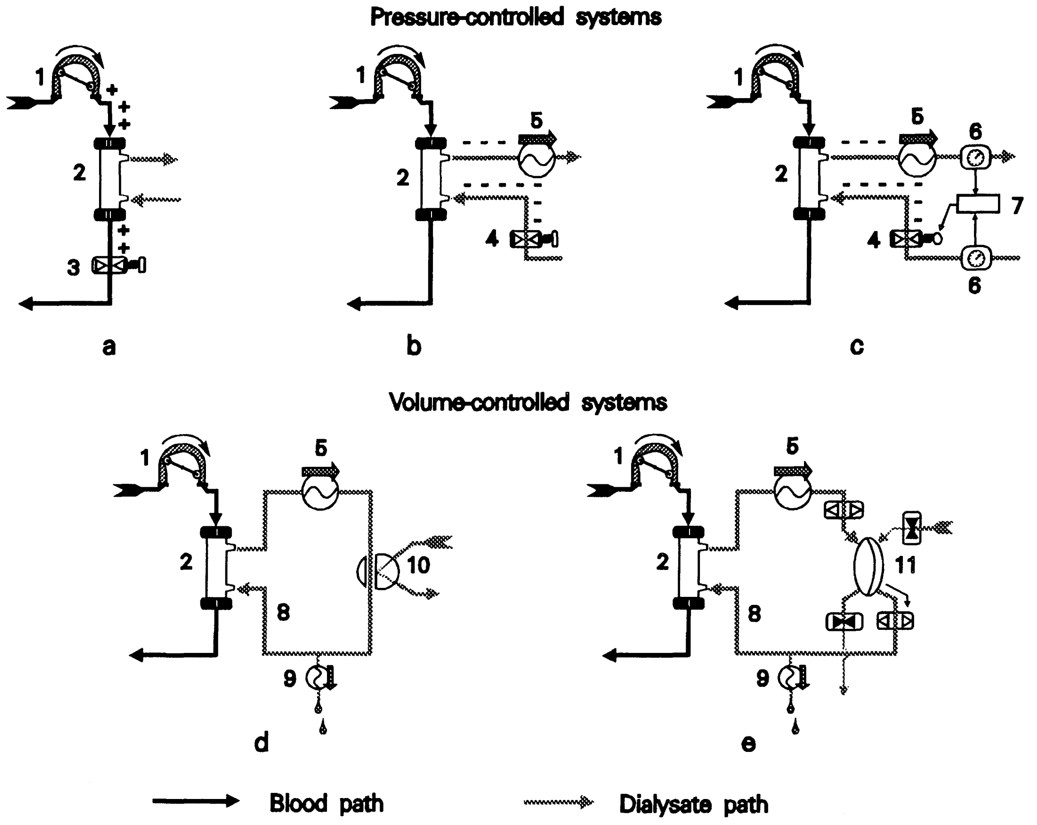

FIG. 12. Systems for ultrafiltration control. (1) blood pump; (2) dialyzer; (3) screw clamp on venous blood line; (4) dialysate line throttle valve; (5) dialysate pump; (6) flow sensor; (7) digital analyzer; (8) closed dialysate circuit; (9) ultrafiltration pump; (10) three-way valve for draining and refilling of dialysate circuit; (11) balancing chamber and valves. See text for explanation.

the dialysate circuit, which in turn increases water flux from blood to dialysate.

This system is vulnerable to a number of inaccuracies. Pressure measurement is not precise and varies with arm movements, fiber clotting, etc., and accurate clinical prediction of ultrafiltration requires exact knowledge of the dialyzer K_{UF} and blood oncotic pressure. A refinement of the system that seeks to overcome these problems [Fig. 12(c)] uses flow sensors (6) on the incoming and outgoing dialysate lines to monitor ultrafiltration more precisely, and to exert feedback control via a digital analyzer (7) that adjusts the throttle valve (4) to maintain the desired rate of fluid removal.

Pressure-based systems serve adequately for dialyzers with cellulose membranes, but use of the newer synthetics, with ultrafiltration coefficients greater than 10 mL/(mm Hg)h, has introduced another problem. The minimum ultrafiltration rate achievable with pressure-controlled systems is that rate generated by the minimum transmembrane hydrostatic pressure. This minimum pressure is the mean blood-chamber pressure, since the system does not generate positive pressure on the dialysate side. Flow resistances in the dialyzer and return lines will almost always produce a pressure of greater than 100 mm Hg; thus, for a dialyzer with a K_{UF} of 30 mL/(mm Hg)h (see Table 1), the minimum ultrafiltration rate would be 3000 mL/h, and could easily reach 5000–6000 mL/h. Removal of 10–20 L of fluid from a patient's circulation over a 3-h period could obviously lead to serious complications, and so in order to use high-UF membranes safely, new ultrafiltration control systems have been devised.

These "volumetric" systems [Fig. 12(d) and 12(e)] regulate ultrafiltration by removing fluid from a closed, rigid dialysate circuit (8) at a measured rate via an ultrafiltration pump (9). Since the dialysate loop is noncompliant, ultrafiltrate crosses the dialysis membrane at a rate that exactly matches the rate of removal by the ultrafiltration pump. Several variations exist, one of which [Fig. 12(d)] uses a closed loop that is drained and refilled at 2-min intervals via a three-way valve (10), and another [Fig. 12(e)] that uses balancing chambers separated by a diaphragm (11) to ensure the equality of dialysate inflow and outflow volume, with exiting dialysate displacing an exactly equal quantity of fresh dialysate into the circuit. In practice, two parallel chambers operating 180° out of phase are used to maintain more constant flow.

5. THE FUTURE

Dialysis is still in many ways a "half-way technology," which prolongs life but does not completely restore patients to a healthy, physiologic state. The definition of adequate dialysis remains elusive, despite our recent enchantment with blood urea. There is much yet to understand about the interaction of the dialysis apparatus with the immune system, and the influence of end-stage renal disease on immunity itself. Microminiaturization of dialysis components for the development of portable or wearable artificial kidneys, and the development of new, efficient membranes with transport profiles that more closely mimic the human kidney are priorities for technical development.

Despite its shortcomings, however, regular dialysis treatment has progressed in 30 yr from a relatively primitive, controversial, and short-term therapy to a highly technological and largely automated procedure backed by a complex and sophisticated body of pathophysiological knowledge, which keeps hundreds of thousands of patients alive for as much as 20 yr and more. If progress continues at that rate during the next few decades, concepts which now seem remote fantasy, such as implantable bioartificial kidneys, may well be realized.

GLOSSARY

Anion: A negatively charged ion.

Biocompatibility: Tendency of a foreign substance not to react with components of the body.

Cation: A positively charged ion.

Clearance: Solute removal capacity of a kidney or dialyzer, defined by total solute removal per unit time divided by plasma concentration.

Collodion: Precipitated nitrocellulose; Used as a dialysis membrane.

Colloid: Large–molecular-weight solutes that diffuse slowly or not at all across a semipermeable membrane.

Complement: A system of blood proteins that participate in host-defense and inflammatory reactions.

Convective Transport: Transfer of solute across a membrane by ultrafiltered solvent; transfer by "solvent drag."

Crystalloid: Small–molecular-weight solutes that diffuse readily across a semipermeable membrane.

Dalton: The unit of molecular weight; the mass of the nucleus of the hydrogen atom; equals 1.00794 u.

Dialysance: Solute removal capacity of a hemodialyzer, defined by total solute removal per unit time divided by plasma-dialysate concentration gradient.

Dialysate: In hemodialysis, the electrolyte solution on the diffusate side of the membrane.

Diffusate: The solution on the side of the dialysis membrane containing diffused crystalloids.

Fractional Excretion: The ratio of rate of urinary excretion to rate of glomerular filtration of a solute.

GFR: Glomerular filtration rate, the rate of ultrafiltration of plasma water at the glomerulus.

Glomerulus: The capillary tuft in the kidney where filtration takes place.

Hemodialysis: Dialysis of blood across an artificial membrane for treatment of kidney failure.

Middle Molecules: Molecules with molecular weight 1500–5000 Da, felt to be responsible for toxicity in kidney failure.

Nephron: The structural unit of renal function, consisting of a glomerulus and tubule.

Permeate: Diffusate.

Retentate: The solution on the side of the dialysis membrane containing retained colloid.

Reverse Osmosis: Transfer of water across a semipermeable membrane against an osmotic gradient, driven by hydrostatic pressure.

Uremia: The complex of symptoms of kidney failure.

INTRODUCTION

The word diamagnetic was introduced—originally as a noun, later as an adjective—by Michael Faraday in 1846. In the *Philosophical Transactions* (Faraday, 1846) one reads, "By a diamagnetic I mean a body through which lines of magnetic force are passing, and which by their action does not assume the usual magnetic state of iron or loadstone." It was constructed from the Greek prefix $\delta\iota\alpha$ (which means by, through, across) and the word *magnetic*—from the Latin word *magneticus*—which described, at that time, the special forces inherent in naturally occurring iron, iron oxides, and other substances.

The operational definition of diamagnetism, quoted in most electromagnetism and materials sciences textbooks for a century and a half, is still valid. A substance shaped in the form of a bar or needle and suspended freely between the poles of magnet is called paramagnetic or magnetic if it orients itself longitudinally with the magnetic lines of force, i.e., pointing towards the poles; it is called diamagnetic if it orients itself equatorially, i.e., perpendicular to the lines of force. Already in 1848 Mrs. Somerville wrote "Substances affected after the manner of bismuth (when suspended between the poles of an electromagnet) are said to be diamagnetic." To this day the semimetal bismuth is taken as the prototype of a diamagnetic substance.

Although the concept of magnetism of materials predated quantum mechanics by some 80 years, magnetism is a purely quantum-mechanical effect. Strictly classical systems in equilibrium cannot display a magnetic moment, even in the presence of a magnetic field. Understanding diamagnetism, therefore, requires a complete quantum-mechanical treatment.

1. THERMODYNAMIC ARGUMENTS

In the presence of an applied external magnetic field **B**, the free energy $F(T,\mathbf{B})$ of a given system at a given temperature T can be expanded in a Taylor series of the form

$$F(T,\mathbf{B})=F_0(T)-\mathbf{M}_0(T)\cdot\mathbf{B}$$
$$-(1/2\mu_0)\sum_{ij}B_i\chi_{ij}(T)B_j. \tag{1}$$

In Eq. (1) the vector $\mathbf{M}_0(T)$ is called the temperature-dependent intrinsic magnetization, and the second-rank quantity $\chi(T)$ is the magnetic susceptibility tensor. The magnetization $\mathbf{M}(T)$ is defined by

$$\mathbf{M}(T)=\mathbf{M}_0(T)+(1/\mu_0)\chi\cdot\mathbf{B}. \tag{2}$$

Materials for which $\mathbf{M}_0(T)$ is nonzero at a particular T are called *ferromagnets* or *ferrimagnets* at that temperature, irrespective of the properties of $\chi(T)$. Such is the case, for instance, of the metals Fe, Co, Ni, and Gd and the compounds CrO_2, EuS, and Fe_3O_4, *inter alia*, at low enough temperatures.

If, on the other hand, $\mathbf{M}_0(T)=0$, then the magnetic properties are dominated by $\chi(T)$. In particular, for isotropic systems where χ is a diagonal tensor, $\chi_{ij}(T) = \chi(T)\delta_{ij}$, if $\chi(T)$ is positive, then the substance is said to be *paramagnetic*, whereas if $\chi(T)$ is negative, then it is labeled *diamagnetic*. The definitions can be extended to particular directions of anisotropic systems.

Examples of paramagnets are Fe, Co, Ni, and Gd at high temperatures, most rare-earth compounds, and gaseous molecular oxygen. Examples of diamagnets include the noble gases He, Ne, Ar, Kr, and Xe, most molecular gases, liquids, and solids, and the semimetals As, Sb, Bi, and graphite.

It should be pointed out that the free energy of a diamagnet increases in the presence of a magnetic field, and therefore the system evolves so as to avoid high-field regions of space; there is a net repulsive force, caused by the magnetic field, acting on the diamagnet. Conversely the free energy of paramagnet decreases in the presence of a magnetic field, with an attendant attractive force.

2. DIAMAGNETISM OF ATOMS, MOLECULES, AND MOLECULAR SOLIDS

Lenz's law in electromagnetism (see ELECTRODYNAMICS, CLASSICAL) establishes that when the magnetic flux through an electrical circuit is changed, an induced current appears so as to oppose the flux change. In classical systems that current rapidly decays through dissipation, and a new state of equilibrium is achieved with no current flowing through the circuit, and with the new value of the magnetic flux permanently established. In quantized systems with a discrete, nondegenerate energy spectrum, such as a closed-shell atom or molecule, the induced current persists for as long as the applied field is present, and the net magnetic field—the sum of the applied field and the internal one generated by the electronic current in the atom—is always smaller than the applied field.

In addition, closed-shell systems, because of their nondegenerate ground state, possess no intrinsic magnetic moment and are therefore diamagnetic. (It should be remembered that intrinsic magnetic moments are caused by nonvanishing orbital or spin angular momenta which are able to reorient themselves in the presence of a magnetic field; that capability of reorientation requires degeneracy of the ground-state manifold.)

2.1 Hamiltonian of Electrons in a Magnetic Field

A well-established result, valid in both classical and quantum mechanics, states that a system of electrons in a magnetic field **B**, defined by a vector potential **A**, such that

$$\nabla\times\mathbf{A}=\mathbf{B}, \tag{3}$$

is described by the following Hamiltonian:

$$H=\frac{1}{2m}\sum_i[\mathbf{p}_i+e\mathbf{A}(\mathbf{r}_i)]^2+V-\sum_i e\phi(\mathbf{r}_i)$$
$$+\frac{e}{m}\sum_i\sigma_i\cdot\nabla\times\mathbf{A}(\mathbf{r}_i). \tag{4}$$

In Eq. (4) m is the mass of the electron, e is the (positive) charge of the proton, V is the internal electrostatic energy of the electronic system, ϕ is the electrostatic (scalar) potential, and $\mathbf{r}_i$, $\mathbf{p}_i$, and $(e/m)\,\sigma_i$ are the position, the momentum, and the spin magnetic moment of the *i*th electron, respectively.

For a single *atom* or *ion* in a uniform magnetic field of magnitude B oriented in the z direction, it is convenient to choose the so-called symmetric gauge

$$\mathbf{A}=\tfrac{1}{2}\mathbf{B}\times\mathbf{r}, \tag{5}$$

where the origin of the gauge is located at the nucleus. Under such conditions the Hamiltonian (4) reduces to

$$H=\sum_i\left[\frac{1}{2m}p_i^2+e\phi(\mathbf{r}_i)+\frac{eB}{2m}(L_{zi}+2\sigma_{zi})+\frac{e^2B^2}{8m}(x_i^2+y_i^2)\right]+V. \tag{6}$$

The terms in the summation correspond, for each electron, to the kinetic energy, the outside potential energy, the coupling of the magnetic moments arising from the orbital (L_{zi}) and the spin (σ_{zi}) magnetic moments of the electrons to the magnetic field, and the weak quadratic term, proportional to B^2.

2.2 Langevin Theory for Closed-Shell Systems

Diamagnetism arises in systems where the contribution from the third term in Eq. (6)—linear in B—vanishes, i.e., for atoms and molecules with a closed-shell structure. The magnetic-field dependence of the energy originates then exclusively from the term quadratic in B. For a system of N *atoms* or *ions* per unit volume, each consisting of n electrons which have an average square radial distance from the nucleus equal to $\langle r^2\rangle$, the summation

$$\sum_i (x_i^2+y_i^2)$$

in Eq. (6) can be replaced by $\frac{2}{3}Nn\langle r^2\rangle$. This substitution results in an excess magnetic energy per unit volume of

$$(e^2B^2/12m)\ nN\langle r^2\rangle,$$

and, consequently, in a diamagnetic susceptibility (Langevin, 1905)

$$\chi=-(\mu_0e^2/6m)\ nN\langle r^2\rangle. \tag{7}$$

If the system (solid, liquid, or gas) consists of N_α atoms or ions of the α type per unit volume, and all these species are closed electronic shells, then the diamagnetic susceptibility of the system is given by

$$\chi=-\frac{\mu_0e^2}{6m}\sum_\alpha n_\alpha N_\alpha\langle r_\alpha^2\rangle, \tag{8}$$

where n_α and $\langle r_\alpha^2\rangle$ are, respectively, the number of electrons on the α atom or ion and the mean value of r^2 for the electrons from their nucleus, for that particular species.

It should be noted that the diamagnetism of closed-shell systems is essentially a very weak perturbation of the nondegenerate ground state caused by the presence of the applied magnetic field. It is therefore a purely quantum-mechanical phenomenon—since it requires a discrete, nondegenerate lowest energy state in the spectrum, a feature that can only be achieved quantum mechanically—and an effect that depends extremely weakly on the temperature. This virtual temperature independence is, once again, caused by the same features of the spectrum: Only at inaccessible temperatures are the excited states appreciably populated, the only way in which the various $\langle r_\alpha^2\rangle$ in Eq. (8) can be affected by the temperature.

3. ORBITAL DIAMAGNETISM OF METALLIC ELECTRONS

Metallic electrons are, by their very nature, itinerant. Their wave functions extend essentially over the entire crystal and their energy spectrum is in the form of bands separated, in some cases, by forbidden energy gaps. The single-electron wave functions (see ELECTRONIC STRUCTURE OF SOLIDS) are in the form of Bloch states, i.e., a product of

1. a plane wave of vector **k**,
2. a periodic function with the full periodicity of the crystal lattice, and
3. a spinor.

Each Bloch function is thus labeled by a **k** vector, a band index ν (a positive integer), and a spin index σ (↑ or ↓). The vector **k** is restricted to a finite region in reciprocal space (**k** space), a polyhedron known as the Brillouin zone. The energy ϵ of each state is given by the band-structure function $\epsilon_\nu(\mathbf{k},\sigma)$, which is continuous in **k** space. These features arise from the solution of the Schrödinger equation in a periodic potential, and from the properties of periodic functions and Fourier series in three dimensions.

The occupation of the one-electron energy bands follows Fermi–Dirac statistics (see STATISTICAL MECHANICS, CLASSICAL; STATISTICAL MECHANICS, QUANTUM), with no more than one electron occupying each state. At very low temperatures, $T \to 0$, the Fermi–Dirac distribution is a step function, with all electronic states with energy $\epsilon < \epsilon_F$ being occupied by one electron, and all states with $\epsilon > \epsilon_F$ being empty. The energy ϵ_F is called the Fermi level and, in a metal, falls in the middle of one or more bands, i.e., not in the middle of a forbidden energy gap. The equation

$$\epsilon_v(\mathbf{k},\sigma) = \epsilon_F \tag{9}$$

defines, for a metal, a surface in **k** space called the Fermi surface (see ELECTRONIC STRUCTURE OF SOLIDS). This surface consists of one or more sheets (one or more for each band v which crosses the Fermi level), is defined within the Brillouin zone, and has all the symmetry and periodic properties of the Brillouin zone and **k** space.

Metallic electrons do not form closed electronic shells, and therefore do not fall in the category discussed in the previous section. The fact that the Fermi level falls in the middle of a continuous energy band guarantees that the ground state of the many-electron system is not part of the discrete spectrum, i.e., the ground state is the lowest of a set of continuum states. The response of metallic electrons to an applied magnetic field is, in general, very complex, and contains several contributions of various characteristics which must be treated separately:

1. If the bands of different spin are not identical and are occupied differently then the system develops a spontaneous local magnetization which, depending on the way it distributes itself, results in magnetic ordering (see MAGNETIC ORDERING IN SOLIDS); these ordered states include ferromagnets, ferrimagnets, antiferromagnets, spiral spin arrangements, etc. (see FERROMAGNETISM AND FERRIMAGNETISM).
2. If the bands of different spin are identical—and identically occupied—in the absence of an applied magnetic field, then the electron spin and its associated magnetic moment are responsible for a rearrangement of the band occupation when a magnetic field is applied; the imbalance in the spin distribution results in a temperature-independent positive susceptibility known as Pauli paramagnetism (see PARAMAGNETISM). For simple metals of columns I, II, III, and IV of the periodic table that contain only fully occupied and/or fully empty *d* and *f* atomic shells, a commonly used approximation is the so-called *free-electron* model. This model replaces the periodic potential of the lattice by a constant, i.e., the periodic oscillations of the potential are completely smoothed out. As a consequence the periodic factor in the Bloch state reduces to a plane wave of vector $\mathbf{G}_v$; the set of $\mathbf{G}_v$'s is infinite but discrete and constitutes the so-called the reciprocal lattice. The energy spectrum for the Bloch states in the free-electron model is given by

$$\epsilon_v(\mathbf{k},\sigma) = \frac{\hbar^2}{2m} (\mathbf{k}+\mathbf{G}_v)^2. \tag{10}$$

In this model the Pauli contribution to the (paramagnetic) susceptibility per unit volume is equal to

$$\chi_{\text{Pauli}} = \mu_0 \frac{\mu^2 m}{\pi^2 \hbar^2} (3\pi^2 Nn)^{1/3}. \tag{11}$$

In Eq. (11) μ is the Bohr magneton, N is the number of metal atoms per unit volume, and n is the number of metallic (conduction) electrons per atom.
3. There is, in addition, an orbital diamagnetic contribution to the susceptibility, known as Landau diamagnetism, discussed below. For the free-electron model this contribution is

$$\chi_{\text{Landau}} = -\mu_0 \frac{\mu^2 m}{3\pi^2 \hbar^2} (3\pi^2 Nn)^{1/3}, \tag{12}$$

i.e., $\chi_{\text{Landau}} = -\frac{1}{3}\chi_{\text{Pauli}}$, which yields a total *paramagnetic* susceptibility

$$\chi_{\text{free electrons}} = \tfrac{2}{3}\chi_{\text{Pauli}} \tag{13}$$

for the free-electron model. The free-electron model, however, has only a very restricted range of applicability. For some substances—the semimetals As, Sb, Bi, and graphite being the most notable examples—real band-structure effects, caused by the periodic potential, produce a large enhancement of the Landau diamagnetism, by factors of up to several hundred. The diamagnetic contribution thus overwhelms the paramagnetic Pauli term; the net result is a negative χ and a diamagnetic solid.

4. The orbital contribution of metallic electrons also includes a diamagnetic term which oscillates with the magnetic field, and is periodic in $1/B$. This oscillatory contribution is called the de Haas–van Alphen effect. Its periods and amplitudes give very precise information on the geometrical and differential properties of the Fermi surface.

3.1 Quantization of Itinerant Electrons in a Magnetic Field

To study diamagnetic effects in metals the effect of the electron-electron interaction can be neglected, and the electrons may be treated as independent particles. Independent electrons moving in a crystal lattice in a magnetic field are described by Eq. (4), with the electron–electron interaction made to vanish, $V=0$, and with the electrostatic term $[-e\phi(\mathbf{r}_i)]$ representing the periodic potential acting on electron i and caused by the lattice of nuclei and ionic cores. The solution of the Schrödinger equation under these conditions is still a very complex and difficult process. The difficulty arises from conflicting periodicities imposed separately by the lattice and the magnetic field. The problem is simple only in the free-electron case, $\phi=0$. The solution was obtained by Landau in 1930, the early days of quantum mechanics. Landau chose the field $\mathbf{B}$ along the z axis and an asymmetric gauge:

$$\mathbf{A}=[0,Bx,0]. \tag{14}$$

The resulting spectrum is

$$\epsilon(\nu,k_z)=(\nu+\tfrac{1}{2})\hbar\omega_c+[\hbar^2/2m]k_z^2, \tag{15}$$

where ν is a nonnegative integer, k_z is the wave vector for motion along the direction of the magnetic field, and ω_c, the so-called cyclotron frequency, is given by

$$\omega_c=eB/m. \tag{16}$$

This spectrum for three-dimensional electrons, which depends only on two quantum numbers (a discrete ν and a continuous k_z), is highly degenerate—each energy is shared by a very large number of states. There is a "hidden" quantum number, k_y, necessary to define the wave function completely. The energy ϵ does not depend on k_y, and all wave functions with the same ν and k_z—no matter what the value of k_y—have the same energy. For each fixed value of the set (ν,k_z), there are

$$L_xL_yeB/2\pi\hbar \tag{17}$$

different k_y states, where L_xL_y is the macroscopic area of the crystal—assumed to be prismatic—perpendicular to the direction of the magnetic field.

Each integer ν defines for the perpendicular motion in the (x,y) plane and for fixed k_z a discrete energy level, called a Landau level.

From this spectrum, Eqs. (15)–(17), its degeneracy, and its dependence on the magnetic field intensity B, all thermodynamic quantities can be calculated for the free-electron model. Some of these quantities are discussed explicitly in the next two subsections.

Extension of Eqs. (15)–(17) to the case of a nonvanishing periodic potential was proposed by Onsager (1952), who based his method on a semiclassical approach. This approach consists of determining electron trajectories and applying to them the Bohr–Sommerfeld "old" quantum-mechanical quantization rules, i.e.,

$$\int_{\text{closed orbit}} \mathbf{p}\cdot d\mathbf{r}=(\nu+\gamma)2\pi\hbar, \tag{18}$$

where ν is a nonnegative integer, γ is a (positive) phase correction which takes the value $\frac{1}{2}$ in the free-electron case, the position $\mathbf{r}$ follows the closed semiclassical trajectories of the electron in the (x,y) plane, $\mathbf{p}$ is the *canonical* momentum

$$\mathbf{p}=\hbar\mathbf{k}-e\mathbf{A}, \tag{19}$$

$\hbar\mathbf{k}$ is interpreted as the *kinetic* momentum, and $-e\mathbf{A}$ is the contribution of the field to the canonical momentum.

The semiclassical equations of motion of electrons in a periodic potential and a magnetic field are given by

$$k_{\text{parallel}}=\text{const}, \tag{20}$$

where k_{parallel} is the component of $\mathbf{k}$ parallel to $\mathbf{B}$,

$$\epsilon_\nu(\mathbf{k},\sigma)=\text{const}, \tag{21}$$

and

$$\hbar\dot{\mathbf{k}} = -e\dot{\mathbf{r}}\times\mathbf{B}, \tag{22}$$

which integrated and with proper choice of the origin yields

$$\hbar\mathbf{k} = -e\mathbf{r}\times\mathbf{B} \tag{23}$$

for the motion perpendicular to **B**.

Insertion of Eqs. (23) and (19) into Eq. (18), use of Stokes's theorem, and application of Eq. (3) yields Onsager's famous result for the quantization of itinerant electron orbits in a uniform magnetic field (Onsager, 1952),

$$\int_{\text{closed orbit}} \mathbf{p}\cdot d\mathbf{r} = e\Phi = (\nu+\gamma)2\pi\hbar, \tag{24}$$

for the motion of the electrons perpendicular to **B**. In Eq. (24) Φ is the magnetic flux encircled by the electron in its trajectory in the plane perpendicular to **B**. In other words the only trajectories that are (quantum-mechanically) allowed are those that, in the plane perpendicular to **B**, encircle a magnetic flux Φ which takes the discrete values

$$\Phi_\nu = (\nu+\gamma)\,\frac{2\pi\hbar}{e}. \tag{25}$$

Because the magnetic flux is quantized, and the value of the magnetic field B is externally determined, the areas of the allowed orbits in real space, A_ν, must take well-defined, discrete values. In addition, Eqs. (20), (21), and (23) state that the orbits in real space in the plane perpendicular to **B** are proportional to—and rotated by an angle of $\pi/2$ from—the corresponding trajectories in **k** space. The cross sections (20) at a constant k_{parallel} of the surface of constant energy in **k** space, Eq. (21), are therefore proportional to the areas A_ν of the allowed orbits in real space. The constant of proportionality between areas in **k** space and real space, as given by Eq. (23), is proportional to B^2, i.e., equal to $(eB/\hbar)^2$. Therefore, the allowed cross-sectional areas S_ν of the surfaces of constant energy in **k** space are given by

$$S_\nu = (\nu+\gamma)\,\frac{2\pi e}{\hbar}\,B. \tag{26}$$

Because the cross-sectional areas in **k** space S_ν perpendicular to **B** are quantized—take only the discrete values given by Eq. (26)—the energies for the motion perpendicular to **B** are also quantized. Two successive levels, which differ by $\Delta\nu = \pm 1$, are separated by an energy $\Delta\epsilon$, which defines, for that particular value of the energy and that particular value of k_z, a cyclotron frequency ω_c^* and an effective cyclotron mass m_c^*:

$$\Delta\epsilon = \hbar\omega_c^* = \hbar eB/m_c^*. \tag{27}$$

When the Onsager rules (26) are applied to the free-electron model, the results (15)–(17) are obtained if $\gamma = \frac{1}{2}$. For this particular case $\omega_c^* = \omega_c$, as given by Eq. (16), and $m_c^* = m$, i.e., the cyclotron mass is equal to the electron mass.

It should be mentioned that transition between two adjacent Landau levels, with conservation of k_{parallel}, can be induced, for electrons near the Fermi level, by microwave or far-infrared radiation; when the frequency ω of that radiation is in the vicinity of ω_c, a resonance—the so-called cyclotron resonance or diamagnetic resonance—is observed.

3.2 Landau Diamagnetism

For noninteracting electrons, the total energy of the system—the metal—is obtained by adding the individual energies of each electron. Since electrons satisfy Fermi–Dirac statistics (see STATISTICAL MECHANICS, QUANTUM), in the limit $T\rightarrow 0$ that total energy is obtained by summing one-electron energies for all states with energy below the Fermi level ϵ_F.

The term $\frac{1}{2}$ in the factor $\nu+\frac{1}{2}$ in Eq. (15)—or equivalently the term γ in the factor $\nu+\gamma$ in Eqs. (25) and (26)—, which is ordinarily called the zero-point energy, guarantees that although upon the application of a magnetic field some states increase their energy and others decrease it, the energy sum over states of contiguous occupation up to the Fermi level always shows an *increase* by an amount proportional to B^2, thus yielding a diamagnetic contribution to the susceptibility. This is the Landau diamagnetic contribution to the susceptibility of metallic electrons.

The summation is, in general, difficult to perform. It can be done numerically—and laboriously—for some specific cases, where the number of carriers is small, i.e., for the semimetals. For the free-electron model the summation can be accomplished in closed form. The result is that quoted in Eq. (12).

3.3 The de Haas–van Alphen Effect

The de Haas–van Alphen effect is an oscillatory variation in the magnetic susceptibility of metals as a function of the magnitude of the *static* magnetic field intensity B. It is an effect observed in strong magnetic fields, for pure specimens, and at low temperatures. These three conditions arise from the necessity to have the Landau levels widely separated, not blurred by electron collision effects with impurities, and populated with a sharp discontinuity at the Fermi level, i.e., a discontinuity in occupation of essentially 1 between the last "occupied" and the first "empty" levels. These conditions may be summarized by two inequalities:

$$k_B T \ll \hbar\omega_c^*, \quad \omega_c^*\tau \gg 1, \tag{28}$$

where ω_c^* is the cyclotron frequency defined by Eq. (27), k_B is Boltzmann's constant, and τ, the relaxation time, is the median time between electron collisions (see THERMODYNAMICS, EQUILIBRIUM; TRANSPORT PHENOMENA).

The *loci* of allowed quantum states—in **k** space—for itinerant electrons in a periodic lattice and a magnetic field are "tubes," i.e., cylindrical shells of well-determined, discrete cross sections, given by Eq. (26). The cylinders, not necessarily of circular cross section, are inside each other in order of either increasing or decreasing energy. For the free-electron model the tubes are concentric circular cylinders of axis parallel to **B**. These highly degenerate tubes, when the conditions (28) are satisfied, are populated by electrons if the energy of their states is lower than ϵ_F, i.e., states are occupied for that part of those tubes that lies inside the Fermi surface (9). Only *some* parts of *some* tubes are populated by electrons. The rest—the states for which $\epsilon > \epsilon_F$—are allowed but empty states. This distribution is illustrated in Fig. 1.

As the magnitude B of the field increases the tubes get more widely separated and contain more states—as indicated by Eqs. (26) and (17). The tubes thus get repopulated at each increasing value of the field. For each orientation (θ,ϕ) of the magnetic field **B** there are discrete values of the field intensity B_ν for which a given tube gets completely depopulated, i.e., it "leaves" the Fermi surface and lies completely outside. These values of the field B_ν satisfy the condition

$$S_\nu = (\nu+\gamma)\,\frac{2\pi e}{\hbar}\,B_\nu = S_{\text{Fermi surface}}(\theta,\phi), \tag{29}$$

where $S_{\text{Fermi surface}}(\theta,\phi)$ is the *extremal* cross-sectional area of the Fermi surface in the direction perpendicular to **B**. This phenomenon of allowed-energy tubes "peeling off" the Fermi surface results in a contribution to the free energy, the magnetization, and the susceptibility of the sample which is periodic in $1/B$, with period

$$\Delta\left(\frac{1}{B}\right) = \frac{2\pi e}{\hbar S_{\text{Fermi surface}}(\theta,\phi)}, \tag{30}$$

i.e., a $1/B$ period inversely proportional to the extremal cross-sectional area of the Fermi surface in the direction (θ,ϕ) perpendicular to **B**.

If the Fermi surface is complex and exhibits several sheets and/or several extremal cross-sectional areas for a given sheet, the magnetization becomes a very complicated oscillatory function. The analysis of the various periods in $1/B$ permits the determination of the corresponding cross-sectional areas.

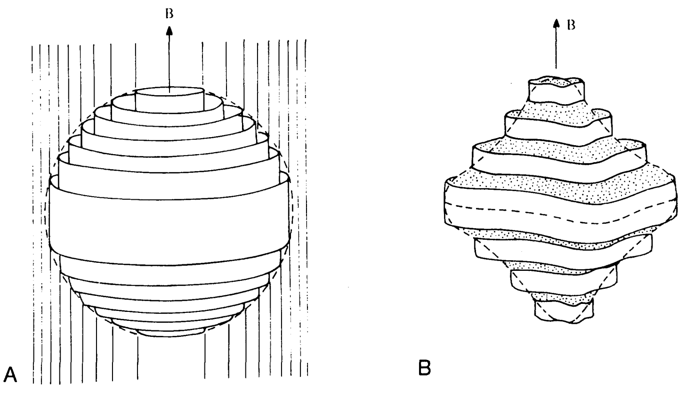

FIG. 1. Schematic representation of the quantization of metallic electrons in a magnetic field. The depicted tubes are the *loci* of allowed states in **k** space. Only the occupied portions of the tubes are drawn. (a) The free-electron model. (b) An arbitrary potential. [From Falicov (1973)].

Studies of the variation of the oscillations with orientation (θ,ϕ) of the magnetic field lead to accurate determination of the geometry and topology of the Fermi surface of the metal under consideration.

The amplitude of the oscillations and its variation with temperature yield information about the separation between the levels—the cyclotron mass m_c^* at the Fermi level for a particular orientation (θ,ϕ), an intrinsic property of the metal—as well as the relaxation time τ, a specific property of the sample under study. The de Haas–van Alphen effect provides the most useful tool to investigate the electronic properties of metals. It yields extremely accurate information on the structural and dynamical properties of itinerant-electron states in solids.

4. DIAMAGNETISM IN SUPERCONDUCTORS

Superconductors are perfect diamagnets for a given range of intensities of applied magnetic fields. They are also perfect conductors, i.e., they have zero resistivity. Although the zero resistivity is a necessary condition for perfect diamagnetism—since it is required for the induced currents in Lenz's law not to decay—by itself it only implies that the magnetic field in the bulk of a superconductor cannot be changed, whatever its value. The expulsion of the field from the bulk of a superconductor is an additional property, known as the Meissner effect (Meissner and Ochsenfeld, 1933). It is illustrated in Fig. 2.

Superconductivity (see SUPERCONDUCTIVITY, LOW TEMPERATURE) is a phase, a state of matter (in the sense that ice and steam are phases of water and diamond and graphite are phases of pure carbon) observed *only* in some solids, mostly metals. The superconducting state has several characteristic properties:

1. When it exists for a given substance, it exists only at temperatures below a so-called transition temperature T_c, and in general down to the absolute zero of the temperature scale 0 K. Historically, substances with the highest known values of T_c have been first pure metals (Hg with $T_c = 4.2$ K, Pb with $T_c = 7.2$ K, and Nb with $T_c = 9.5$ K), later transition-metal compounds (NbN with $T_c = 16.0$ K, V_3Si with $T_c = 17.1$ K, Nb_3Sn with $T_c = 18.05$ K, and Nb_3Ge with $T_c = 23.2$ K), and, since 1986, the so-called *high-T_c* materials, all four- or five-element compounds which contain copper and oxygen (La–Ba–Cu–O with T_c of approximately 30 K, rare-earth–Ba–Cu–O with T_c of approximately 92 K, Bi–Sr–Ca–Cu–O with T_c of approximately 105 K, and—the known record at this time—Tl–Ca–Ba–Cu–O with $T_c = 125$ K) (see SUPERCONDUCTIVITY, LOW-TEMPERATURE; HIGH-TEMPERATURE SUPERCONDUCTIVITY).
2. It exhibits zero dc resistivity, i.e., infinite conductivity for zero-frequency measurements (an effect discovered in mercury by Kamerlingh Onnes in 1911),

$$\rho(\omega=0;T<T_c)=0. \tag{31}$$

3. It exhibits, for weak magnetic fields, perfect diamagnetism, i.e., its magnetic susceptibility is given by

$$\chi=-1 \tag{32}$$

which means that magnetic flux lines are completely expelled from the superconductor and that there is a force pushing superconductors away from magnetic fields. This is the Meissner effect discovered by Meissner and Ochsenfeld (1933).

4. In addition to the effect of high tempera-

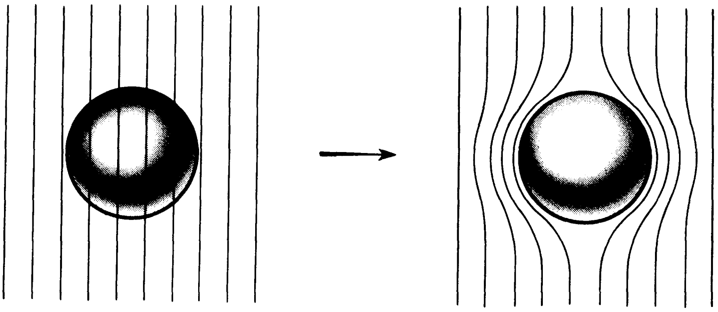

FIG. 2. Schematic representation of the Meissner effect. When a superconducting sphere is cooled in a constant applied magnetic field, below the transition temperature T_c the lines of induction **B** are ejected from the sphere. [From Kittel (1986)].

tures, superconductivity can be destroyed (with a return to the normal metallic state) by either a large enough electric current $I > I_c$ or a large enough applied magnetic field $B > H_c$. The quantities I_c and H_c are called the critical current and the critical magnetic field, respectively.

5. Superconductivity is a macroscopic quantum phenomenon with amplitudes and phases associated with an order parameter ψ. Therefore, interference and diffraction effects can be achieved, in particular the Josephson effect (Josephson, 1962). These effects can be fruitfully employed in processing, storing, and retrieving information, i.e., in computer technology (see SUPERCONDUCTING DEVICES).

4.1 The Meissner Effect

Meissner and Ochsenfeld (1933) discovered that, when a superconductor is cooled below T_c in the presence of a magnetic field, at the transition the lines of induction **B** are completely expelled from the bulk of the sample. In other words, inside the superconductor Eq. (32) is obtained or, equivalently,

$$\mathbf{B} = 0. \tag{33}$$

This result holds up to a given value of the applied field B. In the so-called type-I superconductors there is only one critical field, H_c. For $B > H_c$ superconductivity is destroyed, the flux fully penetrates the sample, and the metal returns to its normal state.

In type-II superconductors there is no field penetration for $B < H_{c1}$ and the superconductor acts as a perfect diamagnet. For intermediate field strengths $H_{c1} < B < H_{c2}$, the magnetic flux lines partially penetrate the superconductor but do not destroy the superconducting state. Since, in general, H_{c2} is very large, this feature of type-II superconductors makes them useful as materials for magnets (see SUPERCONDUCTING MAGNETS). Finally for $B > H_{c2}$ superconductivity is again destroyed with a return of the substance to its normal state. This behavior is illustrated in Fig. 3.

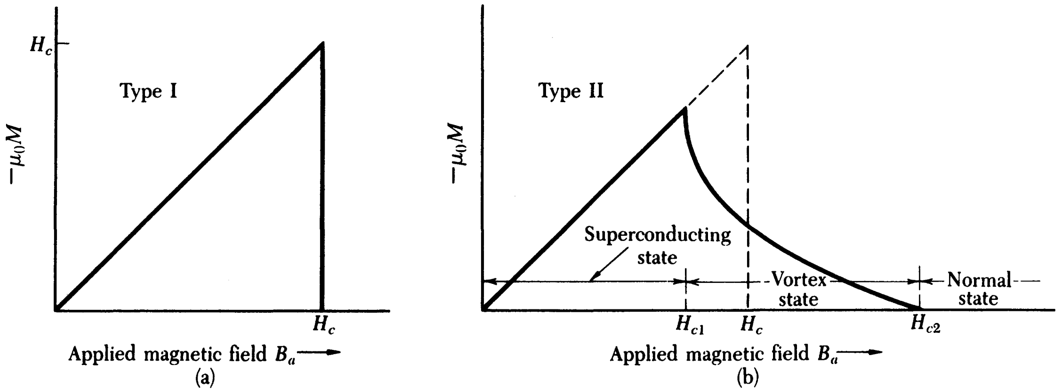
4.2 The London Theory

The London theory (London and London, 1935) is completely classical. It incorporates into Maxwell's equations, phenomenologically, the electrodynamic characteristics of superconductors. The zero-resistivity property (31) requires that, since

$$\rho \mathbf{j} = \mathbf{E},$$

the electric field **E** should vanish everywhere in a superconductor. The Meissner effect, Eqs. (32) and (33), implies vanishing magnetic field **B** in the bulk. These two conditions led London, in 1950, to *postulate* that in a superconductor the current density **j**, instead of being proportional to **E**, as is the case in other media, is proportional to the vector potential **A**,

$$\mathbf{j} = -[1/\mu_0\lambda_L^2]\mathbf{A}, \tag{34}$$



(a) (b)

FIG. 3. (a) Magnetization vs applied magnetic field for a type I superconductor exhibiting the Meissner effect (perfect diamagnetism) below H_c. (b) Magnetization vs applied magnetic field for a type II superconductor. [From Kittel (1986)].

where the constant of proportionality defines the length λ_L, the *London penetration depth.* The London equation (34), by taking the curl on both sides, may also be expressed as

$$\nabla\times\mathbf{j}=[1/\mu_0\lambda_L^2]\mathbf{B}. \tag{35}$$

Since the vector potential **A** is *not*, in general, a physically measurable quantity, and the current density **j** *always is*, Eq. (34) in effect selects a particular gauge, the so-called London gauge. Equation (34) must be consistent with Maxwell's equations. Therefore, it implies that in the absence of charges $\nabla\cdot\mathbf{A}=0$, and that the normal components of **A** are zero on any external surface through which no external current is fed. Additional conditions on the gauge, compatible with the physical boundary conditions, should be imposed on problems with multiply connected geometries.

It is easily seen that the London equation implies the Meissner effect, and that λ_L is the characteristic length describing the penetration and exponential decay of the magnetic field **B** into a superconductor. From Maxwell's equation,

$$\nabla\times\mathbf{B}=\mu_0\mathbf{j}, \tag{36}$$

when the curl is taken on both sides and use is made of Eq. (35) and of Maxwell's other equation, $\nabla\times\mathbf{B}=0$, one obtains

$$\nabla^2\mathbf{B}=\mathbf{B}/\lambda_L^2. \tag{37}$$

Equation (37) does not allow a constant-**B** solution, unless $\mathbf{B}=0$. In addition Eq. (36) guarantees that $\mathbf{j}=0$ wherever **B** vanishes. In a superconductor extending over the half-space $x \geqslant 0$, if the field at the boundary $x=0$ is parallel to the surface and of magnitude B_0, a solution of Eq. (37) yields

$$B(x)=B_0\exp(-x/\lambda_L), \tag{38}$$

i.e., the field decays exponentially into the superconductor, a perfect diamagnet, with characteristic length given by the *London penetration depth.*

4.3 The Ginzburg–Landau Theory

4.3.1 General Formulation. In 1950 Ginzburg and Landau (GL) proposed a macroscopic, phenomenological theory of superconductivity, which was independent of the microscopic aspects of the phenomenon. The theory is quantum-mechanical, in the sense that it includes coherent, macroscopic quantum effects. It is a pioneering theory which, independent of the mechanisms responsible for superconductivity, is still valid today. It contains such diverse phenomena as magnetic-field penetration depths, coherence lengths, magnetic-field flux quantization, magnetic-field dependence of the superconducting order parameter, and the Josephson effect. It can be applied to all superconductors, as well as to superfluid ^{3}He, and has become the prototype theory to study a whole class of phenomena related to spatial dependence in second-order phase transitions.

The GL theory introduces a complex order parameter ψ which is allowed to vary in space. Originally GL interpreted ψ as an amplitude, and $|\psi|^2$ as the density of the "superconducting" electrons (they envisioned a superconductor as two interpenetrating electron fluids: the nondissipative, nonresistive superconducting electron fluid, and the dissipative, resistive "normal" electron fluid). In 1959, however, Gor'kov proved that for temperatures below and close to T_c, equations identical to those of GL could be obtained from the Bardeen–Cooper–Schrieffer (BCS) microscopic theory of superconductivity (1957), and that the GL parameters ψ could be interpreted (except for a trivial constant of proportionality) as what in the BCS theory is known as the energy-gap parameter.

The starting point of the GL theory is the introduction of a magnetic Helmholtz free energy F_{SH} for the superconductor, derived from plausibility arguments:

$$F_{SH}=\int_{\text{superconductor}} d^3r\biggl[F_{N0}+\Delta F(|\psi|^2) + \left(\frac{1}{2m}\right)\left|-i\hbar\nabla\psi-e^*\mathbf{A}\psi\right|^2 + \left(\frac{1}{2\mu_0}\right)B^2(\mathbf{r})\biggr]. \tag{39}$$

Here F_{N0} is the free-energy density of the normal state in the absence of a magnetic field; ΔF is the difference of free-energy densities between the superconducting and the normal states (also in the absence of a field) and is a function of $|\psi|^2$. The third term is the gauge-invariant "superconducting kinetic energy," and the last term is the magnetic-field energy in the superconductor. The vector potential is $\mathbf{A}$, $\mathbf{B}$ is the magnetic field, and e^* is an effective charge, known now to be $-2e$, twice the charge of the electron (the charge of a "Cooper pair" in the BCS theory). All terms in Eq. (39) are functions of the position $\mathbf{r}$, and change with the magnitude and direction of the magnetic field.

Because the proper variables of the magnetic Helmholtz free energy are the temperature T and the magnetization $\mathbf{M}$, where

$$\mathbf{M} = (1/\mu_0) \int_{\text{all space}} d^3r[\mathbf{B}(\mathbf{r}) - \mathbf{B}_a],$$

$$\mathbf{B}_a = \text{applied magnetic field}, \tag{40}$$

F_{SH} is not continuous at the critical fields. The function which is continuous at H_{c1} and H_{c2}, and whose proper variables are T and $\mathbf{B}_a$, is the Gibbs free energy G_{SH}, given by

$$G_{\text{SH}} = F_{\text{SH}} - \mathbf{M}\cdot\mathbf{B}_a. \tag{41}$$

Substitution of Eqs. (39) and (40) into Eq. (41) yields

$$\begin{aligned} G_{\text{SH}} = G_{\text{NH}} + \int_{\text{superconductor}} & d^3r[\Delta F(|\psi|^2) \\ & + (1/2m)|-i\hbar\nabla\psi - e^*\mathbf{A}\psi|^2] \\ & + \frac{1}{2\mu_0} \int \int_{\text{all space}} d^3r[\mathbf{B}(\mathbf{r}) - \mathbf{B}_a]^2, \end{aligned} \tag{42}$$

where

$$G_{\text{NH}} = \int_{\text{superconductor}} d^3r \left[F_{N0} + \frac{B_a^2}{2\mu_0} \right].$$

It should be noted that the last term in Eq. (42) is to be integrated over *the whole space* (both in the superconductor and outside). Minimization of G with respect to the four functions ψ and $\mathbf{A}$ (or equivalently ψ and $\mathbf{B}$) yields the GL equations:

$$\nabla^2\mathbf{A} = \frac{ie^*\hbar}{m}(\psi^*\nabla\psi - \psi\nabla\psi^*) + \frac{\mu_0 e^{*2}}{m}|\psi|^2\mathbf{A}, \tag{43}$$

$$\nabla\times\mathbf{A} = \mathbf{B}_a \text{ on surface}, \tag{44}$$

$$\frac{\partial\Delta F}{\partial\psi^*} + \frac{1}{2m}(-i\hbar\nabla - e^*\mathbf{A})^2\psi = 0, \tag{45}$$

$$(i\hbar\nabla\psi + e^*\mathbf{A}\psi)_{\text{perpendicular}} = 0, \tag{46}$$

where the London gauge

$$\nabla\cdot\mathbf{A} = 0$$

has been chosen.

4.3.2 Penetration Depth and Coherence Length. In singly connected samples with no penetration of the magnetic flux into the bulk superconductor, the phase of ψ can be chosen so that ψ is real throughout the sample. In particular for a one-dimensional, singly connected problem, with quantities varying along the x axis, and with magnetic field and vector potential given by

$$\mathbf{B} = [0,0,B(x)],$$

$$\mathbf{A} = [0,A(x),0],$$

Eqs. (43)-(46) become

$$\frac{d^2A}{dx^2} = (\mu_0 e^{*2}/m)\psi^2 A, \tag{47}$$

$$\frac{dA}{dx} = H_0 \text{ on surface}, \tag{48}$$

$$\frac{\partial\Delta F}{\partial\psi} + \frac{e^{*2}}{m}A^2\psi = \frac{\hbar^2}{m}\frac{d^2\psi}{dx^2}, \tag{49}$$

$$\frac{d\psi}{dx} = 0 \text{ on surface}. \tag{50}$$

For the free-energy difference ΔF, the original GL derivation used a power-series expansion in $|\psi|^2$, and neglected all terms higher than the second. That expansion is still commonly used, and is known to be valid for superconductors at temperatures close to T_c:

$$\Delta F = \frac{H_{cb}^2}{2\mu_0}\left[-2\left(\frac{\psi}{\psi_T}\right)^2 + \left(\frac{\psi}{\psi_T}\right)^4\right], \tag{51}$$

where H_{cb} is the thermodynamic bulk critical field, and ψ_T is the equilibrium value of ψ in the bulk, at temperature T, in the absence of a magnetic field.

The problem of the superconducting half-space discussed above—in Eq. (38)—in connection with the London equation can be solved in the GL theory. Integration of Eqs. (47)-(51), under the assumption of small changes in ψ near the surface, yields for $x > 0$

$$\begin{aligned} \frac{\psi(x,B_a)}{\psi_T} = 1 - \frac{\kappa_0}{(2-\kappa_0^2)\sqrt{8}}\left(\frac{B_a}{H_{cb}}\right)^2 & [e^{-\sqrt{2}\kappa_0 x/\lambda_{\text{L}}} \\ & - \tfrac{1}{2}\kappa_0 e^{-2x/\lambda_{\text{L}}}] \end{aligned} \tag{52}$$

and

$$B(x) \approx B_0 \exp(-x/\lambda_{\mathrm{L}}). \tag{53}$$

Equation (53) reproduces, approximately, Eq. (38). In the GL equations λ_{L}, the London penetration depth, is given by

$$\lambda_{\mathrm{L}}^2 = m/\mu_0 e^{*2}\psi_T^2. \tag{54}$$

In Eq. (52) κ_0 is a dimensionless constant:

$$\kappa_0 = (\sqrt{2}e^*/\hbar)\lambda_{\mathrm{L}}^2 H_{cb}. \tag{55}$$

Two remarks are necessary at this point. First, there are two length scales in the problem: the decay length for magnetic fields, λ_{L}, and the decay length $\lambda_{\mathrm{L}}\sqrt{2}\kappa_0$ for the order parameter ψ, given by the first exponent in Eq. (52). Second, Gor'kov (1959) has shown that

$$\kappa_0 \approx 0.96\lambda_{\mathrm{L}}\xi_0^{-1}, \tag{56}$$

where ξ_0 is the coherence length introduced by Pippard (1953) in connection with the general electromagnetic properties of superconductors (see SUPERCONDUCTIVITY, LOW TEMPERATURE). Values of κ_0 are small (<0.707) for the soft, type-I superconductors (0.01 for Al; 0.3 for Pb), whereas it takes large values (>0.707) for the hard, type-II superconductors [~ 8 for V; extremely large for the new, high-T_c materials (see HIGH-TEMPERATURE SUPERCONDUCTIVITY)].

A type-I superconductor excludes a magnetic field from its bulk completely. If the magnetic field B is increased there is a value H_c for which the superconductivity is suddenly destroyed, the system returns to the normal state, and the magnetic field penetrates the specimen completely. A type-II superconductor excludes the field completely up to a value H_{c1}. Above H_{c1} the field is partially excluded, although the specimen remains superconducting and exhibits zero resistivity. At a higher field, H_{c2}, the flux penetrates completely, superconductivity is destroyed, and the specimen returns to its normal state.

4.3.3 Flux Quantization. In many applications (thin specimens, weak magnetic fields, etc.), the order parameter ψ can be considered to have a constant magnitude $n^{1/2}$, although its phase $\theta(\mathbf{r})$ can vary appreciably in space,

$$\psi = n^{1/2}e^{i\theta(\mathbf{r})}. \tag{57}$$

From standard quantum-mechanical arguments the electrical supercurrent is given in this case by the usual formula

$$\begin{aligned}\mathbf{j} &= \frac{1}{2m}[\psi^*(-i\hbar\nabla - e^*\mathbf{A})\psi \\ &\quad + \psi(i\hbar\nabla - e^*\mathbf{A})\psi^*] \\ &= \frac{ne^*}{m}(\hbar\nabla\theta - e^*\mathbf{A}).\end{aligned} \tag{58}$$

Deep inside any superconductor the magnetic field $\mathbf{B}$ and the electric current $\mathbf{j}$ are zero, and therefore from Eq. (58) one obtains

$$e^*\mathbf{A} = \hbar\nabla\theta. \tag{59}$$

In a multiply connected sample one can find a closed path C which encircles a nonsuperconducting region where there may be a magnetic field. Line integration of Eq. (59) over that path, use of Stokes's theorem, and knowledge that ψ must be single valued yields

$$\begin{aligned}\int_{\text{closed } C} \mathbf{A}\cdot d\mathbf{s} &= \int_{\text{area } C} \nabla\times\mathbf{A}\cdot d\boldsymbol{\sigma} \\ &= \int_{\text{area } C} \mathbf{B}\cdot d\boldsymbol{\sigma} = \Phi \\ &= \frac{\hbar}{e^*}\int_{\text{closed } C} \nabla\theta\cdot d\mathbf{s} \\ &= \frac{\hbar}{e^*}\times 2\pi\nu,\end{aligned} \tag{60}$$

where Φ is the magnetic-field flux, and ν is an arbitrary integer. In other words Eq. (60), taking $|e^*| = 2e$, can be written

$$\Phi = \nu\Phi_0 = \nu\cdot 2.0678\times 10^{-15}\ \mathrm{T\ m^2}, \tag{61}$$

i.e., if a closed path without currents can be established deep inside a multiply connected superconductor, then the magnetic-field flux encircled by that path is quantized in units of Φ_0. The unit of flux, Φ_0, is called a *fluxoid.*

4.3.4 Phase-Current Relationship; The Josephson Effect. From the GL equations it can be easily seen that the order parameter ψ has an indeterminate *arbitrary, constant* phase. In a given superconductor (called 1) its phase θ_1 is completely arbitrary. If, however, there is nearby a second superconductor (called 2), which is *weakly* connected to the first one, although both phases, θ_1 and θ_2, are indeterminate by the *same* additive constant, the *phase difference* between the two,

$$\delta = \theta_2 - \theta_1,$$

is an observable meaningful quantity. As can be seen from Eq. (58), a variation of θ over space is responsible for the existence of a supercurrent. Similarly a phase difference between two weakly coupled, spatially close superconductors produces a current flow between them given by

$$J = J_0 \sin\delta, \qquad (62)$$

where J_0, a constant, describes the maximum possible current which may flow between the two specimens. Equation (62) is Josephson's dc equation relating current and phase difference (Josephson, 1962). It is implicit in the GL equations and applies to any system with a macroscopic, quantum-mechanical, complex order parameter. It can be interpreted in terms of the standard quantum-mechanical uncertainty relation between particle number and wave-function phase.

4.3.5 Magnetic-Field Dependence of the Order Parameter. Detailed solutions of Eqs. (47)–(51) for thin films clearly exhibit a field dependence of the *amplitude* of the order parameter $|\psi|$ on the applied magnetic field strength B_a. As the field is increased the value of $|\psi|$ decreases, and there is a value H_f for which it goes (either continuously or discontinuously) to zero and the film becomes normal. It is found that H_f—the film critical field—depends on H_{cb}, the film thickness d, and the London penetration depth, and that the $|\psi|$ transition to zero at H_f is discontinuous if

$$d/\lambda_L > \sqrt{5}.$$

These results, and many others obtained from the solution of the GL equations for a variety of geometries and situations, have been confirmed by superconducting tunneling experiments.

4.3.6 Quantum Interference Phenomena. Given the following facts:

1. the order parameter ψ is complex;
2. ψ must be single valued;
3. the magnetic field **B** couples to it in a gauge-invariant form and therefore is directly related to the phase θ of ψ; and
4. the GL equations are nonlinear;

it is possible to obtain a large number of interference and diffraction effects which can be fruitfully used in designing interesting electronic devices (see SUPERCONDUCTING DEVICES). It can be said that, in understanding the origins of the diamagnetism in superconductors, scientists and engineers have promoted quantum mechanics to the macroscopic, everyday-use level.

5. CONCLUSION

All diamagnetic effects are quantum-mechanical. The persistence of the currents induced by Lenz's law is caused exclusively by the phase coherence of the quantum-mechanical wave functions, either at the microscopic level—as evidenced in the diamagnetism of atoms, molecules, and metallic electrons—or in their macroscopic manifestations—as in superconductors. One of the principal effects is the gauge-invariant way in which quantum-mechanical phases couple to magnetic fields. This coupling produces, in addition to steady currents that result in a screening of the magnetic field, i.e., normal diamagnetism, a wealth of refraction, interference, and diffraction effects which are directly observable experimentally. The de Haas–van Alphen effect, discussed in Sec. 3, and the Josephson effect and flux quantization in superconductors, presented briefly in Sec. 4, are all manifestations of the relationship between electrical current and quantum-mechanical phase, coherent coupling of magnetic fields to the phases of quantum-mechanical wave functions or order parameters, and the relationship between electrical currents and magnetic fields as given by Maxwell's equations.

GLOSSARY

Antiferromagnet: A substance in which local magnetic moments are arranged in alternating orientations, resulting in no net macroscopic moment.

Bardeen, Cooper, and Schrieffer Theory: See BCS theory.

BCS Theory: A microscopic theory of superconductivity formulated by Bardeen, Cooper, and Schrieffer in 1957.

Bohr–Sommerfeld Quantization Rules: Rules by which the energy of bound electronic states were quantized in the "old" quantum mechanics.

Brillouin Zone: The polyhedron in reciprocal space over which the wave vector **k** is allowed to vary.

Coherence Length: The distance over which the coherence of the quantum-mechanical phase of the superconducting order parameter is preserved.

Cyclotron Resonance: Resonance absorption of electromagnetic radiation obtained when the electromagnetic frequency is equal to the cyclotron frequency of electrons moving in a magnetic field; it is also sometimes called diamagnetic resonance.

de Haas–van Alphen Effect: Oscillatory contribution to the magnetic susceptibility, periodic in $1/B$, caused by the interrelationship of the quantized energy levels and the Fermi surface.

Diamagnet: A substance or body that repels or expels magnetic flux.

Diamagnetic Resonance: See cyclotron resonance.

Fermi–Dirac Statistics: The thermal-equilibrium statistics that applies to particles which satisfy the Pauli exclusion principle, electrons among them.

Fermi Level: The value of the energy that separates occupied from empty states in the limit $T \rightarrow 0$ of Fermi–Dirac statistics.

Fermi Surface: The surface of constant energy in **k** space corresponding to the Fermi level.

Ferrimagnet: A substance in which the arrangement of local magnetic moments exhibits both a uniform value—a macroscopic moment—and a spatially oscillatory component.

Ferromagnet: A substance in which the microscopic magnetic moments are arranged all parallel to one another, with a consequent macroscopic moment.

Fluxoid: The quantum of magnetic flux in multiply connected superconductors (see flux quantization).

Flux Quantization: The property of multiply connected superconductors that restricts the values of the magnetic-field flux inside the sample to integral multiples of a fixed quantity, called the fluxoid.

Ginzburg–Landau Theory (Ginzburg–Landau Equations): A phenomenological quantum theory that describes the electromagnetic properties of superconductors and which allows for spatial variations and coherence effects.

Josephson Effect: Coherent tunneling of electrons between two superconductors separated by a thin nonsuperconducting—normally insulating—layer.

London Theory (London Equation): A macroscopic classical theory which describes the electromagnetic properties of superconductors.

Meissner Effect: The complete exclusion of magnetic flux (perfect diamagnetism) from the body of a superconductor at low enough values of the applied magnetic field.

Paramagnet: A substance that exhibits neither a permanent macroscopic magnetic moment nor long-range order of local moments, and which attracts magnetic flux.

Penetration Depth: The distance over which an outside magnetic field decays into the bulk of a superconductor.

Reciprocal Lattice: The discrete, infinite set of points in reciprocal space which defines the vectors used in the Fourier series for a given periodic structure in three dimensions.

Reciprocal Space (k Space): A mathematical space, with the dimension of inverse length, over which wave vectors and periodicities of Fourier series are defined.

INTRODUCTION

This article discusses the properties of carbon in a range of phases from graphite to diamond, where carbon is generally classified as either diamond or diamondlike. Diamond is a specific cubic crystalline phase of nearly pure carbon. Diamondlike applies to a whole class of carbon phases having some of the properties of both graphite and diamond. The diamondlike phases, which are predominantly amorphous, often contain other elements, primarily hydrogen. All these phases are metastable and will transform into graphite at high temperatures.

Diamondlike material, unlike diamond, is not found naturally. It was first synthesized in the 1950s, and so its development is comparatively recent. Since diamondlike refers to a class of materials with a variety of properties, characterization and deposition methods are emphasized here.

Although diamond and diamondlike carbon are both hard inert materials, the crystalline form of diamond and the amorphous structure of diamondlike carbon give them inherently different properties. Diamond is difficult to deposit as a smooth film because its polycrystalline properties result in a rough-faceted surface. However, thick self-support-

Copyright © WILEY-VCH Verlag GmbH & Co KGaA. All rights reserved.

ing diamond substrates can be obtained with a number of growth techniques or by cutting substrates from larger natural diamonds. Diamondlike carbon, on the other hand, is easily deposited as a smooth film. Under some conditions the surface of the diamondlike material is even smoother than the surface substrate on which it was deposited. However, the inherent stress of the diamondlike material makes it very difficult to deposit films thicker than 1 μm, and thick self-supporting substrates have not been made to date.

1. DIAMOND

In spite of diamond's metastability, it does occur naturally and has been used as jewelry since ancient times. Large diamonds, found in alluvial deposits since 800 B.C., were worn by rulers in the early days of India as a sign of rank and wealth. Most historically relevant diamonds, like the Hope and the Idol's Eye, originally came from India. Some of these diamonds have quite a bloody past.

Approximately 100 tons of diamond are produced annually, of which 80% are synthetic (Dismukes *et al.*, 1991; Bush *et al.*, 1991). Gem-quality diamonds are obtained by mining and represent ~5% of the total production. A 1-carat gem-quality diamond varies in price from $600 to $6000 depending upon its quality (Rio Grand, 1992). The price of diamond grit has been continually decreasing, being $12 to $15 a carat in 1969 and $1 to $2 a carat in 1987 (U.S. Department of the Interior, 1989). In industry, diamond is used primarily for cutting and grinding. However, it also has several niche markets. Diamond is used for knives, heat spreaders for temperature-sensitive electronics, and windows. Furthermore, with the recent development of low-pressure diamond growth techniques, new applications in electronics and optical coatings are becoming important.

After discussing both the natural sources and the synthetic production of diamond, this article emphasizes its unique material properties, some of which are reported in Table 1. Diamond's thermal conductivity, hardness, optical transmission, and electrical properties are considered in comparison to other materials. Finally, the present and possible future applications of diamond are discussed.

1.1 Natural Diamond

The primary natural source of diamonds is the core of ancient volcanoes. The material of these cores is called kimberlite, after the town of Kimberley, South Africa. The diamonds

Table 1. Physical properties of diamond.[a]

Property	Description
Lattice constant	0.356725 nm (silicon is 0.54307 nm)
Density	3.515 kg m^{-3}
Coefficient of expansion	8×10^{-7} (fused quartz is 2.5×10^{-7})
Thermal conductivity	1.5×10^{4} W m^{-1} K^{-1} (copper is 4.2×10^{3} W m^{-1} K^{-1})
Heat capacity	6.2 kJ kg^{-1} K^{-1} (copper is 4.2 kJ kg^{-1} K^{-1})
Thermal stability	Reacts with O_2 at >600 °C Reacts to form graphite in vacuum at >1500 °C
Young's modulus	1.054×10^{12} N m^{-2} (drawn tungsten is 3.5×10^{11} N m^{-2})
Dielectric constant	5.7 (silicon is 11.9)
Band gap	5.5 eV (silicon is 1.1 eV)
Resistivity	$>10^{18}$ Ω m, type IIa, 3.4×10^{-5} Ω m, type IIb[b] (copper is 2×10^{-8} Ω m)
Hole mass[c]	Heavy-hole band, $m^*=2.1\ m_0$ Light-hole band, $m^*=0.7\ m_0$ Split-off band, $m^*=1.06\ m_0$
Hole mobility	0.16 m^2 V^{-1} s^{-1} (silicon is 0.05 m^2 V^{-1} s^{-1})
Electron mobility	0.2 m^2 V^{-1} s^{-1} (silicon is 0.15 m^2 V^{-1} s^{-1})

[b] Boron concentration is 2×10^{27} m^{-3}.

[c] m_0 is electron mass.

were not formed in the volcanoes but were brought up to the surface from regions nearer the earth's center by the volcanic action. The cause and character of these ancient volcanoes are unknown, and no such active volcanoes now exist. Many believe the kimberlite did not originate in the cores as hot lava, since the temperatures common to lava (1000–1200 °C) would be expected either to transform diamond into graphite or to burn it into carbon dioxide. Some diamonds, dated by radioactive isotopes, appear to have originated before the earth. While there is some controversy over the interpretation of the isotope dating, most agree that diamonds originate from material dating at least to the earth's formation (Dodson, 1989).

Natural diamonds are usually mined either from the volcano cores or from the sand of streambeds containing material from the cores. In India and Brazil diamonds are found almost exclusively in water-deposited sediments, while in South Africa and Siberia a larger percentage of diamonds is obtained from the volcano cores. Since less than one part diamond by volume is recovered for every 4×10^7 parts mined material, techniques have been developed to extract the diamond from the ore (Burton, 1978a). After the ore is crushed, its components are separated by density. Diamond, having a density of 3.6 $\mathrm{kg\,m^{-3}}$, is denser than most of the other materials. After this step of processing, about one part in 4×10^5 is diamond. The diamond component is then further concentrated using some of diamond's other unique properties. For example, diamonds are not wetted by water and will adhere to grease or wax. On passage of concentrated gravel in water over a moving belt coated with grease, the diamonds adhere to the grease while the other components are washed away. Since diamond is an insulator whereas most of the other components of the ore are conductive, it can also be separated electrostatically. Diamonds, unlike most of the other ore components, fluorescence when exposed to rays and can thus be further concentrated using x-ray fluorescence as an indicator. The last operation, separating diamond from the refined ore, is always accomplished by hand sorting.

1.2 Synthetic Diamond

Synthetic diamond is formed by two techniques, one using a high-temperature (> 1000 °C), high-pressure ($> 10^5$ atm) liquid and the other using a gas at lower temperatures (< 1000 °C) and low pressures (~ 0.1 atm). The high-pressure process takes advantage of the phase diagram of carbon, shown in Fig. 1. At 1 atm, graphite is the most stable form of carbon, but as the pressure is increased, the diamond phase becomes more stable. Since the transformation of graphite into diamond is an extremely slow process, high temperatures and a catalyst (nickel, iron, or cobalt) are usually required. The carbon–catalyst mixture is heated to liquefy the catalyst, at which time it dissolves the graphite and deposits the carbon as diamond. By use of this technique, diamonds several millimeters in diameter have been formed (Wentorf, 1965). At lower pressures, where graphite is the stable form, the same metals will dissolve diamond and deposit the carbon as graphite.

At sufficiently high pressures and temperatures, which can be obtained by chemical explosives, catalysts are not needed. Diamond formed commercially with the explosive technique is composed of very fine crystals and is used primarily for abrasive (Du Pont, 1965).

The second technique uses a nonequilibrium process to form diamond. The diamond is grown in a mixture of gases containing carbon, hydrogen, and oxygen (Zhu *et al.*, 1991). The surface on which the diamond is to be deposited is heated to between 600 and 1000 °C, causing the carbon-containing gas (usually CH_4) to decompose. The carbon deposits both as graphite and as diamond, but under most conditions the graphite is deposited much faster than the diamond, and after a few minutes only the graphite is evident. However, graphite is known to be etched by H and O atoms and OH radicals, while diamond is comparatively inert. By forming these atoms and radicals either in a plasma or on a very hot surface (> 2000 °C) near the region where the carbon is deposited, any deposited graphite will be etched away, while diamond will continue to be deposited. Figure 2 shows an example of a diamond growth system with a heated substrate for diamond deposition and a hot filament to form the graphite-etching chemical species. The reactive chemical species in some diamond growth systems

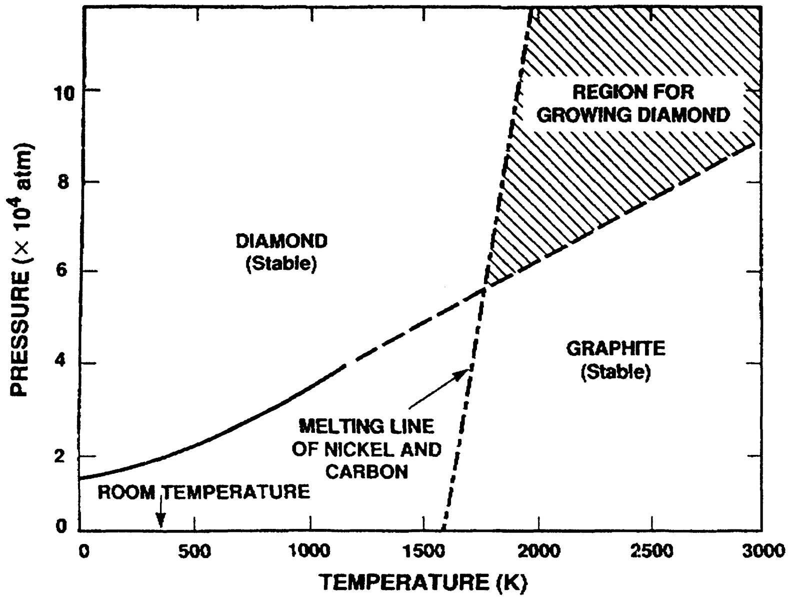

FIG. 1. Pressure–temperature phase diagram of diamond. At high pressures, diamond is the lower-energy phase of carbon. The requirement that a metal catalyst, like Ni, be in the liquid phase to transform graphite into diamond necessitates the growth of diamond above 1700 K.

are formed using a plasma. Some of the highest diamond growth rates (0.1 to 1 mm h^{-1}) are obtained employing chemical reactions between oxygen and acetylene to form the reactive species.

The low-pressure technique deposits diamond over a range of gas compositions. If the concentration of carbon in the gas phase is too small, then the diamond is etched. If the concentration of carbon is too large, then graphite is deposited. Only over a comparatively narrow range of elemental compositions is diamond deposited (Bachmann *et al.*, 1991). Figure 3 shows the experimentally determined atomic concentrations of oxygen, hydrogen, and carbon where diamond is formed. The chemical composition necessary for diamond deposition changes slowly with substrate temperature or gas pressure.

The two diamond growth techniques result in different forms of diamond. The low-pressure approach produces diamond films several micrometers thick and many centimeters across, while the high-pressure technique produces diamonds in the shape of blocks or spheres, usually not much larger than a millimeter across. The low-pressure technique is used to coat windows and cutting tools and

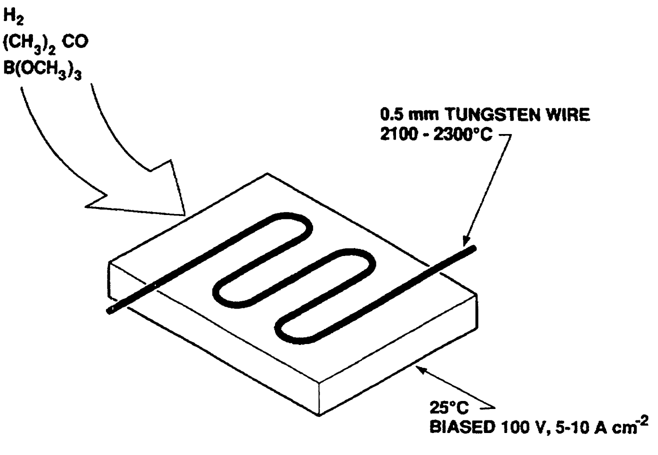

FIG. 2. Schematic diagram of a low-pressure diamond growth system. Although $(CH_3)_2CO$ (acetone) is usually used to grow diamond, nearly any carbon-containing gas will deposit diamond. Boron doping is accomplished with the addition of $B(OCH_3)$ or BH_3. The hot wire can be composed of tungsten (as shown here), tantalum, or rhenium.

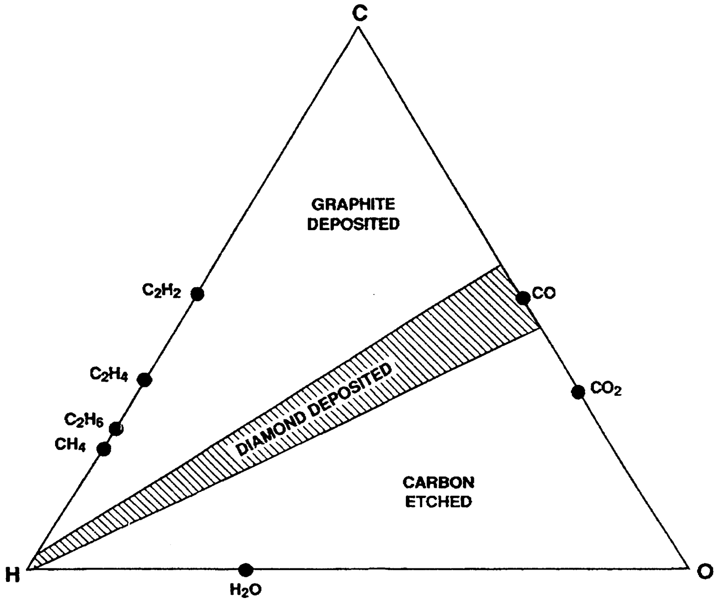

FIG. 3. Chemical atomic concentrations of hydrogen, oxygen, and carbon are shown that will etch diamond and graphite, deposit diamond, and deposit graphite.

has electrical applications. Diamonds produced with the high-pressure process are used primarily for cutting and grinding tools, where the more spherical shape is desired.

1.3 Diamond Typing

Synthetic and natural diamonds can be classified as to their impurity concentration and crystalline perfection. The two most common impurities are nitrogen and boron. Most other elements have extremely low solubility in diamond and therefore are not of general concern. Type I diamond contains high concentrations of nitrogen. This nitrogen either can take only substitutional sites in the carbon lattice or can precipitate as platelets, forming either type Ib or type Ia diamond, respectively. Type IIa diamond contains no measurable nitrogen, as determined by optical absorption. If in addition to containing little to no nitrogen the diamond also contains boron, then it is classified as type IIb. Type IIb diamond is a *p*-type semiconductor.

Natural diamonds are primarily type Ia, with some type IIa and very few type IIb. High-pressure-produced synthetic diamond is almost exclusively type Ib. If metals like Al or Ti that getter nitrogen from the carbon are used with the high-pressure growth technique, then type IIa and type IIb diamonds can be formed.

2. DIAMOND PROPERTIES

2.1 Mechanical Properties

Diamond has several mechanical properties that allow for its use in cutting and machining applications. The theoretical strength α of a brittle material is proportional to $(E\varphi/\lambda)^{1/2}$, where E is the modulus of elasticity, φ is the surface energy, and λ is the distance between atoms. In diamond, $E=1.05\times10^{12}$ N m^{-2}, five times that of steel and ten times that of aluminum alloy; $\varphi=5.3$ J m^{-2}, eight times that of Al; and $\lambda=0.154$ nm, almost half that of iron and Al (Orowan, 1949). Diamond, having among the highest moduli of elasticity and surface energies along with the smallest atomic spacing, is predicted to have a very high fracture strength in tension (1.9×10^{11} N m^{-2}), even along the easiest direction of fracture, normal to the axis with Miller indices $\langle 111\rangle$. The actual strength of diamond is difficult to measure because of the small sample sizes and the inconsistency of samples. However, as for most materials, the theoretical strength is orders of magnitude higher than the measured value under tension of $\sim3\times10^9$ N m^{-2} (Howes, 1965), which is slightly higher than the value for steel wire.

The hardness of many materials scales with their atomic density, and diamond with the highest atomic density is the hardest material at room temperature and pressure, as shown in Fig. 4 (Angus, 1991). Materials with either the diamond or zinc-blende crystal structure are usually harder than materials with the same atomic density but different crystal structures. The hardness also depends on the type and crystal orientation of diamond. Type I with nitrogen impurities is softer than type II. The reason for this is not known, since impurities like nitrogen will harden most other materials.

2.2 Surface Properties

The surface properties of diamond are the result of the almost unique surface chemistry of carbon. Most other materials react with the oxygen and water in the environment. Aluminum and iron, for example, form oxides or hydroxide films. Even very stable compounds, like Si_3N_4, react to form a surface coating of SiO_2. The surface of diamond, however, is extremely stable and unreactive with air, provided the carbon bonds at the surface are terminated with one of a variety of elements, such as hydrogen, fluorine, oxygen, or nitrogen. Just as polyethylene and Teflon are stable and unreactive at room temperature, so the chemical terminated surface of diamond is stable.

This unreactive surface is in part responsible for the extremely low coefficient of friction (0.05) and the low abrasion and wear of diamond. This coefficient, which is less than that for Teflon, actually increases with the addition of lubricating oils. However, since the unreactive property exists only as long as the carbon bonds are terminated, the coefficient can increase to >1 if the chemically bound elements are removed. For example, when diamond is heated to >800 °C in vacuum or when the surface is repeatedly rubbed in vacuum, the elements bound to the surface are removed and the coefficient of friction increases substantially. Often the friction becomes so high as to cause surface damage from abrasion and wear. Both the coefficient of friction, or the wear, and the surface chemistry are dependent upon the crystal orientation and the direction of motion. The surface with Miller indices (111) has the lowest coefficient, 0.05, while the (100) surface has a coefficient of 0.05 in the ⟨110⟩ direction and 0.1 to 0.15 in the ⟨100⟩ direction (Seal, 1953).

2.3 Thermal Properties

Diamond has three unique thermal properties: the highest volumetric heat capacity at high temperatures, one of the lowest heat capacities at lower temperatures, and the highest room-temperature thermal conductivity. At high temperatures near and above the Debye temperature (>1570 °C), the thermal energy of each mole of atoms is $\sim 3RT$, where R is the Boltzmann constant and T is the temperature. Diamond, with the highest atomic density, has the highest volumetric heat capacity. At temperatures <80 °C, well below the Debye temperature, most of the atoms are

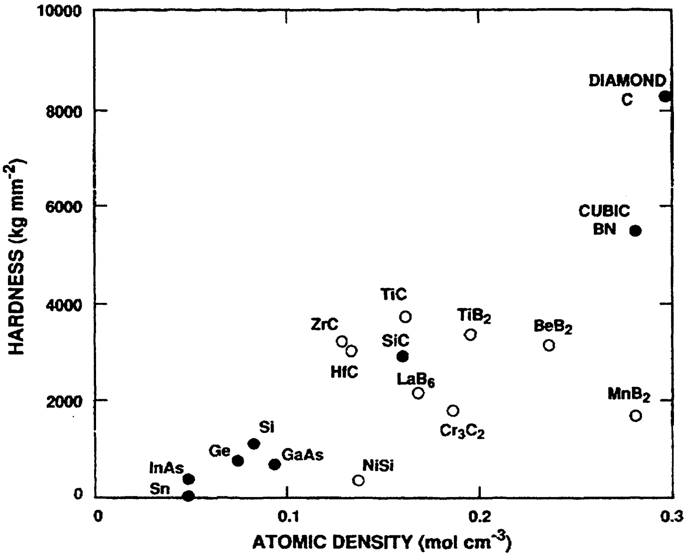

FIG. 4. Material hardness as a function of atomic density. The filled dots represent elements in the diamond crystal structure or compounds in the zinc-blende crystal structure.

in their ground vibrational state and the thermal energy of the lattice is very small. Diamond, having one of the highest Debye temperatures, has one of the lowest low-temperature heat capacities, as shown in Fig. 5.

Diamond's thermal conductivity, shown in Fig. 6, is the result of heat conduction by vibrational energy in the form of phonons. The thermal conductivity is limited by the density of phonons and the density of phonon-scattering centers. The phonon-scattering centers depend upon the purity and crystal quality of the diamond. Type Ia diamond with nitrogen precipitates has from one-fourth to one-tenth the thermal conductivity of the more pure form, type IIa. However, if the nitrogen is not precipitated and is still in substitutional sites, the case for type Ib diamond, then the thermal conductivity is nearly equal to that of type IIa diamond. Most commercial synthetic diamond used for thermal conduction is type Ib, while the natural diamond used for the same property is usually type IIa (Berman, 1979). Low-pressure–produced synthetic diamond, although it has high elemental purity, does not usually have the crystal quality of natural diamond. Therefore, the thermal conductivity of low-pressure synthetic diamond is inferior to that of type IIa natural diamond (Tzeng *et al.*, 1991).

Natural carbon consists of ~99% ^{12}C and ~1% ^{13}C. By making the diamond isotopically pure ^{12}C and by eliminating nitrogen, the density of phonon-scattering centers can be reduced. Such diamonds have ~50% higher room-temperature thermal conductivity than similar diamonds with natural isotopic concentrations. For type IIa diamond, at very low temperatures (<10 K) the mean free path between phonon-scattering events becomes large, and the effective thermal conductivity depends upon the size of the diamond. At these temperatures, diamonds with smooth surfaces have higher thermal conductivity than diamonds with rough surfaces because of specular phonon reflection at the surface (Berman, 1979).

2.4 Optical Properties

Diamond is unique in that it has almost no optical absorption from the extremely low frequencies, approaching dc, to light composed of photons with energies just below the band gap of 5.5 eV (i.e., light with wavelength >220 nm). With the exception of diamond, all of the commonly used window materials have substantial infrared absorption, so that no one material can be used to cover the entire spectrum from 0.2 to >1000 μm. Diamond does have a weak absorption near 5 μm, which is the absorption of a photon by the lattice to form two or more phonons (Edwards and Philipp, 1985). Figure 7 shows the transmission through 1-mm-thick windows of type IIa diamond, LiF, CsI, and fused quartz. LiF is commonly used as an ultraviolet window material, while CsI is a commonly used infrared window material. The ~70% transmission of light through diamond is the result

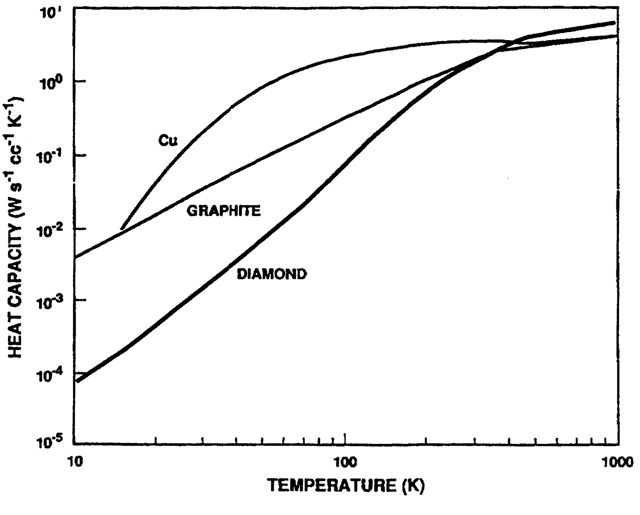

FIG. 5. Volumetric heat capacity as a function of temperature.

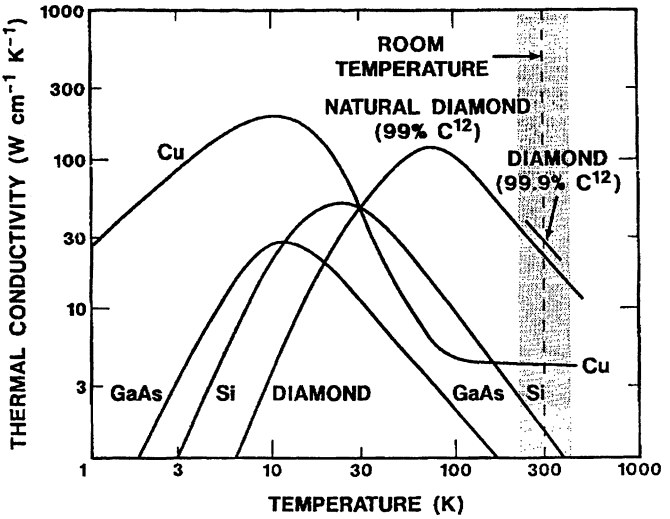

FIG. 6. Thermal conductivity of several materials as a function of temperature. The gray band indicates the temperature range where many semiconductors operate, −25 to 125 °C.

of optical reflection of the light as it passes in and out of the diamond window. Antireflection coating will increase the transmission over a limited spectral range.

Although diamond has the widest range of optical transmission, it has several limitations. Only the highest-purity diamond, type IIa, has this optical property. The other types, containing nitrogen or boron, have additional absorption in both the ultraviolet and infrared electromagnetic spectra. Type IIa diamond often contains internal strains that compromise its optical properties by randomizing the polarization of light passing through it. Types Ia and Ib are reported to have generally less internal strain than type IIa, which may give them superior optical quality over a limited spectral range.

In addition to these transmission properties, color centers can be formed in diamond through radiation damage with > 1-MeV electrons. These color centers are the result of defects that depend upon the impurities in the diamond and heat treatment after radiation. Carbon vacancies in the lattice are believed to be the primary optical defects formed in diamond immediately after radiation. If a radiation-damaged sample is heated above 450 °C, the vacancies diffuse in the crystal, forming new defects. For the case of type Ib diamond, this new defect is believed to be a vacancy associated with a substitutional nitrogen atom. Several other color-center defects have been found and characterized, most of which either are photoluminescent or have

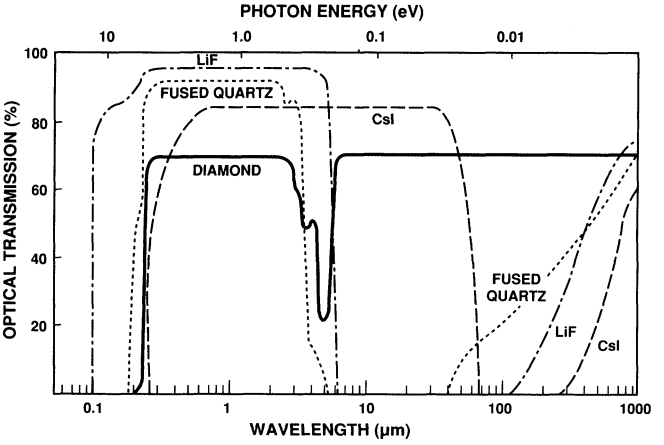

FIG. 7. Optical transmission of diamond, fused quartz, LiF, and CsI as a function of wavelength.

optical absorption in the spectral range from 0.3 to 1 μm.

Color centers produced by radiation damage from electrons or neutrons are often used to change the color of diamonds for cosmetic purposes (Burton, 1978b). Increasing radiation damage usually turns the stones pale green, bottle green, and opaque black. Subsequent heat treatment from 500 to 900 °C for several hours changes type Ia to yellow or amber, type IIa to brown, and type Ib to red or purple.

2.5 Electrical Properties

Diamond is a wide-band-gap (5.5 eV) semiconductor with several unique electrical properties. Two advantageous properties of diamond over the commonly used semiconductors are its high thermal conductivity, as discussed earlier, and its high breakdown electric field. The breakdown electric field of diamonds has not been accurately determined but is between 4×10^6 and 2×10^7 V cm^{-1} (Bazhenov *et al.*, 1985), which is comparable to the breakdown field of $\sim 10^7$ V cm^{-1} for SiO_2. For comparison, the breakdown electric field of silicon and GaAs is between 2×10^5 and 4×10^5 V cm^{-1}.

Semiconducting diamond can be doped either *p* or *n* type to conduct current either by holes in the valence band or by electrons in the conduction band, respectively. Boron is the only known *p*-type dopant for diamond. Other impurities like aluminum or indium, which are used to dope silicon *p*-type, are too large to fit in the diamond lattice and therefore have solubilities too low to be of value as dopants. Even boron is not a very efficient dopant, because it requires ~ 0.36 eV to ionize the boron atom, forming a hole in the valence band. This large ionization energy results in less than 1% of the boron atoms contributing holes to the valence band at room temperature. In addition, most diamond also contains other compensating impurities, like nitrogen, which trap holes, further reducing the hole concentration. If as little as 1% of the boron concentration is replaced with substitutional nitrogen, then the resistance of the diamond can increase by as much as an order of magnitude (Collins and Lightowlers, 1979). When the diamond is heated, more of the boron atoms become ionized, the detrimental effect of the compensating doping is reduced, and boron-doped diamond becomes more conductive. For electrical use, compensating dopants are undesirable, but it is difficult to obtain diamond with < 1% of the boron atoms compensated by impurities or crystal defects.

Phosphorus is the only known *n*-type dopant of diamond (Okano *et al.*, 1990). However, the phosphorus atom is too large to fit in the diamond lattice. This makes it difficult to obtain sufficient phosphorus concentrations for the diamond to be electrically interesting. Carbon-ion implantation has also produced *n*-type diamond (Prins, 1982). Since too much damage results in the formation and graphite and too little damage leaves the diamond insulating, it is difficult to control the doping by this method. Further, if the diamond is heated above 600 °C, much of the damage is annealed and the *n*-type character is degraded. Neither phosphorus doping nor radiation damage produces *n*-type diamond with the degree of resistivity control that can be obtained with silicon and GaAs.

In spite of the difficulty of producing *p*- and *n*-type diamond, both holes and electrons have high mobility in diamond of ~ 2000 cm^2 V^{-1} s^{-1}. This high mobility combined with the large band gap, high breakdown electric field, and high thermal conductivity of diamond make it a desirable semiconductor for high-power, high-frequency, and high-temperature transistors. Diamond transistors have demonstrated power gain at temperatures > 500 °C, and diodes have been operated at 700 °C.

The (111) surface of diamond has a negative electron affinity (NEA) (Himpsel *et al.*, 1979); that is, the energy level of the conduction band is above the minimum energy of electrons in vacuum, as shown in Fig. 8 (Geis *et al.*, 1991b). This NEA property is stable in the presence of oxygen and water. The property is very dependent upon the atoms chemically bound to the diamond surface. Hydrogen and oxygen are believed necessary to maintain the NEA surface of diamond. When the diamond is heated in vacuum to > 800 °C, most of the chemically bounded atoms desorb from the diamond surface and the NEA property is lost. It will be recovered when the diamond surface is again reacted with hydrogen and oxygen. By using the NEA property, cold cathodes have been demonstrated that

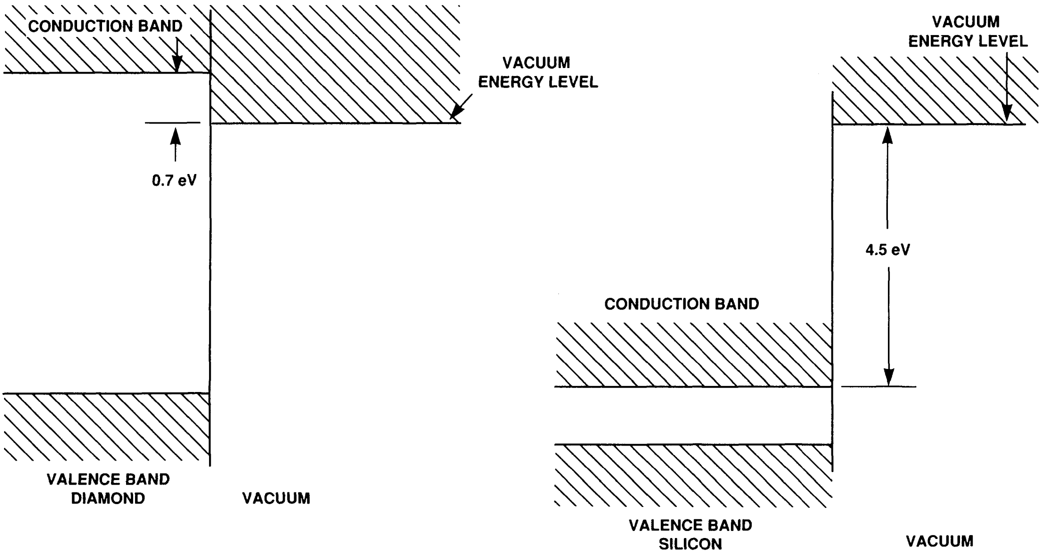

FIG. 8. Energy levels of the conduction and valence bands of diamond and silicon illustrated with reference to vacuum.

are not affected by either oxygen or water (Geis *et al.*, 1991a).

3. USE OF DIAMOND

Diamond, being a comparatively expensive material, generally finds use only when no other cheaper materials will perform as well (Bush, 1979). Diamond's unique hardness, strength, and high thermal conductivity have resulted in its use in cutting and grinding. In this application, diamond usually has an order of magnitude longer lifetime than its competitors, silicon and tungsten carbides. The higher grinding and cutting speeds, longer tool life, and reduced maintenance give diamond a cost advantage. However, ferrous metals like Fe, Ni, and Co, which are used to catalyze the transformation of graphite into diamond at high pressures, will catalyze the transformation of diamond back into graphite at atmospheric pressure. When diamond is used to cut one of these metals, the diamond is quickly eroded away unless it is actively cooled with cutting fluids. Because of this, other materials, like cubic boron nitride, tungsten carbide, and silicon carbide, are often used for machining these ferrous materials.

Diamond's wear resistance and low coefficient of friction have resulted in its use as a bearing in hostile environments, like oil drilling. Because of its ability to maintain a sharp cutting edge with minimal tissue damage, it has also found application in knives for eye and brain surgery. Diamonds are often used as wire drawing dies where high tolerances of wire diameter are desired (Caveney, 1979).

In addition, diamond is used to conduct heat away from temperature-sensitive devices that are required to dissipate high power densities. Semiconductor laser diodes, Gunn oscillators, and IMPATT diodes generate thermal power densities up to 10^6 W cm^{-2}. The performance of these devices degrades quickly with increasing temperature. For most geometries a decrease in thermal resistance of a factor of 2 can be obtained by mounting the device on a diamond substrate rather than a copper substrate.

Diamond is used for windows in spectrometers where a large transmission spectrum is desired. The wide transmission spectrum of diamond combined with its high modulus of elasticity allows diamond anvils to produce extremely high pressure, up to 500 kbar, while still being able to characterize optically the pressurized sample material between the anvils.

Diamond's unique properties could make further applications in lasers and electronics possible. Lasers have been fabricated using the color centers produced in diamond by radiation damage. The high thermal conductivity and heat capacity of diamond might result in high-power visible lasers. Diamond transistors are expected to outperform all other semiconductors in high-frequency high-power generation, if the technical barriers to obtaining large-area, inexpensive device quality diamond substrates can be overcome (Geis, 1991). The NEA property of diamond may result in the replacement of hot cathodes in vacuum electronic applications.

4. DIAMONDLIKE CARBON—GENERAL CONSIDERATIONS

Diamondlike carbon is not a single material, but a broad class of amorphous carbon-based materials that exhibit properties, most importantly high hardness, suggestive of diamond. Carbon can form both a stable threefold-coordinated (π-bonded) crystal structure, graphite, and a metastable fourfold-coordinated (singly bonded) crystalline structure, diamond. In combination with hydrogen, carbon may form polymeric structures containing single or double bonding. By controlled combination of diamond, graphite, and polymeric bonding in an intimately mixed amorphous structure, a wide range of material properties can be obtained. This range of properties can be extended by incorporation of a small fraction of a second element (e.g., Si, W, Ti). Unlike diamond, which can be produced in thin films by chemical vapor deposition (CVD) only at quite high temperature, films of diamondlike carbon can be produced at or even below room temperature. Although these are inferior to diamond in many respects, the ability to deposit a very smooth film of diamondlike carbon on virtually any solid substrate opens a much wider range of application.

4.1 History and Nomenclature

The term "diamondlike carbon" (DLC) was first used by Aisenberg and Chabot (1971) in reference to films deposited from a carbon ion beam. In contrast to other amorphous carbons, this new form of carbon was found to be very hard, electrically insulating, and wear resistant, i.e., diamondlike. Early in the development of techniques for chemical vapor deposition of crystalline diamond, actual diamond films were often conservatively called diamondlike pending confirmation of their crystalline nature. Once the ability to deposit diamond from hydrocarbon vapor was widely accepted, the usage became limited to hard materials composed largely or entirely of carbon but containing no long-range order, diamond or graphitic. Thus, in current usage the term "diamondlike" is descriptive of property only (hard, insulating etc.) and implies the absence of crystalline diamond order. By this definition all diamondlike carbon is amorphous, but not all amorphous carbon is diamondlike. Amorphous carbons (*a*-C) formed by pyrolysis of hydrocarbon resin (glassy carbon), and by sputtering or evaporation of graphite, contain considerable graphite order, are conductive, and are much softer than DLC.

Diamondlike carbon may be produced by a variety of methods and exhibits a wide range of properties. A complex nomenclature has evolved with terms based on the means of preparation (e.g., *i*-C or MSIB *a*-C for mass-selected ion-beam-deposited amorphous carbon) or some inferred structural characteristic of the film (e.g., *ta*-C, meaning tetrahedral amorphous carbon, or even the self-contradictory term "amorphous diamond"). The various forms of DLC may be divided into two broad categories: those formed of carbon only (*i*-C), and those consisting of both hydrogen and carbon, *a*-C:H. A modified form of *a*-C:H contains a small fraction of a third element, *M*, usually a metal, and is designated *M*-C:H. In all cases the film properties are almost entirely controlled by the kinetic energy with which (hydro)carbon species impact the growing surface. *a*-C:H can range from polymeric to graphitic; only *a*-C:H formed near the optimal energy is referred to as hydrogenated DLC. The label *i*-C distinguishes hydrogen-free amorphous carbon, formed from ions or atoms near the optimal energy, from softer, more conductive films formed at lower energy (*a*-C). Table 2 compares several key physical characteristics of the various classes of amorphous and crystalline carbon materials.

A unifying concept for all forms of amorphous carbon is the "hydrocarbon phase diagram" first proposed by Angus and Jansen (1988) (Fig. 9). This diagram maps the degree of fourfold or sp^3 carbon coordination as a function of hydrogen content. The solid line is derived from the theory of random covalent

Table 2. Key physical characteristics of several types of carbon materials.

	Density (g/cm^3)	Optical gap (eV)	Hardness (GPa)	sp^3 (%)	H(%)
Graphite	2.27	0.0	...	0	0
Glassy carbon	1.3–1.6	0.0	2–3	~0	~0
Evaporated C	1.9–2.0	0.4–0.7	2–5	<5	<5
Sputtered C (on Si @ 77 K)	2.2–2.6	0.6–0.9	10	5–10	<5
i-C	2.9–3.4	2.5	100	>85	<5
Hard *a*-C:H	1.6–2.0	1.2–1.6	10–30	40–50	30–50
Soft *a*-C:H	0.9–1.2	1.6–4.0	<5	50–80	50–60
Polyethylene	0.9	6.0	0.01	100	66
Diamond	3.52	5.5	100	100	0

networks (RCN), which is outlined later. Along this curve lie materials with barely sufficient constraint (defined by the degree of carbon–carbon bonding) to be rigid. Materials immediately to the right of the curve may be polymers, while those far to the right must be fluid. Those to the left are rigid solids. Graphite and amorphous carbons with threefold (sp^2) coordination lie at the origin, while diamond and "amorphous diamond" (analogous to amorphous silicon) lie at the top left. Measured sp^3 fractions for hydrogen-free amorphous carbons range from as low 10% to nearly 100%. The dashed curve represents a modification of the random networks that admits large graphitic clusters and is in good agreement with measured sp^3 fractions and compositions of *a*-C:H films.

5. HYDROGENATED DLC (*a*-C:H)

Hard hydrogenated carbon films deposited from a hydrocarbon plasma were first reported by Holland and Ojha (1976). Of all types of diamondlike carbon, *a*-C:H is the easiest and probably cheapest to produce. Properties such as hardness, optical gap, hydrogen content, and density correlate in nearly exactly the same manner for a variety of deposition techniques. This consistency has promoted a good understanding of the underlying atomic structure and its connection to the macroscopic properties of hydrogenated diamondlike carbon.

5.1 Formation of *a*-C:H

Hydrogenated DLC (*a*-C:H) films may be produced by virtually any means that can direct a flux of hydrocarbon ions with kinetic energy in the range 100–400 eV onto a substrate. The substrate temperature may be varied from slightly above to well below room temperature with only a small effect on film properties. Holland and Ojha first reported the CVD of *a*-C:H from hydrocarbon plasma in a parallel-plate reactor in which the substrate was fixed to an electrode to which rf

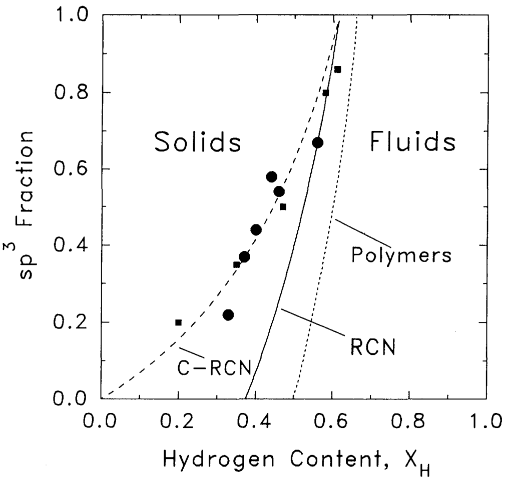

FIG. 9. The hydrocarbon "phase diagram" proposed by Angus and Jansen (1988). The solid curve represents optimally constrained random covalent networks without clustering and the dashed curve is for random networks with large graphitic clusters. The dotted curve represents simple long-chain polymers ranging from polyacetylene to polyethylene. Experimental data are obtained by NMR spectroscopy by Angus and Jansen (squares) and Tamor *et al.* (1991) (circles).

power was applied through a series capacitor. In this configuration, the powered electrode acquires a negative bias determined by the reactor geometry, the applied power, and the type and pressure of the gas. Because virtually any sputtering reactor can be adapted for *a*-C:H deposition, this self-biased CVD technique is widely used. Hydrocarbon plasma may be generated by dc, rf, or microwave discharge, and the substrate may be biased independently, or an accelerated ion source, such as the Kauffmann type, may be used.

5.2 Properties of *a*-C:H

The properties of *a*-C:H films are largely determined by the energy with which hydrocarbon ions arrive at the growing surface. With increasing ion energy *a*-C:H evolves from transparent, hydrogen-rich, polymerlike material to a brittle, nearly opaque, conducting material resembling carbon glass. The most diamondlike properties, maximum hardness and density, are obtained at intermediate energy. Several key properties of *a*-C:H deposited by rf plasma CVD from several precursors are compared as functions of rms self-bias voltage, V_b, in Fig. 10. The average ion energy measured in such systems is typically one-third to one-half the rms bias voltage.

Gas pressure, choice of precursor, and substrate temperature play secondary roles in determining film properties. With increasing gas pressure, collisions with the background of neutral species reduce the effective bombardment energy. At very low energy, precursors may not decompose entirely and some may incorporate nearly intact in the film. Films deposited from benzene may contain pendant benzene groups, while those formed from butane may be highly polymeric. At higher energy densities, film properties are similar for all precursors, but heavier hydrocarbons generally provide proportionately higher deposition rates. Rates up to several microns per hour can be achieved with butane or benzene vapor. The effect of increased substrate temperature during deposition is approximately the same as that of higher ion energy.

5.2.1 Composition—Hydrogen Content. The atomic fraction of hydrogen, X_H, incorporated into *a*-C:H is a key indicator of other film properties. Hydrogen content is controlled mainly by the ion bombardment energy, but is somewhat dependent on precursor. At very low bias X_H can be as high as 0.6, approaching the upper limit of 0.66 permitted for a polymer. The limit on X_H is influenced by the proportion of hydrogen in the source gas; a solid with $X_H > 0.5$ ($H/C > 1$) cannot be formed from benzene or acetylene ($H/C = 1$). For bias above roughly 200 V, where X_H is always less than 0.5, the choice of hydrocarbon has much less influence on film properties. Hydrogen content decreases with increasing bias to minimum of approximately 0.2 for bias of 1000 V.

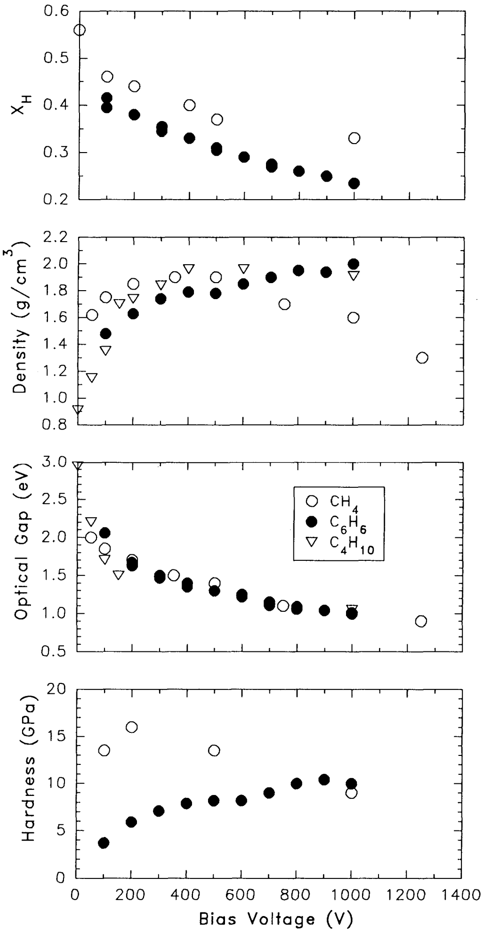

FIG. 10. Key properties of *a*-C:H deposited from hydrocarbon plasma as functions of bias voltage, V_b. Films deposited from three hydrocarbon precursors are compared: methane (○), benzene (●), and butane (▽).

5.2.2 Optical Properties. A critical parameter of a prospective optical coating material is its optical gap, E_g, which is determined from the photon energy ($h\nu$) dependence of the optical absorption (α) near the onset of absorption as

$$(\alpha h\nu)^{1/2}=h\nu-E_g. \qquad (1)$$

This form for the optical absorption edge is typical of amorphous materials where disorder has relieved the requirement of momentum conservation in the absorption process. A gap of 3 eV is required for optical transparency. Figure 10 shows that hard *a*-C:H does not meet this requirement; thin films (less than roughly 0.2 μm) are red-brown in transmission, while thicker films are opaque. Fortunately, this connection between ion energy and optical gap is not rigid. Controlled bombardment by high-energy noble-gas ions (e.g., 1000-eV Ar ions) during growth can increase the optical gap to meet this transparency requirement without sacrifice of other key film properties (Aisenberg and Kimock, 1988). *a*-C:H is quite transparent in the near-infrared range with the exception of a strong absorption band near 3.4 μm due to C-H bond-stretching vibrational modes. Thus *a*-C:H films that are quite opaque in the visible range are well suited for protection of optics for the 4–6-μm atmospheric infrared transmission band.

5.2.3 Mechanical Properties. The density of *a*-C:H correlates well with the hydrocarbon ion energy. Densities as low as 0.9 g/cm^3 for films formed at low energy are consistent with the other polymerlike characteristics (softness, transparency). Such films are similar to another form of hydrocarbon film, called plasma-polymer, which form when little or no potential appears between the plasma and substrate. The film density reaches a maximum of 2.0 g/cm^3 for bias in the 200- to 400-V range, at which the hardness can be as high as 30 GPa, comparable to the hardest ceramics, but far lower than that of diamond (105 GPa). Far less hard, dense, and transparent than diamond, hydrogenated DLC is not very diamondlike in comparison to actual diamond but is certainly the hardest of hydrocarbon materials. With further increase in bombardment energy, the density decreases to only 1.7 g/cm^3, typical of glassy carbon.

Hydrogenated DLC is very slippery and wear resistant even in dry sliding. For steel sliding on *a*-C:H in humid air (55%) coefficients of friction (COF) as low as 0.1 are readily obtained, while much lower values are occasionally observed. For comparison, the friction coefficient for steel on Teflon is approximately 0.05. The COF of *a*-C:H is sensitive to humidity and is reduced considerably in a very dry atmosphere or vacuum (Dimigen *et al.*, 1987). Although quantitative comparison of various measurements is very difficult, wear rates are generally found to be very low. For similar sliding conditions, wear of DLC is always much less than that of other very hard materials such as SiC, Si_3N_4, and TiN.

5.2.4 Chemical and Thermal Stability. Hydrogenated DLC films are extremely resistant to chemical attack by both strong acids and strong bases. However, they are stable only to temperatures between 300 and 400 °C. Although not as hard as films deposited at room temperature, films deposited at elevated temperature retain that hardness and their low friction characteristics to higher temperature (Grill, 1991). Hydrogen devolves from *a*-C:H at higher temperature as the material converts to graphite in several steps (Dischler *et al.*, 1983). After annealing to 600 °C, almost all hydrogen is removed and DLC films become conducting, opaque, and much softer, similar to carbon glass. Turbostatic graphite is formed by annealing to temperatures near 1000 °C.

5.2.5 Electronic Properties. Electronically, *a*-C:H would be best described as a composite of very small conducting islands captured in an insulating matrix. Studies of the temperature dependence of the conductivity indicate that conduction is via thermally activated hopping of charge carriers between localized states. This localization is presumed to occur on graphitic clusters (see later). Addition of dopants including B, P, and various metals increases the conductivity of *a*-C:H. However, this increase is usually accompanied by a decrease in optical gap. Thus it is not certain whether *n*- or *p*-type doping is actually achieved.

5.3 Structure of *a*-C:H

Raman spectroscopy, a probe of the optically active vibrational modes of a material, is one of the most convenient and powerful tools for characterization of both diamond and DLC. Raman spectra of *a*-C:H produced at low and high voltage are compared to the spectrum of a microcrystalline graphite powder in Fig. 11. It is readily apparent that the major features of the *a*-C:H Raman spectrum are derived from those of graphite and that this similarity increases with bias voltage. This indicates that graphitic carbon is present in form of small clusters. (These clusters are two dimensional, with no layer structure as in crystalline graphite.) The correlation between decreasing optical gap and increasingly graphitelike Raman spectrum suggests that the visible optical properties of *a*-C:H are determined by the graphitic component. Robertson and O'Reilly (1987) have made this correlation explicit, showing that the optical gap of a graphitic island or cluster varies as

$$E_g(N) = 6.0/N^{1/2} \text{ eV}, \tag{2}$$

where N is the number of rings in the cluster. The decrease in optical gap corresponds to an increase in cluster size from only a few rings at low voltage to over 100 at high voltage.

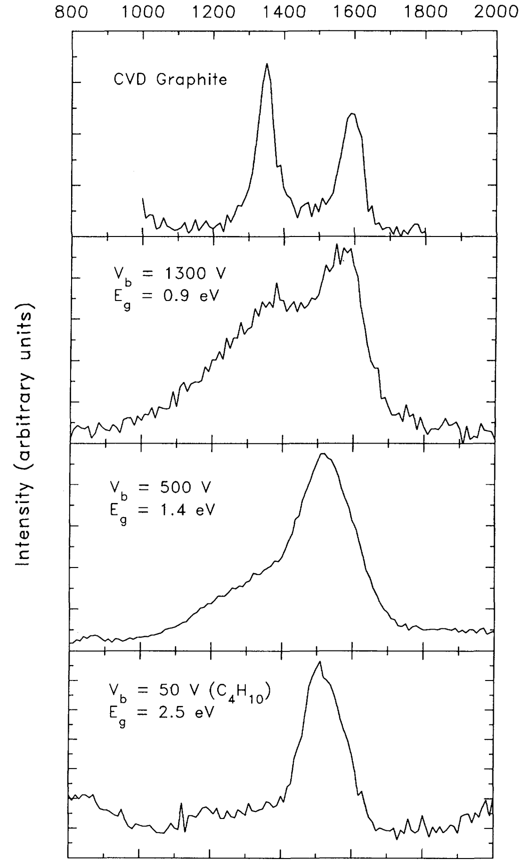

FIG. 11. Raman spectra of a series of *a*-C:H films compared to the spectrum of microcrystalline graphite.

While Raman spectroscopy does suggest the presence of small graphitic structures, it is much less sensitive to the more transparent polymeric or "amorphous diamond" connective structures that determine the bulk properties of DLC. Thus Raman spectroscopy cannot confirm or disprove the presence of a tetrahedrally coordinated component in either *a*-C:H or *i*-C. In contrast, nuclear magnetic resonance (NMR) spectroscopy is a local probe of carbon coordination equally sensitive to all carbon atoms. The strong correlation of increased fourfold carbon coordination with hydrogen content is shown in Fig. 9. A more detailed breakdown of carbon coordinations can permit a qualitative and even semiquantitative connection between local bonding and bulk properties. NMR spectroscopy has been used to sort carbon bonding environments in *a*-C:H into four fractions: threefold with protonation (aromatic or olefinic), threefold without protonation (graphitic), fourfold with protonation (aliphatic or methine), and fourfold without protonation (quaternary) (Tamor *et al.*, 1991). Figure 12 shows the four carbon bonding fractions as functions of bias voltage for a set of films deposited from CH_4. (The fractions of each are labeled f_3^H, f_3^C, f_4^H, f_4^C, respectively, and are normalized such that $f_3^H + f_3^C + f_4^H + f_4^C = 1$.) The overall trend from polymerlike material at low bias to more graphitic at high bias is clear. The fraction of quarternary carbon is maximized at approximately 25% in an intermediate voltage range (200–400 V) and correlates well with film hardness, density, and compressive stress.

5.3.1 Random Covalent Networks.

The connection between local coordination and macroscopic properties is made through the concept of random covalent networks (RCN). Two types of RCN treatments have been applied to *a*-C:H:

1. the theory of optimally constrained networks described by Thorpe (1983), which defines the minimal degree of network connectivity required to achieve macroscopic rigidity, and

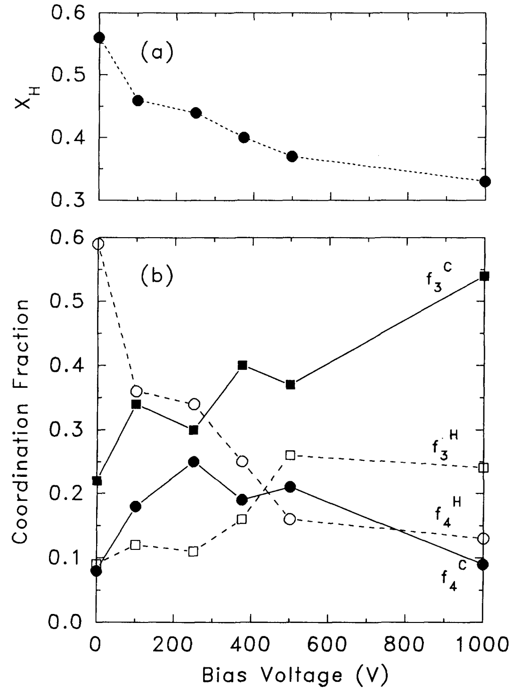

FIG. 12. (a) Hydrogen content of *a*-C:H films estimated from the coordination fractions determined by NMR spectroscopy. (b) The four carbon coordination fractions as functions of bias voltage. The solid symbols are for unprotonated carbon with threefold (f_3^C) and fourfold (f_4^C) coordination as in graphite and diamond, respectively. The open symbols are for protonated carbon with threefold (f_3^H) and fourfold (f_4^H) coordination.

2. a treatment of overconstrained networks in which the degree of overconstraint is connected to macroscopic elastic properties by a simple empirical relationship (He and Thorpe, 1985).

The concept of an optimally constrained network is based on the fundamental statement that a network cannot be rigid unless the number of translational oscillators of nonzero frequency is equal to the number of degrees of freedom in the network, $3N-3$, where N is the (very large) number of nodes in the network. In the absence of clustering, each atom is a node. A straightforward derivation shows that this condition is met when the mean atomic coordination, N_{av} (the average number of bonds to other nodes which are in turn part of the network, i.e., not dangling atoms or clusters), is exactly 2.4. For a random network consisting of carbon and hydrogen only, the overall degree of fourfold carbon coordination must vary with hydrogen content as

$$f_4=f_4^C+f_4^H=(8X_H-3)/5(1-X_H). \qquad (3)$$

This relationship defines the solid curve labeled RCN in the hydrocarbon "phase diagram" shown in Fig. 9. The degree to which overconstraint translates into hardness is determined by the amount of clustering in the network; N_{av} may be inflated by locally overconstrained clusters that cannot contribute to the macroscopic elastic properties (hard peanuts do not make peanut butter any harder). The graphitic clustering inferred from Raman and optical measurements can be accommodated by grouping all threefold-coordinated carbon into larger multiatom nodes and renormalizing to the newly reduced number of nodes. The curve for optimal constraint with large graphitic clusters is given by

$$f_4=5X_H/8(1-X_H), \qquad (4)$$

and is shown on the "phase diagram" as the dashed line labeled C-RCN. The modified form of the RCN model coincides well with the NMR measurements. This indicates that *a*-C:H consists of graphitic clusters, which define most optical properties, locked in a slightly overconstrained network that defines its mechanical properties.

Although formally rigid, optimally constrained networks cannot be macroscopically hard. It must be confirmed that the small degree of overconstraint is sufficient to account for the observed hardness of DLC. He and Thorpe (1985) treated an overconstrained RCN in a simulation in which bonds were randomly deleted from a diamond lattice and the resulting elastic properties calculated as a function of the average constraint in the remaining network. They found an empirical relationship between N_{av} and elastic modulus,

$$E=E_0[(N_{av}-2.4)/(N_0-2.4)]^{1.5}, \qquad (5)$$

where $N_0=4$ and E_0 is the modulus of the original lattice. Because hardness is approximately linear with modulus, this can be used to estimate hardness, H, by replacing E_0 with H_0 for diamond (105 GPa). The hardness of *a*-C:H using N_{av} from the NMR breakdown of carbon coordinations (assuming that graphitic carbon contributes little to hardness) is compared to the measured hardness in Fig. 13. The quantitative agreement confirms that

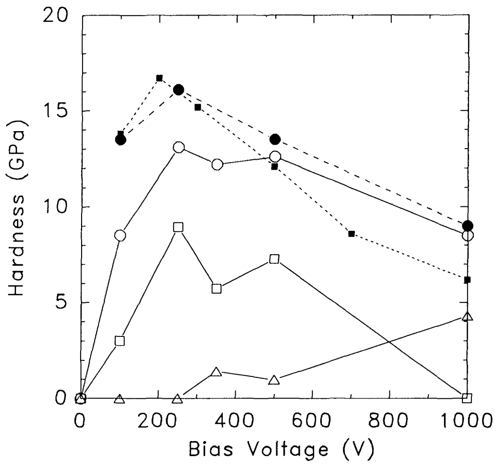

FIG. 13. Measured hardness of *a*-C:H as a function of bias voltage (● and ■) compared to estimates based on NMR measurements of carbon coordination using three assumptions: (1) that all atoms contribute to hardness (○), (2) that graphitically bonded carbon is clustered and so does not contribute to hardness (□), and (3) that quaternary carbon is clustered and so does not contribute (△). These results suggest that while graphitically bonded carbon may contribute somewhat to hardness, dispersed quaternary carbon is essential to sustain the observed hardness of *a*-C:H.

the carbon–carbon bond is so strong that even a small degree of overconstraint is sufficient to account for the hardness of hydrogenated diamondlike carbon. The contribution of quaternary carbon to network hardness is so critical that the opposite assumption of diamond clusters, amorphous or crystalline, implies zero hardness.

5.4 The *a*-C:H Deposition Process

The formation of *a*-C:H involves a complex interaction of chemical and kinetic processes. The mix of ions, neutral species, and radicals in the plasma is dependent upon the source gas, its pressure, and the power applied to the plasma (Koidl *et al.*, 1989). The substrate is bombarded by both energetic ions and diffusing neutral species. Under these conditions, film growth can proceed through a combination of surface and subsurface processes.

On the surface, the bombardment energy promotes formation of a strongly bonded carbon network by driving off hydrogen and loosely bonded carbon. Figure 9 suggests that it may be extremely difficult to produce *a*-C:H that deviates significantly from the C-RCN phase boundary. The strong tendency to hydrogenate is confirmed by studies which show that the hydrogen content of sputtered carbon films is always the same, approximately 35%, unless care is taken to remove residual hydrogen (mainly water vapor) from the reactor (Bhushan *et al.*, 1992). Simultaneous bombardment with a noble gas has been used in attempts to optimize preferential sputtering such that only diamond, the most strongly bonded form of carbon, is accumulated. Simultaneous bombardment has been found to increase the density and transparency of *a*-C:H, probably by reducing the size of the graphitic clusters. Scattered crystals tentatively identified as diamond are sometimes found embedded in the *a*-C:H matrix (Weissmantel, 1982).

Hydrocarbon ions with kinetic energy in excess of 50 eV penetrate several atomic layers into the film. Several calculations have shown that for ion-beam deposition in the absence of hydrogen (*i*-C deposition), this penetration can be tuned to favor a substantial fraction of quaternary bonding (Lifshitz *et al.*, 1989; Kaukonen and Niemenen, 1992). A similar effect may also occur in *a*-C:H, but is impeded by the hydrogen, which ties up dangling bonds, thus impeding formation of a dense quaternary network. The C–H bond is so strong that hydrogen cannot be driven from the film without such violent ion bombardment that the carbon network reverts to graphite. Thus the inability to produce highly overconstrained and harder DLC from hydrocarbon vapor is a consequence of this compromise in ion energy between what would be optimal in the absence of hydrogen (30–80 eV), and what is required to remove a large fraction of the hydrogen.

6. MODIFIED *M*-C:H

Although *a*-C:H is very hard, slippery, and easy to apply to a variety of substrates, it suffers two drawbacks: first, the high compressive stress limits the film thickness to roughly 2 μm, and second, the coefficient of friction is quite high under conditions of high humidity. Dimigen and Hübsch (1983/1984) addressed these problems by incorporating a variety of metals (W, Ta, Ru, Fe, and Ti) into *a*-C:H films by simultaneous sputtering. They found that a inclusion of few percent of metal reduced stress and improved adhesion so that much thicker films could be deposited. The friction coefficients of metal-containing *M*-C:H films were much less dependent on humidity. Iron-containing films exhibited reduced friction (0.04) while Ru-containing films exhibited increased friction (0.7). Incorporation of tungsten was found to increase wear resistance. Other workers have incorporated up to 30% Si into *a*-C:H films (not counting H) and found the friction reduced to 0.05, again independent of humidity, with wear rate comparable to hard *a*-C:H (Oguri and Arai, 1990).

Any element that forms a strong bond to carbon is suitable for incorporation into *M*-C:H. At small *M* content the films remain amorphous, and the additive can be considered a part of the covalent network structure of *a*-C:H. However, as the *M*:C ratio approaches 1, small carbide crystals appear within the amorphous matrix. Annealing also promotes the formation of carbide crystals. Although, strictly speaking, the resulting composite materials do not fit the definition of diamondlike carbon, they have great potential for smooth, slippery, and wear-resistance coatings.

7. HYDROGEN-FREE DLC (*i*-C)

Hydrogen-free DLC represents a subset of the possible carbon structures quite different from those found in *a*-C:H. In the "phase diagram" of Fig. 9, *i*-C lies high on the left axis. As it contains no hydrogen, *i*-C cannot include a polymeric component and must be composed of some combination of networks of sp^3 and sp^2 carbon and possibly graphitic clusters. The first and second dominate the mechanical properties while the last determines the optical properties. The degree of fourfold coordination is controlled by the energy with which carbon atoms or ions arrive at the substrate.

7.1 Formation of *i*-C

The most diamondlike of hydrogen-free DLC is deposited from some variation of a mass-selected or filtered carbon ion beam. Hardness and density are maximized for ion energies in the range 30–80 eV (McKenzie *et al.*, 1991). Just as for *a*-C:H, the substrate may be at or below room temperature. In fact, the substrate must be actively cooled during high-rate deposition. The major challenge in production of *i*-C lies in finding a source of carbon prolific enough to make possible the coating of large areas at reasonable rates. Conventional C-ion sources depend upon ion sputtering of graphite or decomposition of CO gas and ion extraction followed by mass filtering to produce a pure carbon-ion beam. An alternative approach that embodies the essential elements of an ion-beam system employs a cathodic arc discharge on a graphite electrode as an ion source and uses an external bias of the substrate relative to the electrode for the accelerating potential. Magnetic mass filtering must be added to remove the multiatom clusters produced in high-rate erosion of graphite.

Thermal evaporation and sputtering of carbon cannot be used to form *i*-C because the atomic kinetic energy is too low. Under marginal conditions, the ability of the substrate to dissipate the kinetic energy of incoming carbon atoms, through low initial temperature and high thermal conductivity, appears to play an important role in determining the film properties. Carbon films sputtered onto diamond at 77 K exhibit densities as high as 2.8 g/cm^3 and up to 60% sp^3 coordination (Cuomo 1991). Pulsed laser evaporation can impart energies of a few eV and so is an intermediate case between sputtering and ion-beam deposition. Carbon films laser-deposited on low-temperature substrates (77 K) show a systematic increase in density and estimated sp^3 content with increasing thermal conductivity of the substrate. At low laser fluence (of order 10^8 W/cm^2 in a 10-ns pulse), the carbon kinetic energy increases as the laser wavelength decreases, and the sp^3 content and density of the resulting carbon films are found to increase accordingly. For uv-laser (248 nm) evaporation, the ion kinetic energy can exceed 20 eV, approaching the optimal value determined for ion-beam deposition. Indeed, carbon films uv-laser–deposited on high-quality diamond substrates at room temperature have a density 3.2 g/cm^3 and an estimated sp^3 fraction exceeding 85% (Pappas, 1992).

Carbon films produced by laser ablation of carbon at very high laser fluence (10^{12} W/cm^2) appear to be quite different from those formed by evaporation at lower fluence. Above a critical energy density, an extremely hot carbon vapor plume rich in small clusters (C_3,

C_4, etc.) is produced (Collins *et al.*, 1991). Kinetic energies up to several keV are estimated for these small carbon clusters. This carbon stream may be similar to that produced by the cathodic arc. Films deposited from the most energetic portion of the plume are highly insulating and exhibit both density (up to 3.1 g/cm^3) and hardness (typically 40 GPa, but up to 77 GPa) approaching that of diamond, all suggestive of a very high sp^3 content. Microscopic examination of these films shows a nodular structure. The developers of this material have named it "amorphic diamond" and conclude that it is composed of small (100 nm) nodules of quaternary carbon (partially or entirely amorphous) captured in a more graphitic, but nevertheless very strong, matrix. This composite structure permits very high hardness to coexist with relatively low compressive stress. Such a material embodies the mechanical properties expected of "amorphous diamond" but cannot exhibit the corresponding optical properties because of the binding matrix.

7.2 Properties of *i*-C

7.2.1 Optical Properties. In analogy to amorphous silicon, the optical gap of an entirely sp^3 amorphous carbon should be comparable to that of crystalline diamond (5.4 eV). The largest optical gap for *i*-C reported to date is only 2.5 eV. This indicates that even the densest, most diamondlike of carbon films retain some residual nonquaternary carbon. Optical gaps as large as 1.8 eV are reported for uv-laser–evaporated carbon films, while carbon films sputtered onto cold substrates exhibit gaps in the range from 0.6 to 1.0 eV. Because it contains no hydrogen, *i*-C exhibits no C–H stretch absorption band and so is more transparent in the infrared than is *a*-C:H.

7.2.2 Mechanical and Chemical Properties. Without hydrogen to interrupt the connectivity of the carbon network and so reduce the degree of overconstraint, hydrogen-free amorphous carbons are potentially much harder than *a*-C:H even with significant sp^2 bonding. The empirical hardness relationship [Eq. (5)] suggests a minimum of 22 GPa for an all-sp^2 network without clustering. Cold-sputtered carbon films exhibit hardness in this range. For films deposited from a cathodic arc without mass filtering, hardness in the 20- to 40-GPa range is obtained. With mass filtering, hardness and elastic modulus approaching that of diamond are obtained.

The density of *i*-C is maximized with its hardness. Densities as high as 3.1 g/cm^3 have been determined both directly by the sink-float method and indirectly from the electron energy-loss (EELS) spectrum. This is significantly greater than that of graphite (2.2 g/cm^3) and approaches that of diamond (3.4 g/cm^3). Unfortunately, high hardness in *i*-C is accompanied by extremely high compressive stress, which limits film thickness to several hundred nanometers at most. Laser-ablated carbon films are similar in density and hardness, but do not suffer this thickness limitation. Like *a*-C:H, *i*-C exhibits very low wear in sliding friction with steel. The coefficient of friction is usually slightly higher.

7.2.3 Electronic Properties. Like *a*-C:H, *i*-C can be described as a composite of small conducting, presumably graphitic, islands in an insulating matrix. If physically realizable, "amorphous diamond" with absolutely no sp^2 component should be a large-gap amorphous semiconductor. Indeed, the rectifying characteristic of metal–*i*-C junctions are consistent with that of a wide-gap semiconductor (McKenzie *et al.*, 1991).

7.3 Structure of *i*-C

Electron energy-loss spectroscopy (EELS) has proven to be a very powerful analytic tool in the study of thin films of *i*-C. The low-energy EELS spectrum of an *i*-C film deposited from a cathodic arc with mass filtering is compared to the EELS spectra of diamond, graphite, and *a*-C in Fig. 14 (Berger *et al.*, 1988). Two major features are immediately apparent in the EELS spectrum of *i*-C:

1. no features associated with π-π^* transitions near 6 eV are evident, and
2. the $\pi+\sigma$ plasma energy, which is a measure of the volume density of valence electrons, corresponds to a mass density of approximately 3.1 g/cm^3.

Figure 15 compares the higher-energy core-level K(1*s*)-edge EELS spectrum of diamond to those of amorphous carbon films deposited on diamond at room temperature by 248-nm uv-laser evaporation. Although a small feature

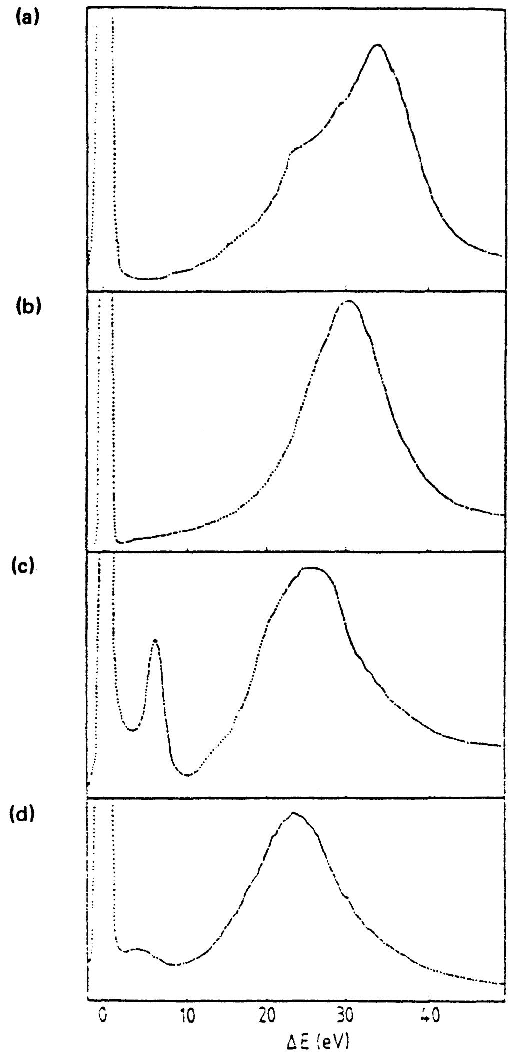

FIG. 14. Low-energy electron energy-loss spectra of carbon materials: (a) diamond, (b) *i*-C, (c) graphite, (d) *a*-C.

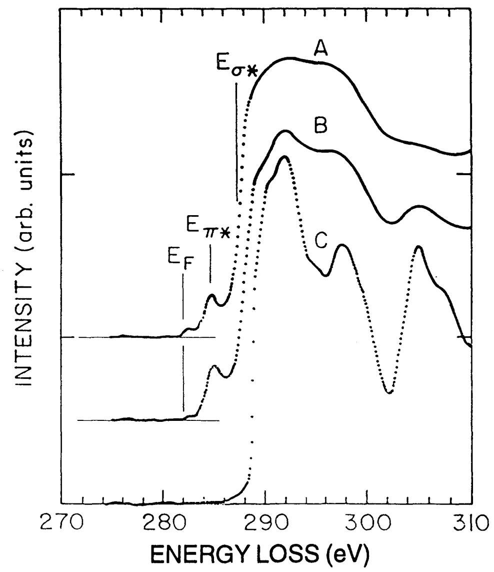

FIG. 15. Core-level [*K*(1*s*)-edge] EELS spectra of carbon films uv-laser evaporated onto cold diamond substrates compared to that of crystalline diamond. Curves A and B are for carbon films deposited on cold (77 K) diamond substrates by uv-laser evaporation. Curve C is for single-crystal diamond. The loss feature associated with residual sp^2-bonded carbon is labeled $E_{\pi*}$. *The edge associated with covalent bonding, both quaternary and graphitic, is labeled* $E_{\sigma*}$. The fraction of integrated intensity below this threshold is used to estimate an sp^3 fraction of 85%. The similarities in the details of the loss features are strongly suggestive of an "amorphous diamond" structure.

due to residual sp^2 bonding is still evident, the similarity of the spectra at higher energy is consistent with an "amorphous diamond" structure.

The radial distribution function (RDF) of *i*-C has been measured by both electron and neutron diffraction (Gaskell *et al.*, 1991). The two most important parameters to be obtained from the RDF are the average distance to the first-nearest neighbors, r_1, which is a measure of bond length, and the average coordination, n_1. For diamond $r_1 = 1.54$ Å and $n_1 = 4$, while for graphite $r_1 = 1.42$ Å and $n_1 = 3$. Amorphous carbon sputtered onto a cold (77 K) silicon substrate has $n_1 = 3.3$, indicative of a small (approximately 10%) fraction of quaternary carbon. However, *i*-C was found to have $r_1 = 1.53$ Å and $n_1 = 4$, essentially the

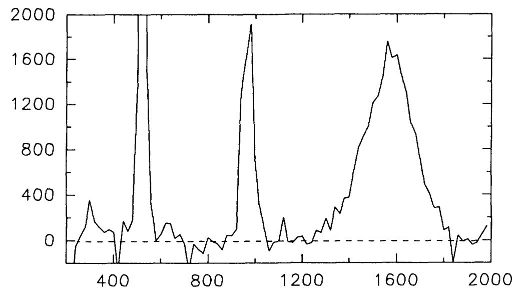

FIG. 16. Raman spectrum of *i*-C. The strong features at 500 and 900 cm^{-1} are the first- and second-order spectra of the Si substrate.

same as diamond. By this measure, *i*-C actually is "amorphous diamond."

Figure 16 shows the Raman spectrum of a film of *i*-C on silicon. The high level of noise in the spectrum is a consequence of the low absorbance of this transparent and very thin (0.1 μm) film. The only clear feature is a broad, symmetric peak at 1600 cm^{-1}. This is evidence for a residual sp^2 component that determines the optical gap. Note that the shape of the peak strongly resembles that for the polymeric *a*-C:H film with a similar 2.5-eV optical gap (see Fig. 11), suggesting graphitic clusters of comparable size. However, the peak is shifted nearly 200 cm^{-1} higher in *i*-C, presumably because of the huge compressive stress in this material. The Raman spectrum of the "amorphous diamond" component is too weak to be detectable in this film, but is expected to resemble that of amorphous silicon with appropriate scaling for the stiffer C–C bond and smaller atomic mass.

7.3.1 Structural Models. It is attractive to describe the densest *i*-C as an amorphous all-quaternary network similar to other amorphous semiconductors. Indeed, the radial distribution function of *i*-C is a very close match to that of amorphous germanium while the EELS spectrum closely resembles that of diamond. Because the stiffness of carbon bonding against bond-angle deformation relative to bond-length distortions is so much greater than in Si and Ge, the stability of such a network was initially somewhat doubtful. However, the large compressive stress in these films may play a key role in stabilizing the highly strained network. Homogeneous "amorphous diamond" may in fact be strongly metastable so long as the compressive stress can be maintained by the film–substrate interface. Phase separation into highly quaternary nodules in a more graphitic matrix may be the mechanism by which laser-ablated carbon maintains a high average sp^3 content without accumulation of unsustainable interfacial stress.

7.3.2 The *i*-C Deposition Process. It appears that the substantial arrival energy of carbon ions correlates with a large steady-state fraction of quaternary carbon. This is counterintuitive in that the excess kinetic energy would be expected to promote annealing to graphite rather than maintaining a highly unstable network structure. Two mechanisms are likely to be in effect. First is "subplantation," a shallow implantation process in which incoming carbon ions continuously rearrange the atomic structure to a depth of a few angstroms with a bias toward disrupting graphitic configurations (which requires only 25 eV) without disturbing quaternary structures (requiring 80 eV). Deposition with too little or too much kinetic energy loses this selectivity. Although a finite steady-state quaternary fraction can be maintained, an entirely quaternary structure should be unattainable by such a mechanism. The second mechanism is stress stabilization. The very large compressive stress that appears in this shallow implantation process may actually shift the relative energies of various bonding configurations in favor of fourfold coordination. As shown in the graphite–diamond phase diagram (Fig. 1), even at room temperature, compressive stress in excess of only 2 GPa is sufficient to stabilize diamond; *i*-C forms with stress up to 8 GPa. It is unclear which mechanism is really driving *i*-C deposition, or whether they can even be separated. In one view, the details of carbon-bonding energetics may be irrelevant and the "optimal" kinetic energy simply that which maximizes compressive stress, while the opposite view holds that stress is an accidental by-product of the kinetic process that maximizes fourfold coordination.

The same interaction between kinetics and compressive stress applies for carbon deposition at suboptimal energy, as in laser evaporation. At lower kinetic energy, insufficient stress is generated to stabilize a largely quaternary network, or rather, the kinetic energy is insufficient to promote a large quaternary fraction. The role of low temperature and high thermal conductivity is to "freeze in" whatever quaternary configurations do form by minimizing and dissipating excess energy, which would otherwise promote annealing to more stable graphitic structures. Immediate covering of the reactive surface also assists in capturing the quaternary component. High instantaneous deposition rates inherent to laser evaporation and ablation assist in this quenching process.

8. APPLICATIONS OF DIAMONDLIKE CARBON

A major impediment to many applications is the very large compressive stresses that appear in all diamondlike amorphous carbon films. For the hardest *a*-C:H the compressive stress approaches 4 GPa, while for the hardest *i*-C the stress is as high as 8 GPa. These enormous compressive stresses limit the thickness of the film to the strength of the interface or the substrate itself. For *a*-C:H, 2 μm is an approximate limit, while for *i*-C, films as thin as 1000 Å are apt to de-adhere. It is possible that the high degree of quaternary coordination required for hardness is actually stabilized by the compressive stress, and so is inseparable from the desirable diamondlike qualities.

Hydrogenated DLC is already in use in several products. Because it is very smooth, thin, flexible, and insulating, *a*-C:H is an ideal protective coating for thin-film magnetic recording media. For hard disks it can virtually eliminate adhesion to the head during stop–start events and so prevent catastrophic failures. For metal-film recording tape, it provides a chemical barrier against oxidation and reduces both tape and tape-head wear. It is used to reduce friction and wear on tape-recording heads and tape-transport guides. *a*-C:H is an ideal protective and antireflection coating for infrared optical objectives made of germanium. With proper choice of thickness and index of refraction, a DLC coating can reduce reflection almost 99% while providing protection against corrosion and particle abrasion. DLC has also been used to stiffen metal-foil high-fidelity tweeter diaphragms and so raise their resonant frequency far beyond the range of human hearing. A form of *a*-C:H formed by a dual–ion-beam process, which increases its transparency and slightly reduces compressive stress while maintaining hardness, is used to form protective coatings on sunglasses and windows for bar-code scanners.

Potential applications include protective coating of glass and plastics, low-friction coatings for sliding and rolling bearings, chemical protection barriers for metals, plastics, and glass, tools (most notably surgical blades), and biocompatible implants. Any material that is inert, transparent, hard as ceramic, and slippery as Teflon and can be deposited on virtually any substrate will certainly find uncountable applications.

ACKNOWLEDGMENT

GLOSSARY

Catalyst: Substance that increases the rate of a chemical reaction. The catalyst is not consumed by the chemical reaction.

Coefficient of Friction: Force required to cause two surfaces to slide on each other. It is unitless, being equal to the force required to cause sliding divided by the force pushing the surfaces together.

Cubic Crystals: Form of crystal in which the minimum repeating unit of atoms has the same symmetry as a cube. Gold, sodium chloride (table salt), silicon, and diamond have cubic crystal forms.

Fluorescence: Emission of light from matter as a result of its being irradiated with energy, usually from ultraviolet light, x rays, or electrons. Dayglow paint is an example of a fluorescent material.

Metastability: Stable condition of an element or compound that is not in its minimum energy state. Diamond is metastable with respect to graphite since graphite is the lowest energy form of carbon.

Miller Indices: Method of defining the planes and axes of crystals. Parentheses ( ) indicate crystal planes, and angle brackets ⟨ ⟩ indicate an axis perpendicular to the planes. For a cubic crystal, consider a cube aligned with the axes of the crystal: the (100) is a set of crystal planes parallel to the square faces of the cube, the (110) is a set of planes perpendicular to the diagonals across any one of the faces of the cube, and the (111) is the set of planes perpendicular to any one of the diagonals connecting any two opposite corners of the cube.

Modulus of Elasticity: Force required to deform a solid elastically. It has units of pressure.

Nonequilibrium: Condition of a chemical system that cannot be characterized by one temperature.

Radical: Atom or molecule in a very chemically reactive state as a result of not having all of its chemical bonding capability satisfied. A hydrogen atom (H) and methane with one hydrogen atom missing (CH_3) are examples of radicals. They react with themselves in a few milliseconds or less, forming H_2 and CH_3CH_3, respectively, However, some radicals can exist in this metastable state for hours or days.

Semiconductors: Solid or liquid whose electrical conductivity is between that of an insulator and a metal. Its conductivity can be changed by several orders of magnitude by incorporating impurities (dopants) at concentrations of a few parts per million.

Semiconductor, *n* Type: Semiconductor in which the electrical current is carried primarily by negatively charged electrons. These mobile electrons originate from positively charged impurities (dopants) or crystal defects in the semiconductor. Phosphorus is an *n*-type dopant of silicon and germanium.

Semiconductor, *p* Type: Semiconductor in which the electrical current is carried primarily by positively charged holes. These holes originate from negatively charged impurities (dopants) or crystal defects in the semiconductor that remove electrons from the conduction band. This forms voids (holes) with an effective positive charge. Boron is a *p*-type dopant of diamond, silicon, and germanium.

Surface Energy: Energy required to increase the surface of a solid or liquid. It has units of energy per area. The surface energy is often very dependent upon impurities that can coat the surface. For example, soap is known to lower substantially the surface energy of water.

Vacancy: Defect in a crystal lattice caused by the removal of an atom.

INTRODUCTION

The analyses of electrical and magnetic properties of insulating solids are two nominally analogous problems in solid state physics that have traditionally borrowed much from each other in both mathematical approach and even terminology: The terms "ferroelectric" and "paraelectric" are, for example, misnomers that found their way into standard usage to describe electrical polarization states in crystals analogous to ferromagnetic and paramagnetic spin states in magnetic materials. There are two important differences, however, between descriptions of the dielectric and magnetic properties of insulators: First, as emphasized by Feynman in 1965, magnetism is an intrinsically quantum mechanical

property of solids, and attempts to describe it semiclassically (e.g., in terms of an array of classical spin vectors) are fundamentally unsound; by comparison, except at cryogenic temperatures, the electrical behavior of polar insulators is intrinsically classical, with polarizations representable by localized vectors. It is the aim of the section that follows below to describe the microscopic "local field" averaging procedure by which these vectors are estimated.

The second difference between magnetic and electrical properties of insulators is that the magnetic spins are well-defined spatially localized quantities, even in the high-temperature disordered paramagnetic state in which the expectation value of the magnetization is zero: $\langle M\rangle = 0$. By comparison, in a few polar insulators, a ferroelectric state arises from ordering (e.g., rotation) of rigid dipoles, such as an N–H– –Cl hydrogen bond or a covalent ion (NH_4^+, SO_4^{-2}); but, in general, ferroelectric materials possess no permanent dipoles, ordered or disordered, in their paraelectric phases. In this sense ferroelectrics and antiferroelectrics are far more complicated that their ferromagnetic and antiferromagnetic analogues. For magnets, the spins exist at all temperatures and the spin magnitude S is independent of T, although the thermal averages $\langle S_z\rangle$ can be quite complicated to evaluate; by comparison, for dielectric crystals the local dipoles $P_i(T)$, whose spatial averages yields a macroscopic polarization P, depend in a nontrivial way on T and often vanish individually at elevated temperatures.

1. POLAR DIELECTRICS

1.1 Local Fields and Polarizability Theory

The development of theories for the dielectric properties of polar materials is far more detailed than for nonpolar materials. This is because in nonpolar materials the interaction constant between the electric field and the solid is generally unknown; even the physical mechanism of interaction may be imprecisely known. By comparison, the interaction of polar solids and applied electric fields is assumed to be dominated by simple Coulombic fields, so that some sort of multipole expansion will describe the result. The problems lie in approximating the medium as continuous and defining dielectric constants (and fields) over length scales that are large compared with nearest-neighbor atomic separations, yet small compared to all other characteristic lengths in the system (e.g., sample size).

Historically, there have been two fundamental problems of great interest: First, is the self-alignment of dipoles in a polar crystal (which we call "ferroelectricity") due to Coulomb forces alone, or are short-range interaction among the ions required? And second, how can one express macroscopic quantities, such as the dielectric constant E, in terms of microscopic atomic parameters, such as the polarizability α of a specific atom or molecule (Clausius–Mosotti relationship)?

It was once assumed that dipoles interacting through only Coulomb fields (no short-range interactions) can provide a model of ferroelectricity. Fröhlich's (1937) model assumes an isotropic medium and calculates certain average values over a sphere of radius large compared with a lattice constant a_0, and small compared with the crystal size r (usually assumed infinite). Outside this sphere, a continuous-medium approximation is made, with a dielectric constant ϵ. Inside the sphere is a vacuum, with a (dimensionless) cavity field G. When the sphere is filled with a material of uniform polarization P, the electric field inside the field changes from E_S to E_S+R, where R is called the reaction field. One finds

$$R=[2(G-1)/(2\epsilon+1)]P(4\pi/3). \tag{1}$$

In the limiting case of one polar molecule within each sphere, one obtains $\epsilon-1=[\epsilon/(2\epsilon+1)](4\pi N\mu^2/kT)$, where N is the number of molecules, each of dipole moment μ, per unit volume. This gives $\epsilon\rightarrow\infty$ as $T\rightarrow 0$ but no phase transition. Thus long-range reorientable dipoles in an isotropic medium cannot spontaneously order to produce ferroelectricity at finite T.

If we assume that the local dipoles do order for an unspecified reason (such as short-range forces), then a numerical estimate for the resulting polarization is 10^{-18} esu in a unit cell of order $4\times4\times4$ Å^3, which produces a Curie constant of 1.4×10^3 K. This is a typical Curie constant in a hydrogen-bonded system such as Rochelle salt or tri-glycine sulfate (TGS) and thus formed the basis of ferroelectric models in which re-orientable permanent dipoles played the main role. The first model of that type was provided by Kobeko and Kurchatov (1930).

This internal-field model of Fröhlich leads algebraically to the expression

$$(\epsilon-1)/(\epsilon+2)=4\pi N\alpha/3, \tag{2}$$

which is known as the Clausius–Mosotti relationship. It can be rewritten as

$$\epsilon=[1+8\pi N\alpha/3]/[1-4\pi N\alpha/3], \tag{3}$$

which requires that the dielectric constant diverge at $N\alpha=3/4\pi$. That is referred to as the "$4\pi/3$ catastrophe" and implies that a finite polarization will arise in zero applied electric field, i.e., ferroelectricity will spontaneously arise.

Onsager (1936) extended Fröhlich's model to modify the internal fields. He replaced the depolarization factor 4π discussed above with a general value β that could vary from 4π to $4\pi\times10^{-2}$. It is largest in systems such as tris-sarcosine calcium chloride (TSCC), in which rigid dipoles truly rotate. This eliminates the unphysical result for polar liquids, such as water, for which Fröhlich's theory predicted ferroelectricity at room temperature. Onsager modified the internal field so that the effective field for permanent dipoles can be quite different from that for induced dipoles. The initial application of Onsager's modified theory was made by Slater (1950) for barium titanate. He assumed that α is temperature dependent because it involves ionic displacements. In $BaTiO_3$, he assumed that all the polarization comes from the Ti ion and one of the oxygen ions (designed O_I). If we write $F_{int}=E+[(4\pi/3)+s]P$ in place of Fröhlich's $E+(4\pi/3)P$, we find for barium titanate that the coefficient s is indeed zero at the cell origin $[(0,0,0)$ or $(\frac{1}{2},\frac{1}{2},\frac{1}{2})]$, but is very different at other ion sites: $s(0,\frac{1}{2},\frac{1}{2})=4.3$; $s(\frac{1}{2},\frac{1}{2},0)=-8.7$; $s(\frac{1}{2},0,0)=-15$; *and* $s(0,0,\frac{1}{2})=+30$. (It is useful to distinguish between displacement vector $D=E+4\pi P$ and the internal field $F_{int}=E+\beta P$, where typically $\beta=4\pi/3$. Here, the dielectric constant $\epsilon=dD/dE=1+4\pi\,dP/dE$ is defined for a substance, averaged over a volume large compared with that of the unit cell, whereas the polarizability of any one atom or ion is $\alpha=\mu/F^{int}$.) The criterion for the onset of ferroelectricity in this case then becomes

$$\left(\frac{4\pi}{3}\right)\frac{\Sigma(\alpha_{elec}+\alpha_{ion})}{V}=1, \tag{4}$$

where the sum is over all ions in unit cell of volume V. Slater determined for barium titanate that $(4\pi/3)\Sigma(\alpha_{ion}/V)=0.39$. Thus, in real ferroelectrics, the local fields at different ionic sites may produce an enhancement of the effects originally described by Fröhlich.

2. FERROELECTRICS

In many textbooks, a ferroelectric is defined as a solid that exhibits hysteresis behavior in its $P(E)$ polarization response to applied electric fields. Such a definition is unfortunate because it includes electrets (in which the hysteresis arises entirely from defects and impurities) and also crystals in which $P(E)$ is both lossy and nonlinear but which possess no collective phenomena, ordering temperatures, pyroelectricity, domains, or reversible lattice polarization. A more physical definition of a ferroelectric is that as a polar crystal whose dipoles are intrinsic to the lattice structure and can be reversed by application of a sufficiently large electric field. With this definition, it is necessary but not sufficient for materials to be both piezoelectric and pyroelectric in order for them to be ferroelectric. It is not necessary for ferroelectrics to have a phase transition to a paraelectric phase; many ferroelectrics remain ferroelectric up to their melting point or decomposition temperatures. An operative definition of a ferroelectric is a crystal belonging to a pyroelectric point symmetry class (C_n, C_{nv}, or C_{1h}) that can be switched electrically (coercive field E_c less than breakdown field E_B). Some authors choose to delete the switching requirement and hence to include highly conducting polar metals and semiconductors (e.g., SnTe) as ferroelectric.

Antiferroelectrics can be defined in an analogous way as crystals having pairs of oppositely directed dipoles in their lattice structure, i.e., consisting of two sublattices, each of which is ferroelectrically ordered, but in opposite directions. It is possible to confirm such structures via x-ray crystallography. However, there is no low-field electrical response that yields an unambiguous "signature" of antiferroelectricity. When large electric fields are applied to antiferroelectrics, two *P*(*E*) hysteresis loops are often observed, as shown in Fig. 1(b).

2.1 Hysteresis

It is helpful to discuss the hysteresis *P*(*E*) relationship in Fig. 1 in terms of the three parameters that determine it: E_c, the coercive field, is the *nominal* field required to switch the polarization; P_S, the saturation value of polarization, is extrapolated from asymptotically large applied field *E*; and P_r, the remnant polarization, is the polarization remaining after the applied field is switched off. In reality, E_c is not a constant. It has strong dependence on thickness *d*, increasing from ca. kV/cm in bulk to ~MV/cm at $d \cong 50$ nm. It also depends on the duration of the applied field; as discussed in Sec. 10, a dielectric with a breakdown voltage of 50 V applied as a 30-μs pulse may not tolerate 20 V for 1 s or stand off 5 V applied dc for a month. And E_c depends upon repetitive cycling (fatigue), usually decreasing with increasing number of cycles *N*.

The spontaneous saturation polarization P_S does not vary much with thickness, contrary to textbooks that predict its disappearance, due to depolarization effects at the surfaces, in very thin films. Here, P_S may even increase as $d \rightarrow 40$–50 nm, for reasons discussed in the "finite-size effects" section below. P_r does decrease markedly with fatigue. This behavior is probably due to the decoration of electrode interfaces (and grain boundaries, in ceramic specimens) with accumulated charged defects. Such defects may be intrinsic. For example, pairs of oxygen vacancies and lead vacancies in PZT ($PbZr_{1-x}Ti_xO_3$) form strong dipoles that compensate the lattice polarization and often preclude switching.

An obvious question to ask about the hysteresis curve in Fig. 1 is why the hysteresis loop is not square. Why does P_r not equal P_S? The finite slope of *P* versus *E* at E_C is easier to explain; it arises from a distribution of local coercive fields, due to domain wall structures and to defects. But why is P_S so much larger than P_r, often $\approx 2P_r$? In a pure single crystal, P_r should be only slightly less than P_S. Since a single-domain, polarized state is the ground state of the system below T_c, the effect of a finite temperature *T* is to put a small fraction of dipoles in the antiparallel configuration: % anti$=e^{-\mathbf{E}\cdot\mathbf{P}/kT}/(e^{+\mathbf{E}\cdot\mathbf{P}/kT}+e^{-\mathbf{E}\cdot\mathbf{P}/kT})$. However, under normal circumstances this fraction is small; $EP/kT \approx (10^6 V/m)\ (10^{-2} C/m^2)/(0.03\ eV) \approx (3\times 10ex^5\ J/m^3)/eV \approx 2\times 10^{19}\epsilon_0 = 2\times 10^8$.

There is also a linear response causing $P_S > P_r$, but this effect is also too small to explain observed data with $P_S \gg P_r$. Even if 100% of the dipoles are lined up along $\hat{z}$ in the absence of an applied field, in an applied field the dipoles will increase in length through charge separation of + and −. This linear response $\Delta P = \epsilon_0 \epsilon E$ is fairly small (even though ϵ increases during switching due to domain wall contribution).

So, in hysteresis curves where $P_S \gg 1.1P_r$, one may assume that a certain amount of backswitching is occurring where domains flip back after an insufficiently long voltage pulse is applied. The primary cause of backswitching is defect dipoles (such as Pb-O vacancy pairs in PZT). These are very slow to reorient and thus cause $P_r \ll P_S$ unless very low

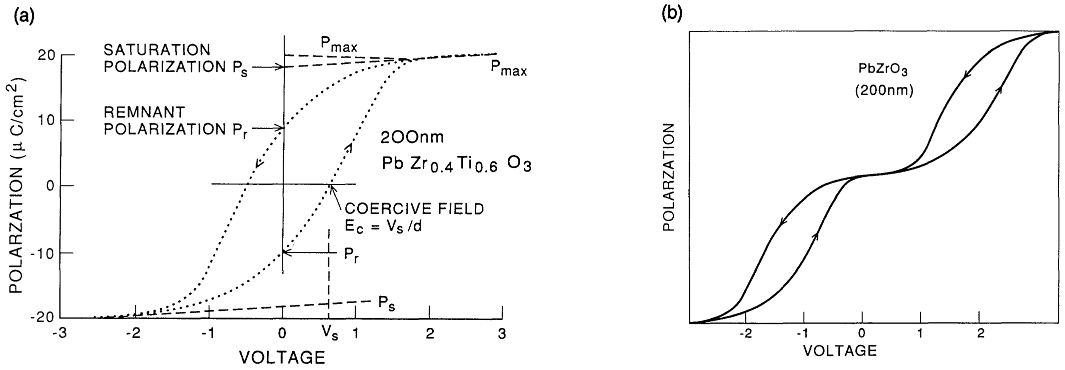

FIG. 1. Hystersis behavior *P*(*E*): (a) in a ferroelectric; (b) in an antiferroelectric.

frequencies are used to measure hysteresis. Backswitching will be greater in ceramics than in single crystals and greater in fatigued ceramics than in virgin specimens.

Backswitching is the reason why both switching and nonswitching current transients ($+E_C$ applied to $-P_r$ and $+P_r$ states, respectively) look qualitatively similar in PZT ceramics [Fig. 2(a)]. If there were no backswitching, we would expect the nonswitching current transient to look like that in Fig. 2(b), which is a voltage spike followed by a monotonic decay.

2.2 Switching Kinetics

Some elementary texts suggest that when a large external field is applied to a ferroelectric crystal, the dipoles reorient simultaneously and almost instantly. This, in fact, would occur at extremely high fields; but at normal fields in the kV/cm–MV/cm range, another mechanism is energetically easier: Domains nucleate, primarily through inhomogeneous nucleation processes at electrode interfaces and defect sites (grain boundaries in ceramics). These domains fluctuate in size until a critical radius is achieved. Then rapid growth occurs as one-dimensional needlelike domains, parallel and antiparallel to the applied field. Finally, the domain walls spread out sideways until the specimen is ~100% reversed from its initial polarization. The last step is usually the rate-limiting step, although in some ferroelectrics (GASH, guanidinium aluminum sulfate hexahydrate) the nucleation step is, and in others (TGS, triglycine sulfate), each step requires comparable time.

When sideways domain growth is the rate-limiting step, Stadler has shown, the switching time varies as $E^{-3/2}$ at high fields. This is in contrast to the activation field dependence $t_S = t_0 e^{-\alpha/E}$ observed generally at low fields.

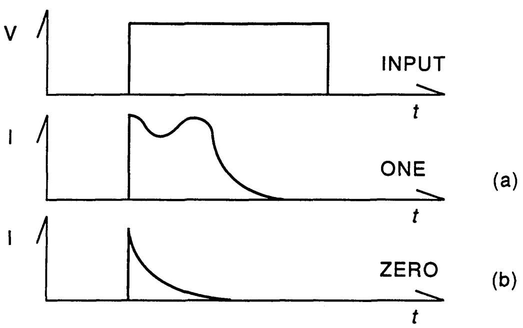

FIG. 2. Displacment current transient $i(t)$ in (a) switching ferroelectric, compared with (b) the nonswitching response.

Ishibashi (1986) has developed a theory of switching based upon earlier models of crystal growth due to Kolmogorov and Avrami. His model, summarized in Eq. (5) below, involves a characteristic switching time t_S, the dominant dimensionality d of domain growth, and the spontaneous polarization P. This three-parameter theory predicts the shape of the displacement current transient $i(t)$ quite well in KNO_3 and PZT at various temperatures and field (see Fig. 2),

$$
\begin{aligned}
i(t) &= \frac{2A\,\Delta P(t)}{\partial t} \\
&= (2P_s A n t_0^{-1})\left(\frac{t}{t_0}\right)^{n-1} \exp\left[-\left(\frac{t}{t_0}\right)^{n}\right], \qquad (5)
\end{aligned}
$$

where A is the electrode area; n, an exponent characterizing domain growth; and t_0, a characteristic growth time depending upon temperature and applied field.

It is found experimentally that there are significant effects in ferroelectrics that arise from finite sizes for the individual grains or, in the case of films, from the film thickness. The most significant effect is that the coercive field increases by about 10^3 as films decrease in thickness from 100 μm to a few tens of nm. Many physical parameters, including coercive field, vary as well with grain size r, typically as $r^{1/2}$ or $r^{-1/2}$.

2.3 Mean-Field Theory of Phase Transitions

In 1937, Landau developed a simple theory that qualitatively describes many of the phenomena exhibited by ferroelectrics near their Curie temperatures. The theory assumes that all dipoles i and j interact equally with each other, independent of separation distance V_{ij}. That is equivalent to an infinite-range potential and hence to replacing the sum of two-particle interactions by an effective field due to $n-1$ particles acting on the remaining particle. This kind of "mean-field" or "molecular-field" theory was first used by Van der Waals to describe the gas–liquid phase transition and by Weiss to describe ferromagnetic–paramagnetic ordering transitions. For fluids and magnets such a mean-field theory gives results only qualitatively in agreement with experiment, because the actual microscopic interactions are extremely short range. However, in ferroelectrics (and, incidentally, in superconductors) the interactions are very long range, being fundamentally Coulombic—which falls off very slowly, as $1/r$—so that mean-field theory gives good quantitative agreement with ferroelectrics experiments.

Landau's assumption is that the crystal's free energy $G(P,T)$ can be expanded in a power series in polarization P near the Curie temperature T_C:

$$G(P,T)=\tfrac{1}{2}A(T-T_C)P^2+\tfrac{1}{4}BP^4+\tfrac{1}{6}CP^6, \qquad (6)$$

where the linear temperature dependence of the quadratic term arises directly from the assumption of infinite-range forces (mean field) and the coefficients B and C are assumed to have no important temperature dependences.

If B and C are both positive, a continuous or "second-order" phase transition occurs at T_C. That is, the expectation value $\langle P(T)\rangle$ varies continuously to zero at T_C and discontinuities are found only in second order, i.e., $\partial P/\partial T$ has a jump at the Curie temperature. If B is negative but C is positive, a discontinuous phase transition is observed at $T_0=T_C$. There is a finite jump in $\langle P(T)\rangle$ and T_C and two (bistable) solutions to minimizing $G(P,T_C)$ exist, one with $\langle P\rangle=0$ and one nonzero. Other quantities may also be discontinuous at such first-order transitions, including spontaneous strain, so that crystals undergoing first-order transitions often crack at the transition temperature.

For first-order transitions, the are three temperatures of importance in addition to the actual transition temperature T_0. These may be understood in general by reference to Fig. 3, which shows the shape of the free energy $G(T,P)$; $G(T,X)$ is equivalent to $G(T,P)$, where X is the displacement of ions that produces the polarization P, and P is proportional to X. Below T_0, only the ferroelectric (FE) phase can exist. Between T_0 and $T_C=T_0+3B^2/16AC$ ($=T_0+7.7$ K in BaTiO$_3$) the nonpolar phase is metastable and the FE phase is stable. (T_C is the extrapolated T at which the FE transition would become continuous, i.e., the Curie temperature extrapolated from the low-T phase.) Between T_C and T_1, the nonpolar phase is stable and the polar phase is metastable and can be induced by applied field;

$$T_1=T_0+4B^2/AC(=T_0+10 \text{ K in BaTiO}_3) \qquad (7)$$

(*n.b.*: T_1-T_0 is the width of the thermal hysteresis). Between T_1 and T_2, the ferroelectric phase can be induced *only* by an applied field

$$T_2=T_0+9B^2/20AC(=T_0+18\ ^\circ\text{C in BaTiO}_3). \qquad (8)$$

In this discussion T_0 is the actual transition temperature at which there are three equal minima in the free energy $G(X)$; T_1 is the temperature at which $G(X)$ develops an inflection point. See Fig. 3.

The coefficient B may be a function of other parameters, such as hydrostatic pressure, uniaxial stress S, or electric field E, along the polar axis (i.e., the field E_j "conjugate" to the spontaneous polarization P_j), and B may change sign as a function of these parameters. The point in phase space where $B\ (E,T)$ [or $B(S,T)$] changes sign is called a "*tri*critical

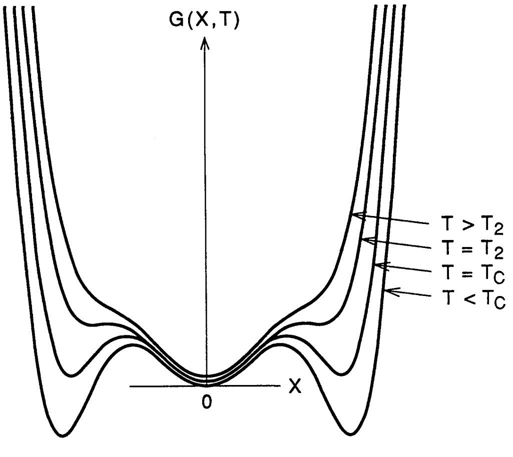

FIG. 3. Free energies $G(T,P)$ versus temperature from Landau theory. Above T_c but below T_1, the free-energy minimum at $P=0$ is deeper than those on the sides ($P\neq 0$); in this range the nonpolar phase is stable but the polar phase is metastable and can remain for long times. Above T_1, but below T_2, the minima in the free energy at positive and negative P grow smaller as T increases, until at T_2 only inflection points in $G(p)$ remain. A stable ferroelectric phase can be induced by an applied electric field between T_c and T_2. A metastable ferroelectric phase can remain even after the field is turned off between T_c and T_1. Ferroelectricity cannot be induced by any applied field above T_2. The text gives numerical values for T_2–T_c and T_1–T_c for BaTiO$_3$.

point" because it connects *three* lines of continuous phase boundaries, one of which lies in the $E=0$ plane, and two which extend into $\pm E$ space, as shown in Fig. 4.

A different kind of critical point can occur when the field is applied perpendicular to the polar axis. Such a case is illustrated in Fig. 5 for $NaNO_2$, which has ferroelectric phase separated from paraelectric phase by a spirally modulated (incommensurate) phase. As the applied field is increased, the intermediate phase disappears and the ferroelectric and paraelectric phases approach each other tangentially. The point where they come together is called a Lifshitz point.

For conjugate fields E_j, there may be quite different phase diagrams, such as that in Fig. 6, which illustrates a triple point (coexistence of three phases), a tricritical point (discussed above) where the transition changes from continuous to discontinuous, and even a critical end point, like that in gas–liquid systems. Note that a critical end point is possible only where the applied field is the conjugate field, because in this case it is not a symmetry-breaking field. That is, there is no need for a phase boundary between ferroelectric and paraelectric states in the presence of a large electric field along the polar direction. [Similarly, there is no need for a phase boundary between ferromagnetic (FM) and paramagnetic (PM) states in finite magnetic fields, as shown in Fig. 7. FI in this figure designates a six-sublattice ferrimagnetic state.]

The simple free energy given above describes many real ferroelectrics extremely well. The coefficients *A*, *B*, and *C* are greatly over-determined from available experimental data. Usually *A* is determined from measurement of dielectric constants $\epsilon(T)=(\partial^2G/\partial P^2)^{-1}=4\pi\mathscr{C}/(T-T_C)$, where $\mathscr{C}$ is called the Curie constant and should not be confused with *C* in the free-energy expansion. *B* is determined from graphing ϵ^{-1} vs P^2 $[\epsilon^{-1}=A(T-T_C)+3BP^2+5\delta P^4)]$ and *C* is determined from P_S just below T_0, where $P_S^2=-B/C$.

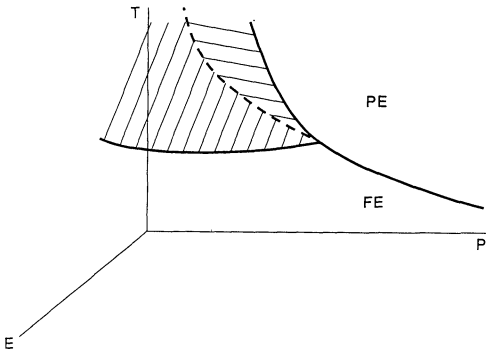

FIG. 4. Free energy surfaces $G(T,E)$ near a tricritical point.

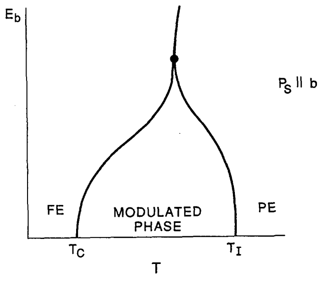

FIG. 5. Phase diagram near a Lifshitz point.

But many additional experimental measurements give a self-consistency check. For example, the width of thermal hysteresis is given by $\Delta T=T_1-T_0=B^2/4AC$. The specific heat jump is given by $\frac{1}{2}AP_S^2(T_0)+\frac{1}{4}P_s^4(T_0)\partial B/\partial T$, and so forth. For the best studied ferroelectrics *A*, *B*, and *C* are each known to better than 5% accuracy; e.g., in TGS, $A=3.92\times10^{-3}\ K^{-1}$; $B=8.0\times10^{-10}$ cgs; $C=5.04\times10^{-18}$ cgs. In $BaTiO_3$, $A=7.4\times10^{-5}\ K^{-1}$; *B* is negative and depends linearly on *T* as $B=18\times10^{-15}(T-T_2)$, $T_2=175\ ^\circ C$; $C=33.4\times10^{-23}$ cgs.

Unfortunately, the free energy discussed above is too simple to describe some complicated ferroelectrics. For some crystals the order parameter that describes the lattice instability is not polarization *P* but some other variable, such as strain e_j, with polarization coupled nonlinearly to e_j. In these systems, termed "improper" ferroelectrics, the spontaneous polarization of the low-symmetry state

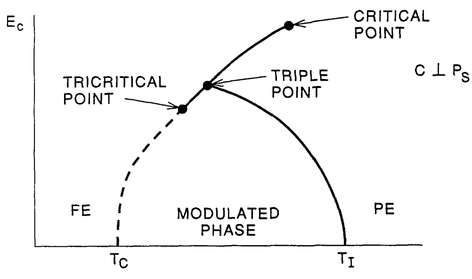

FIG. 6. Phase diagram illustrating triple point, tricritical point, and critical end point. Figures 5 and 6 schematically approximate the real situation in $NaNO_2$.

arises as a kind of "accident" or secondary effect at the phase transition. The complexities and higher-order terms required in the free energies of real ferroelectrics (for which the order parameter is often multidimensional) have generated whole books (e.g., Toledano and Toledano, 1987). A particularly interesting category is that of modulated structures (whose periodic repeat distances are *incommensurate* with the lattice spacing A_0 of the normal phase); these require gradient terms in the free energies G.

2.4 Order–Disorder versus Displacive Systems

In a purely order–disorder system, ions sit in a double-well potential $V(r)$ which is totally independent of temperature T. As temperature rises, the expectation value of average ionic position $\langle r \rangle$ changes dramatically because of Bose population factors, moving from a position often centered on a bond (e.g., O–H–O) to one off center (O–H– –O) with a net dipole. Such an order–disorder model of ferroelectricity is highly attractive by virtue of the fact that the two sides of the double well may be labeled according to fictitious "pseudospin" states $+\frac{1}{2}$ and $-\frac{1}{2}$, and of the extremely complex spin formalism borrowed wholecloth from the analogous problems in ferromagnetism. Unfortunately, there seem to be no real ferroelectrics which closely approximate this spin theory.

In a displacive system, on the other hand, the shape of the double well $V(r,t)$ is explicitly dependent upon T, approximating that of the free energy discussed above. In this case, the ions also move from a centered value ($r=0$, $P=0$) to an asymmetric position, but the change in thermal population of energy levels is negligible; rather, it is the levels themselves that vary in energy with T. [This contrast is analogous to that of raising the energy of a system of molecules isothermally by doing work on it, e.g., compressing it (which changes the energy level spacing without modifying the population of each level), compared with simply heating it, by which the populations of each energy state change but the energy levels remain fixed.] Many real dielectrics approximate a perfectly displacive system. That is, most of the change in $\langle r_j \rangle$ comes from changes in the shape of $V(r,T)$, not from the changes in populations of energy levels within a T-independent potential V.

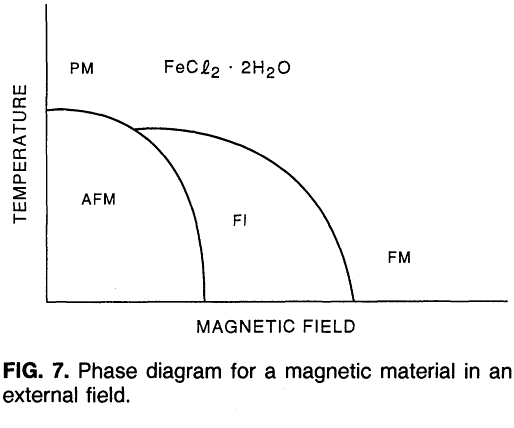

FIG. 7. Phase diagram for a magnetic material in an external field.

Of course, there are real crystals with dynamics intermediate between order–disorder and displacive, in which changes in $V(T)$ account for about half the change in $\langle r_j \rangle$. In some systems, one sublattice undergoes an order–disorder transition (e.g., O–H– –O in KH_2PO_4) which drives a displacive instability in a second sublattice (K^+ or P^+ in KH_2PO_4).

It was once considered that all hydrogen-bonded systems were order–disorder in character. That is untrue: asymmetric hydrogen bonds, such as those in triglycine sulfate, Rochelle salt, or tris-sarcosine calcium chloride (e.g., N–H– –Cl) do not generally produce order–disorder dynamics and are more accurately described as displacive.

An old rule of thumb is that the entropy change is large at an order–disorder transition ($\Delta S \sim 1$ cal/g·K) and small at a displacive transition ($\Delta S \sim 0.1$ cal/g·K), but the experimental values span a continuum without an obvious bimodal distribution. So there is reason to believe that most systems are partially displacive in their kinetics and partially disordered. Precise x-ray data show disorder phenomena very near T_C in even the most displacive of systems (e.g., $PbTiO_3$).

Displacive structural phase transitions are necessarily accompanied by a "soft" (i.e., unstable) optical phonon whose energy approaches zero as $T \rightarrow T_C$. As first outlined by Cochran (1960, 1961) for ferroelectrics, this instability may be described as a subtle cancellation between the long-range and short-range contributions to the frequency of a long-wavelength ($k=0$) transverse optical (TO) phonon:

$$\omega_{TO}^2(T) = R_0' - 4\pi(Ze)^2/V(T), \qquad (9)$$

where $V(T)$ is the unit cell volume, and R_0' is a short-range steric force constant not due to electric charge. [By comparison, for longitudinal (LO) modes the two contributions have the same sign, and so complete softening of $\omega_{LO} \rightarrow 0$ is impossible.] For order–disorder transitions, a soft optical phonon is unexpected. However, damping of one mode often diverges as $T \rightarrow T_C$, so that for $T \rightarrow T_C$ only a diffusional response is observed. In both cases, the peak of the imaginary part of the dielectric constant shifts to $\omega = 0$, but the details differ.

2.5 Ultraweak Ferroelectrics

There are three broad categories of ferroelectrics, classified according to the magnitude of their Curie constants $\mathscr{C}$. In the first category, $\mathscr{C} \approx 10^5$ K and $\mathscr{C}/T_C \approx 10^3$. It is exemplified by $KNbO_3$, $BaTiO_3$, $LiNbO_3$, and other oxides having no permanent dipoles in their paraelectric phases. The second category has $\mathscr{C} \approx 10^3$ K and $\mathscr{C}/T_C \approx 10$. In this group the early 1930 model of Kobeko and Kurchatov is a reasonable approximation; it views ferroelectricity as arising from a rigid rotationlike orientation of permanent dipoles (giving $\mathscr{C} = 3T_C$, as discussed in a section which follows). The third category has $\mathscr{C} < 10^2$ K and $\mathscr{C}/T_C < 1$. It is exemplified by TSCC, $(CH_3NHCH_2COOH)_3.CaCl_2$. In this system, Kozlov *et al.* (1983) were able to show that it is a displacive ferroelectric satisfying Cochran's equation [Eq. (9)], but the instability is in a short-range force constant R_0' in the shell-model description with negligibly small Coulombic terms. As a result, it has both soft transverse TO and longitudinal LO modes, although the TO necessarily reaches zero frequency as T approaches T_0 before the LO does.

2.6 Domain Structures

Magnetic domains are separated by domain walls that are thick ($\geqslant 10$ nm) and permit a continuous rotation either out of the plane of magnetization (Bloch walls) or, in thin films, in-plane (Néel walls). In contrast, ferroelectric domains are usually separated by very thin ($\leqslant 1$ nm) walls of straight edges (Fig. 8). The angles between these walls are restricted by the symmetry of the ferroelectric phase and may include needlelike, zig-zag, and polyhedral arrays (Fig. 9). Under some circumstances thought to be nonequilibrium, the ferroelectric domain boundaries may be quite wavy or "rough," as in lead germanate. These rough domains approximate spin-1/2 Ising model simulations.

As typical examples of differing domain patterns, one might cite TGS (tri-glycine sulfate) as a ferroelectric with only 180° domains (antiparallel polarizations) and barium titanate with both 90° (polarizations at right angles) and 180° domains. In the latter material the 90° domains are not truly at right angles, but lie at $\pm 36'$ from 90°, which permits their observation in crossed polarizers (and also causes considerable internal strain). These 90° domains form angles of 45° with each other. That eliminates (or at least minimizes) the creation of $\nabla \cdot \mathbf{P}$ nonzero space charge; and they form an angle of either 22.5° or 67.5° with the electrodes. In general, domain walls form in a way that permits continuity of strain (lattice deformation) in addition to continuity of the component of electric polarization **P** normal to the domain walls. This requires in piezoelectric Rochelle Salt a chevron structure having 2° differences in the local optical axis, which permits visual observation.

In very thin magnetic films with Néel walls, the critical switching field H_c varies with thickness d as $d^{-4/3}$ (Néel's law). A similar thickness dependence is found for electrical

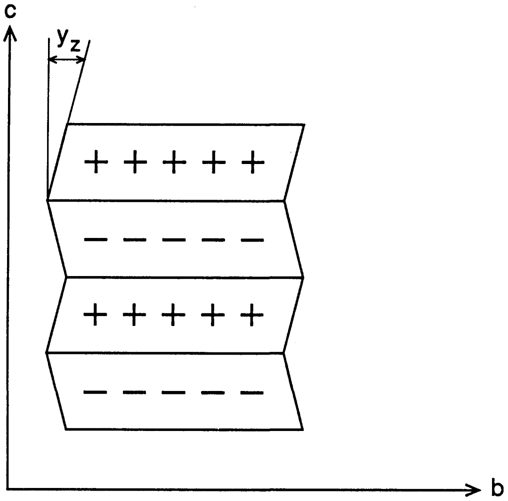

FIG. 8. Straight-line domain wall structures in Rochelle salt. From Kanzig (1957).

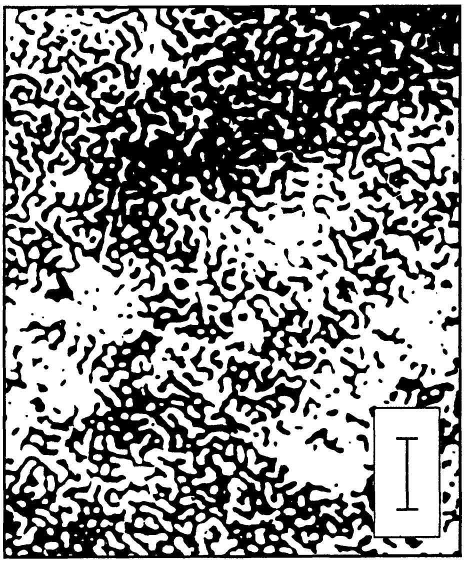

FIG. 9. More complex domain wall configurations in ferroelectrics. From Shur *et al.* (1989).

coercive field E_c versus thickness in dielectric films thinner than 100 nm, but there is no direct evidence that the domain walls differ in geometry for thin and thick ferroelectric films in a manner analogous to Bloch versus Néel walls in ferromagnets (Fig. 10); here the Bloch walls, which have spins rotating out of the surface of the material, are stable for thicker films, whereas the Néel walls, in which spins always lie in the plane of the film, are stable for thinner films.

3. FERROELASTICS

A ferroelastic crystal is one exhibiting hysteresis behavior in its stress–strain relationship, analogous to that between P and E in a ferroelectric. The symmetry classes that can exhibit ferroelasticity have been enumerated by Aizu in 1970. Not all ferroelastics are ferroelectric, or even polar: for example, the C_{2h} phase of LaP_5O_{14} is ferroelastic, and the $D_{2h} \leftrightarrow C_{2h}$ transition is termed a ferroelastic transition (because it is from a ferroelastic state to a nonferroelastic state). Ferroelastic states are bistable at zero applied stress. Not all ferroelectric states are ferroelastic. Ferroelectricity and ferroelastic states can coexist in complex ways; for example, $Ba_2NaNb_5O_{15}$ is both ferroelastic and ferroelectric between 543 and 580 K, and the ferroelastic domains are distinct from the ferroelectric domains, so that at least four physically distinct elastic-electric domains or states coexist.

4. ELECTRET EFFECTS

An electret is a material in which free charge, usually termed "space charge" (electrons or mobile ions), may be electrically driven to the surfaces by application of an electric field. Electrets exhibit many of the macroscopic characteristics usually identified with ferroelectrics—including hysteresis in their $P(E)$ relationship—but they are not ferroelectric: They possess no microscopic dipoles and exhibit no collective phenomena such as an ordering temperature.

The traditional electret is carnauba wax. An example of more current interest is polyvinylidene fluoride (PVF_2). Both materials are able to store charge at their surfaces corresponding to kV of potential differences between the front and back surfaces and to retain it for long times (weeks). Depending upon the charging techniques (whether by proximity or direct contact) and the nature of the electrode interface, the charge state that results can be the same as that of the contact electrode ("homocharge") or opposite ("heterocharge").

Because the polarization in an electret involves ion transport over microscopic distances, it is slow to reverse electrically compared to ferroelectrics (ms vs ns). However, in many real ferroelectrics, electretlike space charge effects may also be present, in addition to the lattice polarization. This greatly com-

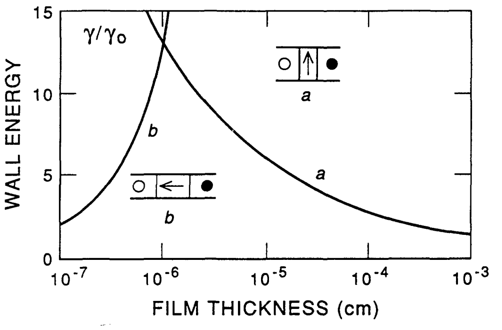

FIG. 10. Néel [curve (a)] and Bloch [curve (b)] wall energies in a ferromagnet versus film thickness. From Chikazumi (1985).

plicates the experimental evaluation of quantities such as remnant polarization P_r, spontaneous polarization P_S, coercive field E_C, and switching time t_S. One characteristic symptom of electret effects is the non-Ohmic current-voltage relationship (Langmuir–Child's law)—a quadratic $I=aV^2$ dependence is observed for space-charge limited current flow in an insulator. Electret effects may be created in insulators exposed to ionizing radiation.

5. ELECTROSTRICTION

Electrostriction is a phenomenon described by a quadratic relationship between strain and electric field. It is present in all solids, including glasses. By comparison, piezoelectricity is a linear relationship between strain and electric field. It is present in only 20 of the 32 point-group symmetries (crystal classes). Of these 20, only 10 have a unique polar axis. These 10 are pyroelectric, with a net polarization that changes with T. Pyroelectrics which can have their polarization reversed (switched) by application of an external electric field are called ferroelectrics. This distinction between pyroelectrics and ferroelectrics is thus purely practical and empirical; there are no symmetry differences between the two.

6. ELECTROCALORIC EFFECT

Various discussions of the electrocaloric effect exist in the literature, which seem to disagree qualitatively with each other. Fatuzzo and Merz (1967) state that the electrocaloric effect is the change in temperature for a ferroelectric crystal whose polarization changes rapidly, and that it occurs (for large fields) only *above* T_C, where $\Delta T=\beta TP^2\times(2C_p\rho)^{-1}$, and application of an electric field changes polarization P from zero to finite values. Below T_C they state that (large) electric fields change $+P$ to $-P$ which produces no change in ΔT. The maximum effect, they state, in $BaTiO_3$ is $\Delta T\approx 2$ K for $T\approx T_C+1$ K.

By comparison, Mitsui *et al.* (1976) claim that the electrocaloric effect can occur only below T_C, since $(\delta T)_{S,x}=(T/C)(\partial Pi/\partial T)_{x,E}$, where $P_i=0$ above T_C and $=P_S$ below T_C, since

$$(\delta T)_{S,x}=\left(-\frac{T}{C}\right)\left(\frac{\partial P_i}{\partial T}\right)_{x,E}(\delta E_i)_{\partial,x}. \tag{10}$$

Since $\partial P_i/\partial T<0$, heat $T\,dS$ must be taken out of the crystal in isothermal conditions if E is $\|P_S$.

Jona and Shirane (1962) disagree with Mitsui *et al.* and point out that ΔT in KDP is 1 K at $E=10$ kV/cm and T_C+1 K.

In any case, the electrocaloric effect arises because of the difference between isothermal and adiabatic dielectric constants. The correct interpretation is as follows.

In ferroelectrics with second-order phase transitions, applied fields cannot shift T_C or induce a polarization above T_C. Hence, in such systems (e.g., TGS), the electrocaloric effect vanishes above T_C, since $\partial P_i/\partial T=0$. Below T_C, $\Delta T=-\beta TP^2/\rho C_p$ is nonzero, provided the applied field does not induce switching from $-P$ to $+P$.

In ferroelectrics with first-order transitions, applied fields above T_0 (but less than T_2) cause large increases in P, from zero to values nearly those of P_S below T_0. In these systems (e.g., $BaTiO_3$, where $T_2=T_C+18$ K) the electrocaloric effect is largest *above* T_0 (1 K per 10 kV/cm) but below T_C and T_2.

7. PIEZOELECTRICITY

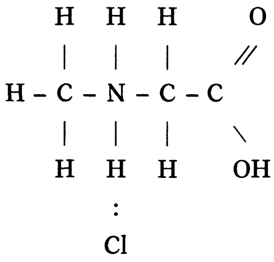
All ferroelectrics are necessarily pyroelectric (a change in polarization is generated by a temperature change ΔT) as well as piezoelectric. Piezoelectricity is defined as a change in electric polarization P with change in applied stress σ. The piezoelectric tensor is third-rank, since it couples a vector polarization with a second-rank stress tensor. The inverse effect, of an applied electric field producing a stress (and strain), is termed "electrostriction." Electrostriction necessarily contributes to the free-energy coefficient B in the Landau theory free energy discussed in Sec. 2.3. For example, in KNO_3, $B=-30$ (cgs) when electrostriction is included, whereas $B=-4$ (cgs) when electrostriction is ignored. Thus, the effect of electrostriction in KNO_3 is to make its phase transition far more discontinuous. Note that a quadratic electrostrictive term will be nonzero in all solids (including glasses), independent of their symmetry.

8. NUMERICAL VALUES

8.1 Spontaneous Polarization

The maximum value of P_S that might be possible in a solid is that in which a single electrical charge e is displaced by a bond length L in each unit cell. Assuming $L=1$ Å, this gives a dipole of 10^{-29} C m per unit cell volume. In crystals with small unit cells ($V \approx 3\times3\times3$ Å) such as ABO_3 perovskites, this produces a polarization of approximately $P_S = ed/V = (10^{-29})/(27\times10^{-30}) = 0.4\ \mathrm{C/m^2}$, in rather close agreement with the maximum values observed experimentally in perovskites such as $PbTiO_3$.

P_S can of course be much lower. In smectic-C^* ferroelectric liquid crystals and other materials with large and complex unit cells, the value of P_S is greatly reduced by the large cell volume V, which appears in the denominator in the equation above. In other systems the charge displacement d is very small, because the ferroelectric phase transition involves an eigenvector (often a rigid or nearly rigid rotation) that very slightly displaces net charge. Tris-sarcosine calcium chloride (TSCC) is probably the best example of such a weak ferroelectric; in it the rotation of hydrogen-bonded sarcosine molecules



$$\begin{array}{ccccccccc} & & H & & H & & H & & O \\ & & | & & | & & | & & // \\ H & - & C & - & N & - & C & - & C \\ & & | & & | & & | & & \backslash \\ & & H & & H & & H & & OH \\ & & & & : & & & & \\ & & & & Cl & & & & \end{array}$$

yields $P_S = 2.7 \times 10^{-3}\ \mathrm{C/m^2}$, more than a thousand times weaker than in $KNbO_3$ or $PbTiO_3$.

A listing of P_S values for 20 well-studied ferroelectrics is given in Table 1, together with other pertinent parameters. In Table 1 the acronyms TGS, TGSe, and TGFB stand for triglycine sulfate, triglycine selenate, and triglycine fluoroberyllate, respectively. TSCC and MASD are tris-sarcosine calcium chloride and methyl ammonium sulfate dodecahydrate (alum).

8.2 Curie Constant

8.2.1 Quantum Cryogenic Effects. In analogy with ferromagnets, in which the magnetic susceptibility often obeys a Curie–Weiss law of form

$$\chi(T) = \chi_0 + [\mathscr{C}/(T-T_c)], \tag{11}$$

where $\mathscr{C}$ is called the Curie constant and T_c the Curie temperature (which may differ from the actual phase transition temperature T_0), dielectric solids often exhibit the same functional form for their dielectric constant,

$$\epsilon(T) = \epsilon_0 + [\mathscr{C}/(T-T_c)]. \tag{12}$$

If $T_c > 0$ the material is usually ferroelectric, with a spontaneous polarization over some finite temperature range. In some materials, such as $KTaO_3$ and $SrTiO_3$, this Curie–Weiss law is satisfied over a large temperature range but becomes invalid near T_c, which is near absolute zero, and no phase transition actually occurs. That is, a dielectric crystal may satisfy the equation above over a wide temperature range, with a positive value of Curie temperature T_c, but have no actual phase transition.

In the specific cases of pure $SrTiO_3$ or $KTaO_3$, the reason for this anomalous behavior is due to explicitly quantum effects. Equation (12) above can be derived microscopically from the anharmonic theory of lattice dynamics; see for example, Kozlov *et al.* (1983). In such a rigorous treatment a population factor $\bar{n}(T) = [e^{\hbar\omega/kT} - 1]^{-1}$ appears, which in the high-temperature approximation becomes $kT/\hbar\omega$. This term leads to the linear dependence of $\epsilon^{-1}(T)$ upon T in Eq. (12) above. However, it is impossible to make this approximation near $T=0$, and Eq. (12) fails. Such quantum ferroelectric phenomena have been studied carefully in crystals of the $SrTiO_3$ and $KTaO_3$ family, doped with substitutional ions that vary T_c, and in TSCC doped with bromine.

8.2.2 Calculating Curie Constants. In the Weiss theory of magnetism the Curie constant $\mathscr{C}$ in Eq. (11) describing the temperature dependence of the magnetic susceptibility in the paramagnetic phase is not an independent parameter but is given by

$$\mathscr{C} = Ng^2\mu_B^2 S(S+1)/3k_B, \tag{13}$$

Table 1. Experimental properties of some well-studied ferroelectrics.

where N is the number of spins per unit volume of magnitude S; g, the gyromagnetic ratio; μ_B, the Bohr magneton; and k_B, Boltzmann's constant. In contrast to this situation, the Curie constant $\mathscr{C}$ appearing in Eq. (12) in the dielectric susceptibility of ferroelectric crystals in their paraelectric phases above T_c is more often regarded as an empirical parameter without a precise microscopic origin. From 1930 through 1955, however, a considerable effort was made to calculate $\mathscr{C}$ for real crystals by physical models. The first of such models was that of Kobeko and Kurchatov (1930), who used a model of rotating dipoles in which the polarizability α of each dipole p_i is given by $\alpha=p_i^2/3k_BT$. The internal field is then given by

$$E_r=E_a+(\beta/4\pi)P, \tag{14}$$

where E_a is the applied field, P is the polarization, and β is called the Lorentz factor. For an array of point dipoles in a simple cubic (or random) lattice, $\beta=4\pi/3$ and $\mathscr{C}=3T_c$ exactly.

A few ferroelectrics empirically satisfy these predictions. Methylammonium aluminum sulfate dodecahydrate alum (MASD) has $\beta=4.51 \approx 4\pi/3$ and $\mathscr{C}=2.9T_c$, in excellent agreement with predictions. TSCC and Rochelle salt are also rather close, suggesting that a rigid-rotation model of localized dipoles is a fair description of their phase-transition kinetics; however, many other materials disagree with these constraints by many orders of magnitude (see Table 1).

Typically, the ABO_3 oxides have Curie constants $\mathscr{C} \approx 10^5\,K \approx 10^3T_c$. These "strong" ferroelectrics do not seem amenable to physical models involving permanent dipoles. Rather, their behavior involves ionic displacements that are created below T_c. Thus, they may often be characterized primarily as "displacive" rather than "order–disorder" systems. Such simple labels may be helpful in generic labeling, but they are misleading in specific cases. Whereas ABO_3 perovskites are probably displacive in their dynamics as a group, $BaTiO_3$ is more accurately described as order–disorder. And among hydrogen-bonded systems (often generically viewed as order–disorder), TSCC is quite displacive, with underdamped "soft" optical photons in both paraelectric and ferroelectric phases—despite its numerical agreement for $\mathscr{C}$ and β with Kobeko–Kurchatov theory mentioned above. Most real crystals possess some displacive characteristics and some order–disorder properties in their behavior near transitions.

8.2.3 Numerical Self-Consistency of Mean-Field Theory. The Landau theory described in Sec. 2.3 has a few empirical parameters. These parameters are overdetermined for most dielectric materials by the available experiments; thus, a check on the self-consistency of the theory is usually possible. One such internal check is that the entropy change at T_c (or T_0) times the Curie constant $\mathscr{C}$ should equal 2π times the square of the spontaneous polarization:

$$\mathscr{C}\Delta s=2\pi P_S^2. \tag{15}$$

In practice, as shown in Table 1, this relationship is satisfied only within factors of 2 or 3. [We compare in Table 1 the Lorentz factor $\beta=4\pi T_c/\mathscr{C}$ with another factor $\beta'=2T_c\Delta S/P_S^2$ that should equal β of Eq. (14) if Eq. (15) is true.] The reason is that the coefficients (e.g., γ and δ) appearing in the free-energy expression of Eq. (15) are assumed in the simplest theory to be temperature independent. In reality, they all vary continuously with temperature (although they are not singular at T_c), so that Eq. (15) above is only an approximation, always good to an order of magnitude, but never exact.

8.3 Dielectric Constants

As discussed in Sec. 8.2.1, many dielectric materials exhibit a Curie-law dependence for their dielectric constants:

$$\epsilon(T)=4\pi\mathscr{C}/(T-T_C)+\epsilon_0. \tag{16}$$

This Curie-law dependence can be derived from a simple model of the dielectric function for the material. Noting that the frequencies of longitudinal and transverse waves in any material must respectively lie at the zeroes and poles of the dielectric constant (required by Maxwell's equations), and that the dielectric function is usually modeled as

$$\epsilon(\omega)=\epsilon_\infty+(\epsilon_0-\epsilon_\infty)/({\omega_{TO}}^2-\omega^2), \tag{17}$$

one obtains the relationship

$$\epsilon_0(T)/\epsilon_\infty=\omega_{LO}^2/\omega_{TO}^2(T), \tag{18}$$

where LO and TO designate longitudinal optic and transverse optic phonon frequencies. In this equation, the transverse optic phonon frequency is often found to be strongly temperature dependent, but the longitudinal mode usually nearly temperature independent. The equation is referred to as the Lyddane–Sachs–Teller relationship (Lyddane *et al.*, 1941), and the temperature-dependent transverse optical phonon branch termed the "soft mode." In Cochran's original soft-mode theory this temperature dependence is explicit, since

$$\omega^2(T)=R_0-4\pi Z^2e^2/3V(T) \tag{19}$$

for the transverse mode, where $V(T)$ is the unit cell volume, permits a subtle cancellation of long-range Coulombic forces (Ze is the effective charge) and short-range forces R_0; whereas for longitudinal modes,

$$\omega_{\mathrm{LO}}^2(T)=R_0+8\pi Z^2e^2/3\epsilon_\infty V(T) \tag{20}$$

is very weakly temperature dependent unless R_0 is extremely small (as in TSCC and one or two other ferroelectrics). Note that the longitudinal phonon frequency above is always nonzero at all temperatures, but the transverse mode can vanish by accidental cancellation of two terms.

A fuller derivation of related equations for cases of many optical modes and phonon damping has been given by Kurosawa (1961) and by Cowley (1963).

9. PREPARATION OF DIELECTRIC THIN FILMS

9.1 Sputtering

Dielectric thin films are often prepared by rf or magnetron sputtering, using either metal or ceramic targets. ABO_3 perovskites deposited in this way are of good stoichiometry and flatness over a full 4- or 5-in. substrate wafer. They can be prepared pinhole-free in thickness from 40 to 1000 nm.

9.2 Sol-Gel

Solution-gelation wet-chemistry techniques using solutions such as barium or lead acetate and zirconium and titanium propoxides can be used to prepare ABO_3 dielectric perovskites. Usually mixed in a common solvent and then hydrolyzed, these solutions gel to yield fine-grained ferroelectric ceramics (40–100 nm) of exceptional quality ($P_S \approx 50\%$ of single-crystal values) when annealed at ca. 850 K. They can be spin-cast at 1500–2000 rpm to give films of superior stoichiometry and uniform density in comparison with those obtained by sputtering.

9.3 Slip-Casting, Thermal Evaporation, and Electron-Beam Evaporation

Other techniques of dielectric thin-film deposition include slip-casting (melting of powder on a metal substrate), thermal evaporation, and electron-beam co-evaporation. Slip-casting and thermal evaporation have both been used for high-quality KNO_3 films; electron-beam coevaporation of BaF_2 and MgF_2 yields high-quality $BaMgF_4$ ferroelectric films.

9.4 MOCVD

Metal-oxide chemical vapor deposition [see CVD (CHEMICAL VAPOR DEPOSITION)] is superior to both sputtering (*q.v.*) and sol-gel spin-on techniques for commercial processing of high-quality dielectric films. Sputtering suffers from target aging (for ceramic targets) and poor defect concentrations. Sol-gel spin-on techniques give poor step coverage for microelectronics applications. A deposition technique superior to both for commercial device processing is MOCVD. In lead-based dielectrics the Pb is often added as tetraethyl lead. More recently liquid-phase room-temperature CVD using sol-gel as the injected material has permitted replacement of this highly toxic tetraethyl lead. uv is often used to break the organic bonds.

9.5 MBE

The highest quality dielectric films can be prepared by molecular beam epitaxy (*q.v.*). This technique is expensive and requires high vacuum. It was developed for semiconductor technology but has recently been applied to dielectrics, including ferroelectric $BaMgF_4$ thin films.

9.6 Continuous Methods

For organic ferroelectrics, continuous sheet production is possible. TGS and PVF_2 (polyvinylidene fluoride) are prepared as continuous sheet and then poled (poling is the process of orienting domains, initially random, by applying an external electric field) at very high fields (MV/cm for PVF_2). Applications include large-area pyroelectric detectors.

9.7 Ferroelectric Liquid Crystals

Certain classes of liquid crystals (the smectic-C* chiral structures) are truly ferroelectric. They may be prepared in oriented thin films in which proprietary surface treatments unwind the cholesteric structures and permit high-speed switching devices to be fabricated. The production of such organic ferroelectric films is in general complex.

9.8 New Applications of High Dielectric Films

The primary recent applications of high dielectric thin films are in

1. capacitors for DRAMs (dynamic random access memories);
2. ferroelectric switching devices (including RAMs);
3. pyroelectric detectors; and
4. integrating capacitors in CCDs (charge coupled devices).

9.8.1 DRAMs. The development of high-density (e.g. 64-Mbit) submicron memory devices has generated new interest in very high-dielectric films to minimize the trenching that would otherwise be required to achieve the requisite capacitance. By replacing SiO_2 with a ferroelectric such as $PbTiO_3$ or a high-dielectric paraelectric such as $Ba_xSr_{1-x}TiO_3$, one can obtain an increase of ×100 in dielectric constant and hence capacitance. At present, several large Japanese corporations favor $Ba_xSr_{1-x}TiO_3$ films for this application, whereas several US corporations are developing $PbZr_{1-x}TiO_3$ films for the same DRAM applications. Note that for this use the film never switches polarization (all the applied voltage pulses have the same polarity), so fatigue (decrease in P_S with operation) is not a problem. However, other aging processes, such as dc breakdown, remain as important failure mechanisms.

9.8.2 Ferroelectric Memories. Thin ferroelectric films may also be used in memory applications involving polarization switching. Three kinds of ferroelectric memories exist in prototype form at this time, but none is in commercial use yet.

The first is a switched capacitor array in which the ferroelectric films (usually 2×2 μm^2 in cross-sectional area and 0.25 μm thick) store the "1" or "0" in the binary Boolean algebra of the computer as $+P_r$ or $-P_r$ polarization states. The memory is read (destructively) by switching the device and comparing the current transient $i(t)$ for the cell in question ($+P_r$ or $-P_r$) with the $i(t)$ from a reference cell that is always in the $-P_r$ state. For this reason it is important to understand theoretically the detailed kinetics of $i(t)$ switching currents. At present, prototype 16-kbit ferroelectric RAM memories have been fabricated by several companies, having 5-V standard silicon VLSI logic levels (or 3 V for GaAs) and very high speeds (10 ns read/write). Their extreme radiation hardness makes them attractive for aerospace applications as electrically erasable programmable read-only memory (EEPROM) or magnetic bubble memory replacement. $PbZr_{1-x}Ti_xO_3$ is favored at present as the cell material.

The second type of ferroelectric memory is the true ferroelectric FET (field-effect transistor). In this device the ferroelectric film is deposited in the gate region of the FET. Depending upon its polarization ($+P_r$ or $-P_r$), the source-to-drain current is altered. This current level can be read without switching (nondestructive read-out, NDRO), a distinct advantage. At present NDRO FETs using this design are being made at Westinghouse with $BaMgF_4$ as the ferroelectric film; the original ferroelectric FETS were made in Osaka in the 1970s with $PbZr_{1-x}Ti_xO_3$.

9.8.3 Optoelectronics. The third generic type of ferroelectric memory of interest is the optically read array. The polarization state of a ferroelectric cell can be read by means of a laser, using beam deflection, phase shift, or other mechanisms. In 1976 Westinghouse developed a 1-kb bismuth titanate memory ($Bi_4Ti_3O_{12}$) that could be read by beam deflection.

The primary disadvantage is that the device must be thick (ca. 100 μm) enough to produce significant beam deflection. This in turn necessitates large operating voltages (>100 V), so that the resulting device cannot be integrated into standard silicon integrated circuits, which operate at 5 V.

9.8.4 Pyroelectrics. Pyroelectric detectors can be fabricated from either bulk or films. They can achieve subnanosecond response times. The pyroelectric coefficient is proportional to the temperature derivative of the spontaneous polarization,

$$p=k\frac{dP}{dT}. \tag{21}$$

This coefficient is large near phase transition temperatures, but in general pyroelectric detectors must operate over a wide temperature range, so that divergences in dP/dT are undesirable.

At present triglycine sulfate (TGS) is the most commonly used pyroelectric. Its figure of merit for this application is not the largest known, but it can be grown cheaply from aqueous solutions in large-area specimens. Other cheaper pyroelectric systems include poled PVF_2 (polyvinylidene fluoride), which has relatively poor figures of merit but can be fabricated in continuous sheet. It is used for inexpensive detectors, such as "intruder alarms." Sol-gel or MOD (metal-organic deposition) KTN ($KTa_{1-x}Nb_xO_3$) is also a good pyroelectric.

10. NONPOLAR DIELECTRICS AND DIELECTRIC BREAKDOWN

Although most of this article is devoted to the dielectric properties of polar insulators, including ferroelectrics, considerable interest exists in the dielectric response of nonpolar materials, including both dielectric liquids (and glasses) and crystals.

As pointed out by O'Dwyer (1964) in his classic text on the subject, all materials conduct electricity to some degree, and all suffer breakdown in sufficiently high fields. However, only "intrinsic breakdown" in dielectric solids is qualitatively unique as a failure mechanism; by contrast, "thermal breakdown" in insulators is not qualitatively different from melting in metals at high currents, and "avalanche breakdown" in solids differs only quantitatively from spark discharge in gases.

In general, these three breakdown mechanisms are important in both polar and nonpolar insulators. They are particularly well understood in alkali halides. We note parenthetically that dielectric breakdown in liquids is much less well understood.

Commercial applications of insulating layers to prevent electrical shorting are especially important at present in the microelectronics industry. For devices such as random-access memories the dielectric materials used are primarily silicon nitride (Si_3N_4), silicon dioxide (SiO_2), and tantalum oxide (Ta_2O_5).

10.1 Intrinsic Breakdown in Insulators

Intrinsic breakdown is a purely electronic process in which the rise in lattice (phonon) temperature is negligible (this, in turn, requires that the ratio of electrical to thermal conductivity is very low).

The principal characteristics of intrinsic breakdown in insulators are as follows.

1. It occurs at low temperatures (i.e., 300 K or below).
2. The breakdown field strength E_B is independent of specimen size or shape and independent of electrode material and shape.
3. The breakdown occurs quickly (μs or less).

Intrinsic breakdown is observed in alkali halides, mica, glass, and most polymers. It was first analyzed by Zener in 1934 on the basis of quantum mechanical tunneling of electrons from the valence band to the conduction band.

10.2 dc Thermal Breakdown

The principal characteristics of thermal breakdown are these:

1. It occurs at high temperatures.
2. The breakdown field E_B depends upon specimen size and shape and on the geometry and thermal properties of the electrodes.
3. Breakdown takes time (ms or longer).
4. ac values of E_B are lower than dc and decrease with increasing frequency.

In this situation the critical electric field E_B (min) is given by

$$-\nabla\cdot(K\nabla T)=\sigma E_B^2(\text{min}), \tag{22}$$

where K is the thermal conductivity tensor.

10.3 Impulse Thermal Breakdown

This is the opposite extreme of dc thermal breakdown. It occurs when the field is applied very quickly, as in a switched capacitor (e.g., ferroelectric memory). Its distinguishing characteristics are the following.

1. It occurs at high temperatures.
2. Breakdown field E_B is fairly independent of sample size and shape.
3. E_B varies greatly with length of time field is applied (i.e., duty cycle in a memory), always decreasing for long times of applied field.

This mechanism is equivalent to what in recent literature has been termed "time-dependent dc breakdown" in ferroelectric memories. In this case the critical field $E_B(\mathrm{min})$ is given by

$$C_v \frac{dT}{dt} = \sigma E_B^2(\mathrm{min}). \tag{23}$$

This process is favored in materials with high electrical conductivity and low thermal conductivity.

10.4 Avalanche Breakdown

Avalanche breakdown is observed in very thin materials, especially mica. It occurs

1. at low temperatures,
2. in thin slabs of dielectrics with very low electrical conductivity and very high E_B,
3. if the applied voltage is ramped up slowly, the current response is very noisy. If a high voltage is applied suddenly, the time required for breakdown has a large statistical variation.

This process physically involves a single electron leaving the cathode and exciting another conduction electron by collision ionization. Avalanche breakdown is a kind of intermediate process between intrinsic breakdown and thermal breakdown inasmuch as it is electronically initiated but has subsequent thermal steps.

10.5 Mathematical Models of Intrinsic Breakdown

10.5.1 Polar Materials. Theories describing intrinsic breakdown in solids are based either upon the single-electron approximation, in which the electron delivers only a small percentage of its total kinetic energy in each collision [the "high-energy" criterion of Fröhlich (1937)], or upon collective excitation models. With the former the result for E_B is

$$E_B = \frac{\pi^2}{2}\frac{e^3}{aIM}\left(m\hbar \ln\frac{\gamma}{\omega_t}\right)^{1/2}\left(1+\frac{2}{e^{\hbar\omega_t/kt}-1}\right)^{1/2}, \tag{24}$$

where

$$\gamma = \frac{\sqrt{2}\pi}{a\omega_t}\left(\frac{I\epsilon_\infty}{m\epsilon_0}\right)^{1/2};$$

ω_t is the transverse optical phonon frequency of long wavelength; ϵ_∞ and ϵ_0 are the high- and low-frequency dielectric constants; a is the nearest neighbor distance; I is the ionization energy; M is the reduced mass of the ions (assuming a two-atom cell, as in alkali halides; and e and m are the charge and (effective) mass of the electron.

10.5.2 Nonpolar Materials. Dielectric breakdown theories for nonpolar bodies were developed on the basis of the deformable-atom hypothesis of Bloch. They involve the solving of the Boltzmann transport equation with an applied field and collisions with both conduction electrons and phonons. Ionization of valence electrons and diffusion are key elements of the model. The specific models consist of neglecting certain of these terms in the general Boltzmann equation, which in its most general form is intractable.

10.5.3 Collective Breakdown. All theories based on the assumption of low conduction-electron densities lead essentially to avalanche breakdown, to be discussed below. The high-density theories describe true intrinsic breakdown. For them a collective electron model is most appropriate.

For polar crystals the result is

$$E_B = f\left(\frac{T_0}{\theta}\right)\left(\frac{me\omega_t}{\hbar}\right)\left(\frac{\epsilon_0}{\epsilon_\infty}\right)^{1/2}(\epsilon_\infty^{-1}-\epsilon_0^{1}), \tag{25}$$

where T_0/θ is a reduced temperature.

Application to non-polar crystals generally involves an unknown interaction constant, which, however, can be approximated by the electron mobility. The low-temperature result is

$$E_B = 0.14\hbar N^{1/2}[m\mu(T)]^{-1}, \tag{26}$$

where N is the number of atoms per unit volume.

10.5.4 Glasses/Amorphous Dielectrics. Amorphous dielectrics are defined as those with a large number of electron states within the bandgap. The breakdown field in this case is given by

$$E_{\mathrm{B}}=\left(\frac{\hbar\omega_t}{2.3D\Delta V}\right)^{1/2} e^{\Delta V/2KT_0}, \tag{27}$$

where ΔV is the binding energy of shallow donors; T_0, the lattice temperature (assumed slightly lower than T_e, the electron temperature); and D, a constant given by

$$D=e^2\tau_c\tau_s\gamma/m\hbar\omega n(t_0), \tag{28}$$

where τ_c and τ_s are the relaxation times for conduction electrons and shallow donors, and n is the conduction-electron population density.

10.6 Models of Thermal Breakdown

Steady-state thermal breakdown occurs when the general equation

$$C_v\frac{dT}{dt}-\nabla\cdot(K\nabla T)=\sigma E_{\mathrm{B}}^2 \tag{29}$$

can be solved by neglecting the first term in Eq. (29) above. It is necessary to consider the realistic case where the electrodes are not perfect thermal insulators; otherwise breakdown occurs at any finite applied voltage.

In the one-dimensional case, the solutions of Eq. (29) yield a maximum breakdown voltage V_{B} (not field E_{B}) given by

$$V_{\mathrm{B}}^2\cong\gamma\int_{T_0}^{\infty}\frac{K}{\sigma}\,dT, \tag{30}$$

which for the case of exponential electrical conduction,

$$\sigma=\sigma_0e^{-\phi/kT}, \tag{31}$$

yields

$$V_{\mathrm{B}}^2\cong\left(\frac{\gamma\kappa KT_0^2}{\sigma_0\phi}\right)^{1/2} e^{\phi/2KT_0}. \tag{32}$$

In the impulse approximation appropriate to fast switching, the result of neglecting the $\nabla\cdot(K\nabla T)$ term in Eq. (27) is

$$E_{\mathrm{B}}=\left(\frac{3C_vKT_0^2}{\sigma\phi t_c}\right)^{1/2} e^{\phi/2KT_0}, \tag{33}$$

where t_c is the rise time of the applied field (assumed linear).

10.7 Models of Avalanche Breakdown

Avalanche can arise by field emission of electrons from the valence band to the conduction band (Zener, 1934) or it can arise by collision ionization of electrons in the valence band. In the former case Zener obtained a result related to Fowler–Nordheim emission:

$$P=(eEa/\hbar)\exp(-\pi^2maI^2/h^2eE) \tag{34}$$

for the probability of valence-conduction band transition per unit time. This results in

$$E_c\sim10^9\ \mathrm{V/m} \tag{35}$$

over a wide range of rise times [E_c is proportional to $\ln^{-1}(At_c^2)$, where t_c is the rise time; this is a rather weak dependence on rise time].

In the latter case (collision ionization), avalanche results at 10^8 V/m in 1-μs rise time and produces 10^{12} electrons (40 generations). Typically this occurs at a lower threshold E_{B} than does Zener avalanche.

10.8 Breakdown in Specific Materials

Alkali halides typically break down at 600 MV/m, with a maximum factor of about 2.0 between their dc breakdown fields (lower) and 10^6-s^{-1} fields (higher). The breakdown is anisotropic; that is, E_{B} is lower along certain directions, e.g., [110]. The breakdown mechanism is intrinsic (or avalanche) below 300 K, thermal above 300 K.

Soda-lime glass and silica glass (fused quartz) exhibit intrinsic or avalanche mechanisms for their breakdown. [This is true of crystalline quartz, also, up to 300 K.] For the glasses, the breakdown is intrinsic up to 300 K and avalanche above ambient temperatures.

Mica has intrinsic (or avalanche) failure up to 400 K and thermal breakdown at higher temperatures; $E_{\mathrm{B}}\approx1.2\times10^2$ V/m.

Most polymers (polymethyl methacrylate, polyethylene, polystyrene, polyisobutylene) are avalanche up to 230 K, and some up to 400 K. The breakdown field E_{B} is typically proportional to the square root of Young's modulus for the polymer.

GLOSSARY

Antiferroelectric: A crystal structure having sublattices polarized such that the net polarization is zero.

Coercive Field: The minimum electric field required to switch the electric polarization in a ferroelectric crystal.

Electret: A substance (not necessarily ferroelectric) in which an electric polarization can be induced and switched by application of an electric field that causes charged-ion transport to the surface(s). Electrets do not produce polarization via switching of lattice polarization (unlike ferroelectrics), but have occasionally been used for similar applications. They include carnauba wax, Teflon, and other noncrystalline materials.

Electrocaloric Effect: Heating of a ferroelectric via application of an electric field.

Electrostriction: The change in linear dimension for a substance under application of an external electric field.

Ferroelastic: A crystal having a hysteretic relationship between uniaxial stress and strain.

Ferroelectric: A crystal having a hysteretic relationship between lattice polarization and applied electric field.

Hysteresis: Nonlinear relationship between electric polarization P (and displacement vector D) and applied electric field E such that two stable states of ("remnant") polarization exist at zero applied field and the polarization $P(E)$ at applied fields depends upon the initial value.

Paraelectric: A crystal having no electric polarization in zero applied electric field.

Pyroelectric: A crystal of point group symmetry C_n, C_{nv}, or C_{1h}, in which a change in temperature produces a change in electric polarization.

PZT: A mixed compound of adjustable percentages of lead zirconate and lead titanate widely used in ferroelectric devices in ceramic form.

Remnant Polarization: The value of electric polarization in zero applied field for a ferroelectric.

Spontaneous Polarization: The value of electric polarization in a ferroelectric that is linearly extrapolated from $P(E)$ values near saturation, at large electric fields E; P_S is usually slightly greater than the remnant polarization and represents the maximum achievable polarization in thermal equilibrium if fields within the specimen were uniform.

INTRODUCTION

The diesel engine, invented in Germany towards the end of the 19th century, is now manufactured and used throughout the world. Its major advantage over other types of power plants is higher efficiency in converting fuel energy to output power. High efficiency in the diesel engine results from a combustion process characterized by spontaneous ignition of fuel injected into the combustion chamber near the end of the compression stroke, nonhomogeneous fuel-air mixtures containing more oxygen than required for complete combustion, an unthrottled flow of air into the engine, and a high compression ratio.

In comparison to the spark-ignition engine, the diesel engine, while significantly more efficient, has a heavier structure, produces more noise, and is more costly. Diesel engine combustion, because of its nonhomogeneous fuel-air mixtures, also produces soot in addition to the gaseous products of combustion.

Since the rate of fuel combustion is controlled by fuel injection rate and the rate of mixing between fuel and air, the diesel engine can be highly turbocharged without significant effects on the rate of combustion. By this means, output power can be significantly increased above that obtained using combustion air at ambient pressure.

These characteristics have led the diesel engine to be used in a wide range of applications. Diesel engines are built in sizes from about 0.5 L/cylinder up to about 1300 L/cylinder. Applications include stationary engines, on-highway vehicle engines, military and civil off-highway engines, locomotive engines, and large marine engines.

Increasingly severe environmental regulations are causing changes in diesel engine design to reduce the quantity of undesirable exhaust emissions. Many of these changes involve the fuel injection system. However, the complete combustion process is under close scrutiny despite difficulties in analysis due to the complexity of the mixing process between fuel and air as well as the subsequent combustion. Since the major attribute of the diesel engine is high efficiency, emission controls must not cause significant depreciation of efficiency; otherwise the major advantage of the diesel engine is lost. A range of potential solutions is available that seem likely to satisfy both environmental and economic goals.

1. PRINCIPLES OF OPERATION

1.1 Operating Cycle

The diesel engine cycle is made up of the following events: First, air is compressed by a piston in a cylinder through a compression ratio of between 14 and 22 (depending on engine size and design). Fuel is introduced into the air by means of a high-pressure fuel injection system when the piston is near the end of its compression stroke, and the fuel ignites spontaneously because of the high air temperature. Heat is added to the air by the exothermic reactions between the fuel and the oxygen contained in the air. Next, the hot, high-temperature products of combustion are expanded to produce work, and the products

digital Encyclopedia of Applied Physics

of combustion are then exhausted to the atmosphere. Finally, the cylinder is filled with a fresh charge of air in preparation for the next cycle.

Diesel engines are built using either two or four piston strokes to accomplish this cycle. In the four-stroke cycle the first (upward) stroke is one of compression. Fuel injection, ignition, and combustion take place with the piston near the top of its stroke. Expansion occurs during the second (downward) stroke. Exhaust valve(s) in the cylinder head are then opened, and the third (upward) stroke displaces the exhaust products out of the engine. Exhaust valves are then closed, intake valves are opened, and the fourth (downward) stroke draws a fresh air charge into the cylinder.

In the two-stroke cycle, compression, injection, ignition, and combustion and expansion occur as in the four-stroke cycle. Near the end of the expansion stroke, the piston uncovers exhaust ports in the cylinder wall (or alternatively, exhaust valves in the cylinder head are opened), and exhaust products are pushed from the cylinder by the residual cylinder pressure. With further downward movement, the piston uncovers another set of (inlet) ports, through which fresh air is pushed by an external air compressor. Additional exhaust products are displaced from the cylinder by the incoming air. After the piston reverses direction and all ports (or valves) are closed, the cylinder contains fresh air as well as some 15%–30% of residual combustion products that escape the scavenging process.

The diesel cycle, as visualized by its inventor Rudolph Diesel (1858–1913), employed a combustion event in which the cylinder pressure was held constant by control of the rate of fuel injection and hence the rate at which heat was added to the air. In practice, combustion rates are tailored for optimum efficiency and minimum exhaust emissions, rather than to meet the constant-pressure criterion.

1.2 Features of Combustion

The principal characteristics of the diesel engine are dictated by its unique ignition and combustion process. The fuel is introduced into the combustion chamber under high pressure in the form of jets issuing through several orifices in the tip of the injector nozzle (see Fig. 1). Each conical fuel jet immediately

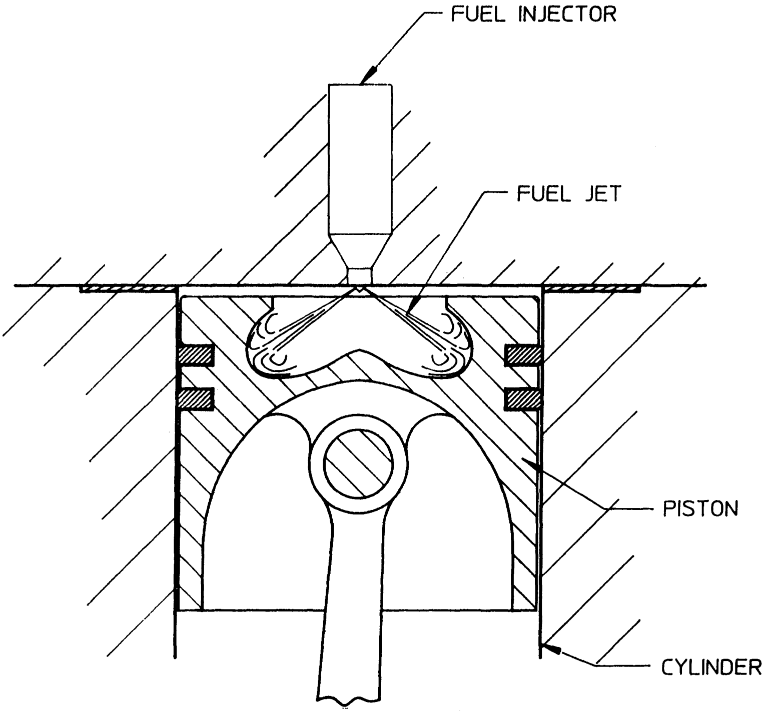

FIG. 1. Fuel injection in a direct-injection diesel engine combustion chamber.

begins to entrain air from the combustion chamber and, as a result, the fuel-air ratio within the jet decreases along the length of the jet as well as from the jet center line towards the outer surface of the jet. Ignition occurs spontaneously at locations within the jet where the fuel-air ratio and temperature combine to minimize ignition delay. Because the fuel-air ratio within the jet varies over a wide range, suitable conditions for ignition are always present and ignition is reliable irrespective of the total quantity of fuel injected, provided air temperatures are sufficiently high. The initial rate of combustion depends strongly on the length of the ignition delay period. A longer ignition delay gives time for more fuel and air to become mixed before ignition. This quantity of mixture burns quickly and gives rise to the objectionable "knocking" sound often associated with diesel engines. Ignition delay increases as the temperature of the compressed air decreases. Therefore reductions in compression ratio, ambient air temperature, or the temperature of the engine coolant increase the ignition delay.

The subsequent combustion rate is controlled by the rate of injection of the remaining fuel and the rate of entrainment of air into the fuel jet. High air entrainment rates increase combustion rates and therefore produce faster rates of pressure rise in the cylinder. Gas temperature is also increased, which in turn increases the quantity of nitrogen oxides in the exhaust. On the other hand, low air entrainment rates produce regions in the combustion chamber where the fuel-air ratio is too high for complete combustion. Partial combustion in these regions produces soot and hydrocarbons in the exhaust gas. Diesel engine combustion-system research is therefore mainly directed to striking an acceptable balance in fuel-air mixing rate.

In engines designed for high-speed service, the mixing rates between fuel and air may be too low to allow combustion to be completed quickly. Such engines often use the indirect injection (IDI) system (see Fig. 2), in which the fuel is injected into a smaller chamber in the cylinder head (precombustion chamber) which is connected to the cylinder volume by one or more orifices. During the compression stroke, air forced into the precombustion chamber is highly turbulent and combustion is therefore rapid. Unburned and partially

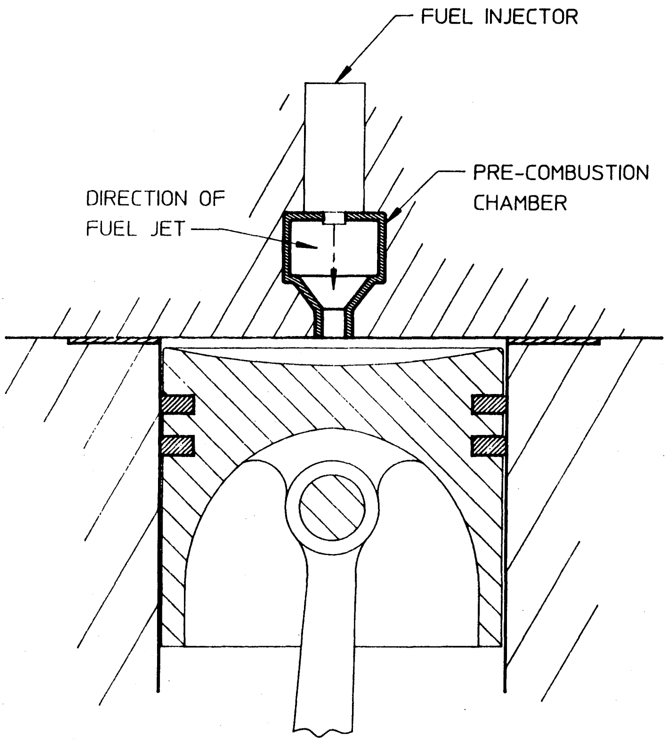

FIG. 2. An indirect injection system with a single orifice between precombustion chamber and cylinder.

burned fuel is ejected from the precombustion chamber by the high-pressure combustion products, and combustion is quickly completed in the cylinder volume as the jet(s) from the precombustion chamber mix with the air in the cylinder volume. Engines with injection directly into the cylinder volume (direct injection, or DI engines, as in Fig. 1) are suitable for lower rotational speeds and have the advantage of higher efficiency than IDI engines because of less turbulence and therefore lower heat losses.

As a result of its combustion process, the diesel engine has certain characteristics that are significantly different from the spark-ignition engine:

1. The diesel engine requires a higher compression ratio in order to produce (spontaneous) compression ignition of the fuel. Maximum cylinder pressures are therefore higher than in the spark-ignition engine.
2. In addition to the higher compression ratio, a fuel having a short ignition delay is required in order to reduce the ignition delay period.
3. The torque produced by the diesel engine tends to increase linearly with the overall fuel-air ratio in the cylinder. At maximum torque, the overall fuel-air ratio is limited to about 60% of the stoichiometric fuel-air ratio in order to prevent excessive exhaust smoke. (The spark ignition engine is constrained to operate with near-stoichiometric mixtures, since flame speeds become too low with large amounts of excess air.)
4. The torque of a four-stroke cycle engine (diesel or spark ignition) is

   $$T=\left(\frac{1}{4\pi}\right)F\rho Q_f V_d \eta_v \eta_i \eta_m, \qquad (1)$$

   where F is the mass ratio of fuel to air in the combustion chamber, ρ is the density of the air inducted into the engine cylinder, Q_f is the fuel heating value, V_d is the displacement of the engine cylinders, and η_v, η_i, and η_m are the volumetric efficiency (actual engine mass air rate divided by theoretical mass air rate), indicated efficiency (net power produced by compression and expansion strokes divided by rate of fuel energy supplied), and mechanical efficiency (output power divided by net power produced by the compression and expansion strokes), respectively. In the diesel engine, the torque of the engine is controlled by varying the fuel-air ratio (F) by changing the quantity of fuel injected. In the spark-ignition engine, fuel-air ratio is constant (approximately), but inlet density (ρ) is changed by means of the throttle.

The use of lower fuel-air ratios and high compression ratios has important consequences on indicated efficiency, as shown in Fig. 3. At full power, current diesel engines can produce brake efficiencies approaching 50%, primarily as a result of these two factors.

1.3 Turbocharging

The relationship for engine power is

$$P=2\pi TN \qquad (2)$$

or

$$P=\tfrac{1}{2}F\rho Q_f V_d N \eta_v \eta_i \eta_m \qquad (3)$$

for the four-stroke cycle, where N is the rotational speed of the engine. The lower fuel-air ratios used in the diesel engine reduce the power produced for a given displacement volume, under the assumption of equal inlet density and engine speed. This disadvantage can be largely offset by turbocharging, which increases inlet density above that of the ambient atmosphere. A turbocharger consists of a centrifugal compressor and a turbine, usually of the radial-inflow type, connected to a common shaft (see Fig. 4). Exhaust gases from the engine cylinders drive the turbine, while ambient air is compressed by the compressor and supplied to the cylinders, thus increasing the inlet density and raising the engine power. A heat exchanger (called either intercooler or aftercooler) is used to cool the compressed air to further increase inlet density. The intercooler uses either engine coolant or ambient air as the heat sink.

The diesel combustion process is particularly well suited for turbocharging since increases in inlet pressure and temperature reduce ignition delay. The amount of pressure boost that can be used is limited only by the loads imposed on the engine structure by the increased cylinder pressures, the increased heat transfer rates to the combustion chamber surfaces, and turbocharger efficiency. This tolerance to high inlet pressure allows diesel engines to be designed with very high mean

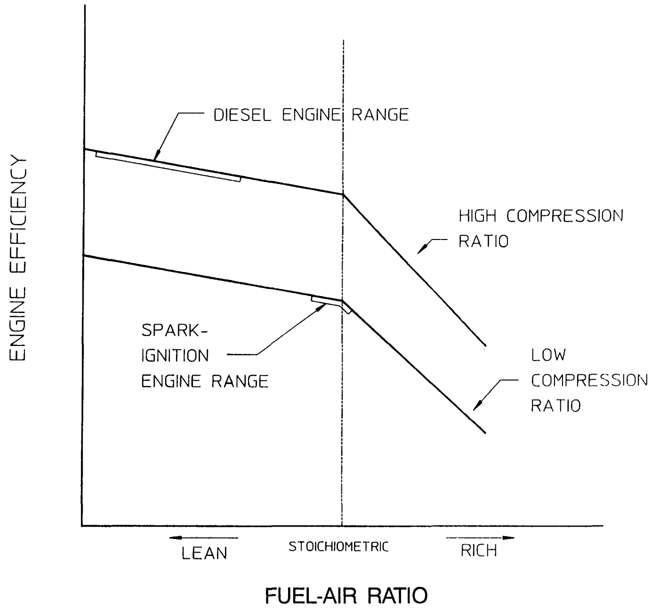

FIG. 3. The effect of compression ratio and fuel-air ratio on indicated efficiency, showing the operating ranges of diesel and spark-ignition engines.

effective pressures (MEP), where, for four-stroke engines,

$$\mathrm{MEP}=\frac{P}{[V_d(N/2)]}. \qquad (4)$$

Turbocharging and intercooling also increase engine efficiency. While output power increases with turbocharging and intercooling, engine friction remains about constant, and so the mechanical efficiency increases. This is reflected in increased fuel economy.

2. APPLICATIONS

The high efficiency of the diesel engine makes it attractive wherever superior fuel economy is of primary concern. Also of importance in some applications (i.e., military and marine applications) is the relatively low vapor pressure of diesel fuel, which lessens fire and explosion hazards.

Weighed against the high efficiency of the diesel are several factors deriving from its thermodynamic cycle. The diesel engine tends to be heavier than the spark-ignition engine because of its higher compression ratio, which requires a stiffer, therefore heavier, structure to resist the higher pressure loads. Engine starting is more difficult in cold climates because ignition delay increases as temperature decreases. Power output for a given engine volume is relatively low unless the diesel is highly turbocharged. Combustion noise tends to be higher than in the spark-ignition engine, particularly under conditions where the ignition delay is long (idling, low ambient temperature). The heavier structure, the precision-machined fuel injection system, and the need for a high-strength forged steel crankshaft increase the cost of the diesel relative to the spark-ignition engine.

As a result, the diesel engine has found its primary applications where the required power levels are high and of long duration (i.e., where fuel costs are a major consideration), where size and weight are of less importance (e.g., in stationary applications or in large vehicles), and in applications not requiring frequent starts or very low noise levels. In such applications, reliability and long engine life are important, and diesel engine designers have responded by providing engines capable of thousands of hours of operation at full power with minimum maintenance needs.

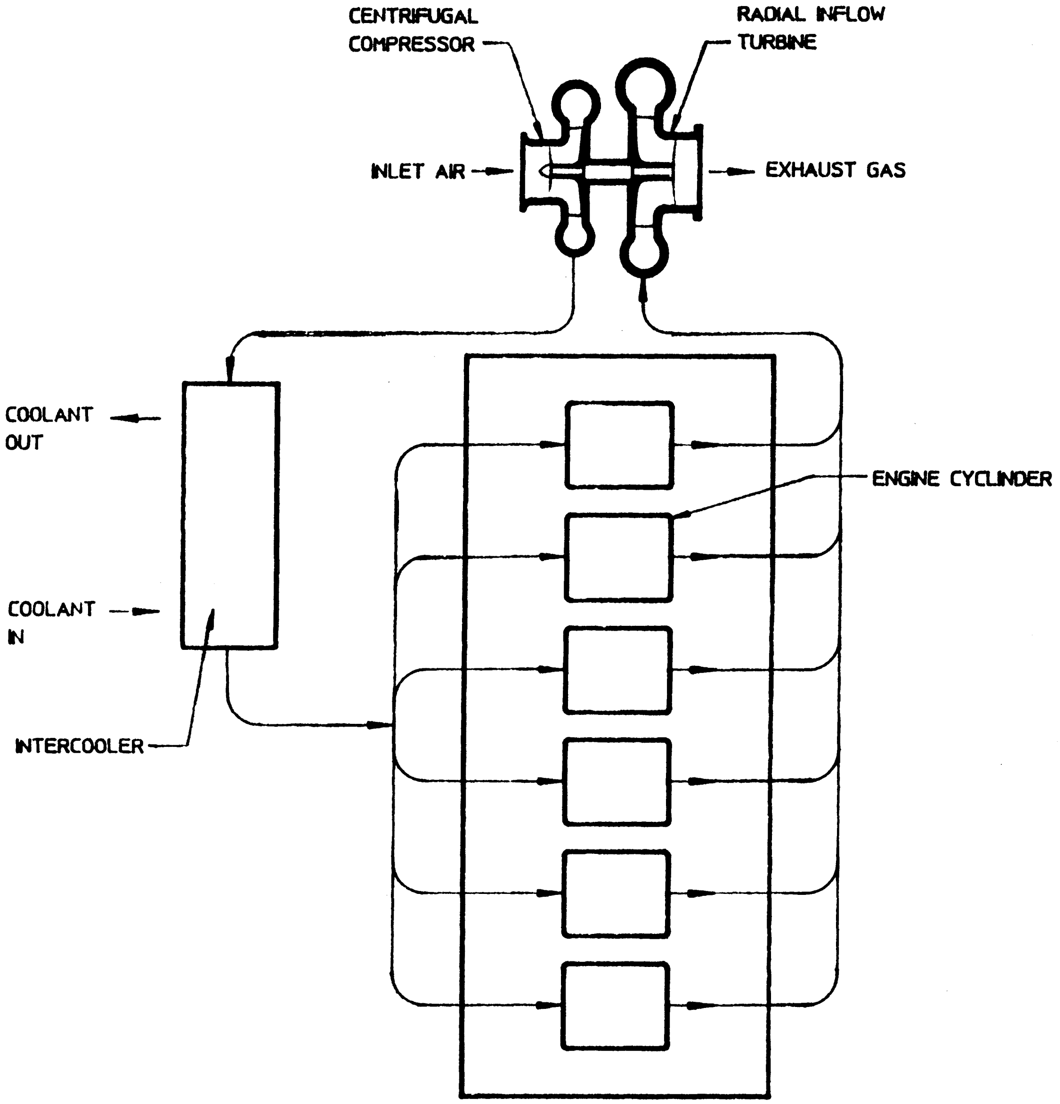

FIG. 4. Turbocharger and intercooler on a six-cylinder diesel engine.

In the United States, where fuel prices are still relatively low, the diesel engine has not supplanted spark-ignition engines for use in automobiles because its advantage in fuel economy is not sufficient to counteract the disadvantages of more difficult starting, and higher weight, volume, cost, and noise. Greater use of automobile diesels is found wherever fuel prices are high. These engines usually employ the indirect-injection (IDI) combustion chamber to allow higher engine speeds, may incorporate a turbocharger with or without an intercooler, and use an electrically heated element (glow plug) in the combustion chamber to assist in starting the engine in cold weather.

In heavy-duty trucks, buses, farm machinery, earth-moving equipment, and military vehicles the diesel engine is dominant. These engines are of the direct-injection design for maximum fuel economy. Turbocharging and intercooling are widely used in such engines. Engine durability is an important design criterion. The diesel engine also enjoys widespread use for electrical power generation, main propulsion as well as auxiliary power

Table 1. Characteristics of typical diesel engines in various applications.

Application	Cylinder diameter (mm)	Piston stroke (mm)	Power per cylinder[a] (kW)	Mean effective pressure[a] (bar)	Speed[a] (rev/s)	Combustion chamber[b]	Strokes per cycle	Air induction system[c]	Compression ratio	Specific engine weight[a] (kg/kW)	Brake efficiency[a,d] (%)

for boats and ships, and railway power for diesel-electric locomotives.

The salient characteristics of typical diesel engines used in various applications are shown in Table 1. As seen in this table, diesel engines are built in an extraordinary range of sizes and powers. Cylinder diameters range over an order of magnitude, and displacement volumes range from less than 0.5 L/cylinder to over 1300 L/cylinder. On the other hand, mean effective pressure is independent of engine size or speed and rather depends on the amount of turbocharging used.

Average piston speed (the product of twice the crankshaft rotational speed and the stroke length) varies between about 7 and 13 m/s, with smaller values used to prolong engine life by reducing wear on cylinder liners, pistons, and piston rings. Given the relatively small range of piston speeds, rotational speed decreases quickly as stroke increases.

The optimum compression ratio is affected by several factors. As the designed rotational speed decreases, longer ignition delays are acceptable and therefore compression ratio can be decreased. Engines that are housed in heated enclosures (e.g., large stationary and marine engines) can accept a lower compression ratio without starting problems because low inlet air temperatures are avoided. Larger engine cylinders lose a relatively smaller amount of heat from the air during the compression stroke, and a lower compression ratio will produce an acceptable ignition delay. Since at the same internal gas pressure engine structural stresses increase as cylinder size increases, it is desirable to decrease compression ratio in the larger engines. This trend is seen in Table 1.

In engines with the same MEP and piston speed, power per unit piston area is constant. At the same time, the weight tends to increase as the cube of cylinder diameter. The specific engine weight (engine weight divided by engine power) therefore tends to be proportional to cylinder diameter. Although the engines of Table 1 have somewhat different MEPs and piston speeds, the trend of increasing specific weight with cylinder diameter is evident.

Brake efficiency of these example engines varies from about 30% to 48%. The lowest value is for an automobile engine with the relatively inefficient IDI combustion system. This engine also has the highest piston speed (which increases friction losses) and these two factors contribute to its relatively low efficiency. The low piston speed, low rotational speed that gives a long time period for combustion, and careful attention to design details that are economically feasible in an expensive engine all contribute to the high efficiency of the large marine engine.

3. DESIGN CONSIDERATIONS

3.1 Fuel Injection Systems

The component most critical to satisfactory diesel combustion is the fuel injection system. This system must inject precise quantities of fuel to each of several cylinders once each engine cycle. Fuel injection pressure may be as high as 2000 bar. The duration of the injection event ranges from 2° to 30° of crankshaft rotation, depending on engine torque demand. This corresponds to injection time intervals from 0.1 to 2 ms at an engine speed of 40 revolutions per second. Injection timing (the crankshaft position where injection starts) is critical and is controlled to within ±1 crankshaft degree.

A common method used to meet these requirements is a "pump-line-nozzle" fuel injection system (see Fig. 5). A camshaft drives several pump pistons (one for each engine cylinder) within their respective cylinders. Each piston delivers high-pressure fuel through a tube to an injection nozzle inserted through the cylinder head of the engine. One fuel injection event occurs each cycle in each engine cylinder. Injection timing is established by the phasing of camshaft rotation relation to crankshaft rotation. Upon delivery of fuel to the injection nozzle, fuel pressure within the nozzle lifts the "needle," permitting fuel to exit from the nozzle through multiple orifices into the combustion chamber. When fuel delivery ceases, a spring returns the needle to its seat.

The quantity of fuel delivered to the nozzle is controlled by rotating the pump piston.

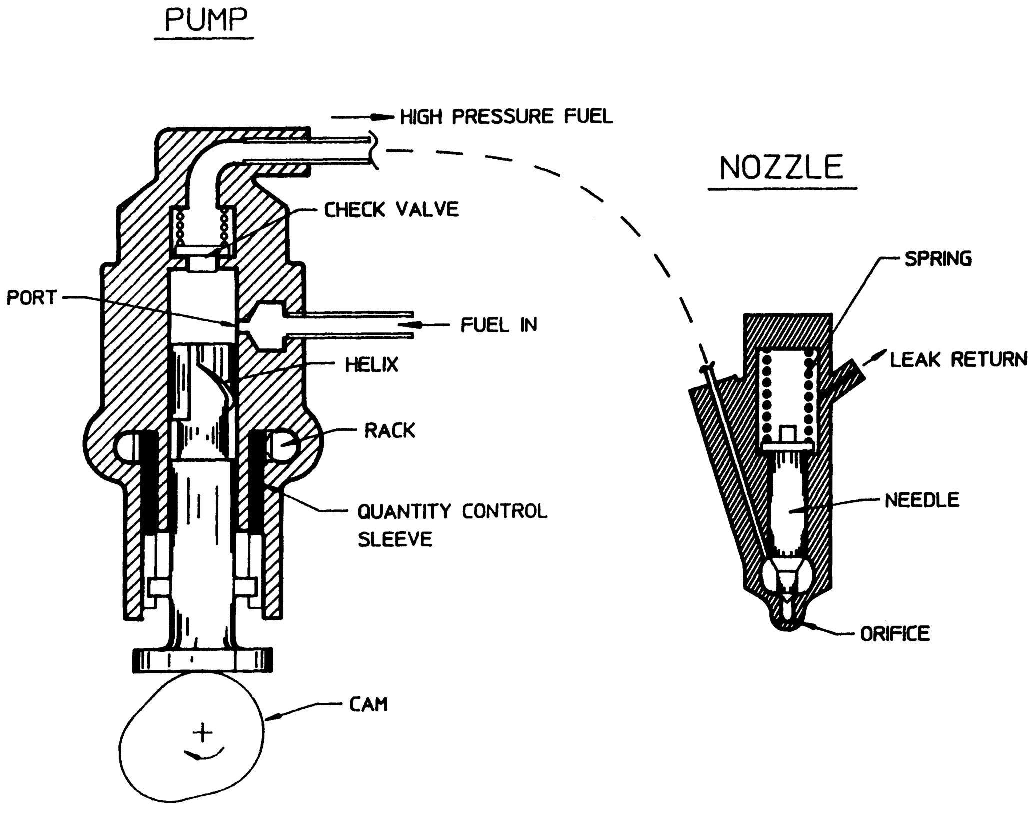

FIG. 5. Pump-line-nozzle fuel injection system for one engine cylinder.

With the piston positioned as shown in Fig. 5, the pump cylinder is filled with fuel from a low-pressure supply pump through a port in the cylinder wall. Fuel delivery to the nozzle commences when the top of the piston covers the port. Fuel delivery ceases when a helix machined in the piston uncovers the port and fuel from above the piston flows out of the port through a slot in the pump piston. By rotation of the piston, the vertical piston position where fuel delivery ceases can be made to occur either sooner or later, thus decreasing or increasing the quantity of fuel delivered.

In smaller engines, such as those used in automobiles and trucks, a multi-cylinder pump is often used in which each pump piston is connected to a nozzle in each engine cylinder. Larger engines may have a separate single-piston pump, connecting tube, and nozzle for each engine cylinder. Alternatively, both large and small engines may combine a single pump piston and injector into a single unit (a "unit" injector) installed in each engine cylinder head that eliminates the connecting tubing and is driven by an overhead camshaft.

With the advent of strict limits on exhaust emissions from diesel engines, the necessity for better control of fuel injection has resulted in the development of ways to control various fuel injection parameters electronically. A few of these systems will be described. Figure 6 shows a pump piston and cylinder containing a movable timing control sleeve. The principles of operation are the same as those described for the pump-line-nozzle system of Fig. 5, except that the port in the cylinder wall is contained in the movable timing control sleeve. Moving the sleeve upward delays the start of injection; injection start becomes earlier when the sleeve is moved downward. The actual start of injection is measured by a needle lift sensor attached to the nozzle body, and a closed-loop control system ensures that the actual start of injection matches the required timing. A computer is used to generate the desired timing schedule on the basis of inputs from other engine sensors (engine temperature, engine speed, delivered fuel quantity). Fuel quantity control is obtained by rotation of the pump piston, as previously described.

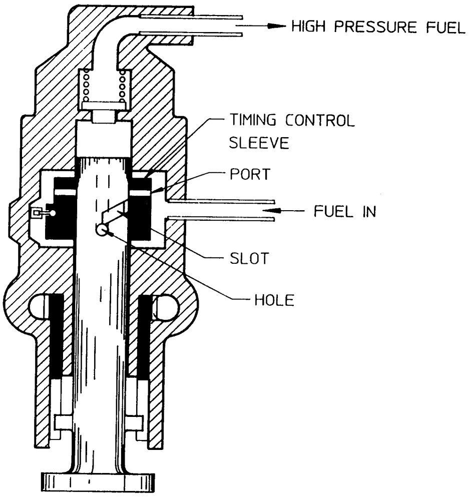

FIG. 6. Injection pump with timing control sleeve.

In another approach, the opening and closing of the port is accomplished by a fast-acting high-pressure solenoid valve rather than by the pump piston (see Fig. 7). The solenoid valve is closed to commence injection. Injection ceases when the solenoid valve is opened and the fuel above the pump piston is returned to the fuel tank. By this arrangement, injection quantity is controlled by the length of time that the solenoid valve is closed, and start of injection is controlled by the time of closing of the solenoid valve. The operation of the solenoid valve is controlled by a computer which obtains various input signals (engine speed, operator's power demand from the accelerator pedal position, engine temperature, and inlet air pressure and temperature).

The need for a camshaft to drive the pump piston can be eliminated with a common-rail fuel injection system. One example is shown in Fig. 8. Here, a high-pressure feed pump (not shown) continuously supplies fuel to all the injectors. Each injector contains an electronically controlled three-way two-position valve. When high-pressure fuel is directed to the space above the injector needle, the needle is held down on its seat and no injection occurs. When the three-way valve connects the space above the needle to the fuel return line, the fuel pressure at the lower end of the needle raises the needle and fuel injection starts. This arrangement permits not only control of fuel delivery quantity and time of injection start, but also the rate of needle lift (by sizing the control orifice diameter) and hence the injection rate during the early part of the injection event. Closed-loop control is

effected, as usual, by various sensor inputs to a computer control unit.

3.2 Exhaust Emission Control

Diesel exhaust emissions are now a major concern of diesel engine manufacturers, particularly for engines used in highway vehicles. For these engines, legislative groups have set emission standards that have become increasingly stringent as environmental concerns increase. Emissions standards of similar severity will eventually be applied to nonvehicular engines.

Emittants controlled by laws are nitrogen oxides, carbon monoxide, hydrocarbons, and particulate matter. Nitrogen oxides are formed

in the combustion chamber at locations where gas temperatures are high. In the burning fuel jet, regions where the fuel-air mixture is nearly stoichiometric produce the highest temperatures and thus are the source of most of the nitrogen oxides. Carbon monoxide is produced during the fuel burning process as the fuel carbon oxidizes, first to carbon monoxide and then to carbon dioxide. Since the $CO \rightarrow CO_2$ reaction rate is relatively fast and the diesel engine combustion chamber contains excess oxygen, carbon monoxide emissions are rarely a problem for diesel engines. Hydrocarbon emissions result from unburned or partially burned fuel, and the sources are the fuel-rich core of the fuel jet, the walls of the combustion chamber that may be wetted by the fuel jet, and crevices in the combustion chamber (e.g., the small space between piston and cylinder above the top piston ring) where the gases are cooled by the adjacent metal and combustion is therefore suppressed. Exhaust particulates consist of agglomerates of tiny carbon particles (soot) as well as various hydrocarbons species that adsorb on the carbon. Particulate emissions are associated with fuel-rich combustion. Lubricating oil that enters the combustion chamber past the piston rings or leaks into the exhaust stream past the intake or exhaust valve guides is also an important source of particulate emissions. An injection event that ends with low-velocity injection of the last fuel injected is certain to produce both soot and hydrocarbon emissions.

While diesel exhaust emissions are strongly affected by engine design details, the overall fuel-air ratio is also an important factor (see Fig. 9). The rapid increase of particulate emissions and exhaust smoke as fuel-air ratio increases limits the diesel engine to fuel-air ratios less than about 60% of the stoichiometric fuel-air ratio. Nitrogen oxides are less sensitive to fuel-air ratio because, regardless of fuel injection quantity and the overall fuel-air ratio, portions of the fuel jet burn at near-stoichiometric levels of fuel-air ratio producing high local temperatures. Carbon monoxide is not formed in large amounts until the overall fuel-air ratio exceeds stoichiometric. Hydrocarbon emissions are too engine-specific to include in Fig. 9.

In diesel engine development, control of nitrogen oxides and particulate emissions is the major concern. The problem is difficult because the most effective control techniques to reduce nitrogen oxides tend to increase particulates. Further, the undesirable emissions are generated during a combustion event which is dominated by a complex turbulent mixing process that is difficult to control. The development of catalysts to reduce nitrogen oxides in the exhaust has not yet been achieved

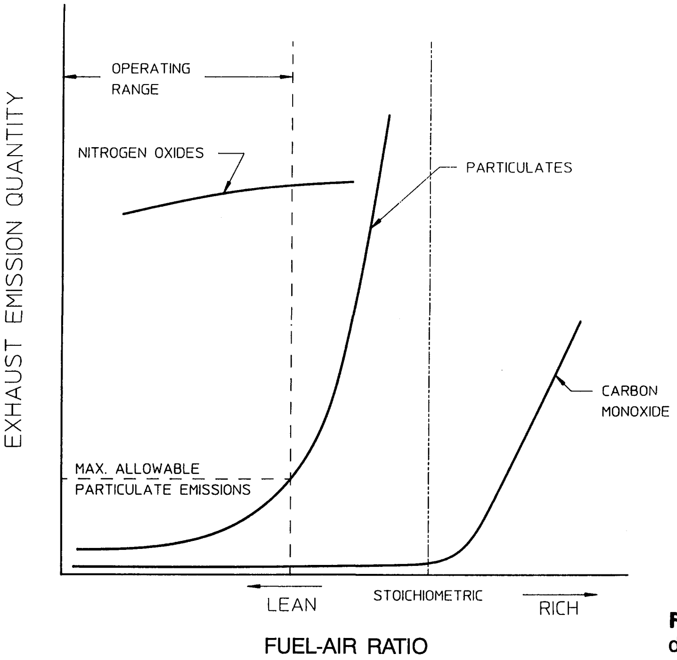

FIG. 9. Effect of overall fuel-air ratio on diesel engine exhaust emissions.

because of the large amounts of excess oxygen in the exhaust.

Despite these difficulties, the exhaust emissions of diesel engines have been greatly reduced from their precontrol levels. Particulate emissions are now about 30% of those before legislative requirements, and nitrogen oxides are about 20% of the precontrol levels. These improvements have been made by alterations to the combustion process through detail changes in design. Some of these are

1. increases in fuel injection pressure to increase the mixing rate of the fuel jet to reduce particulate emissions, combined with a later injection event to reduce emissions of NO_x;
2. reduction in crevice volume, reduction in the volume of unused air spaces in the combustion chamber, and modification of turbocharger air delivery characteristics to increase the amount of air available for combustion, thus allowing a lower overall fuel-air ratio for the same power;
3. design of inlet ports to optimize the swirling motion of the air in the combustion chamber, for improved mixing;
4. improvements in fuel injection systems to eliminate low fuel-jet velocity at the end of the injection event, and to provide better control of injection timing;
5. reduction in oil consumption; and
6. careful matching of the shape of the combustion chamber to the number of fuel jets, the cylinder air motion, and the penetration distance of the fuel jets into the combustion air.

With such modifications, the diesel engine has been able to meet current legislative requirements. As emission regulations become more severe, additional control methods must be applied. Some of these are currently under development.

1. Filters can be used to remove a large fraction of the particulate matter from the exhaust. These filters must be periodically cleaned to prevent excessive exhaust gas pressure losses, and the filtering-cleaning cycle is short because of the relatively large quantity of exhaust soot as well as the limits to filter size imposed by vehicle installation. One method of cleaning is to burn off the collected particulate matter periodically. A burner or electrical heater can be used to ignite the collected soot. Alternatively or in combination, the filter medium (made from porous ceramic) can be doped with a catalytic material to reduce the ignition temperature or a fuel additive containing a soluble catalyst can be used.
2. Cooled exhaust gas can be recirculated and mixed with the inducted air charge. The addition of this inert gas reduces combustion temperature and therefore reduces the quantity of nitrogen oxides, but the decrease in oxygen content of the combustion gas tends to increase particulate emissions.
3. Further modifications to the fuel injection process are possible: higher pressures and more precise control of injection rate, perhaps with these parameters controlled by continuous measurement of exhaust emission levels.

The development of diesel engines with very low emissions can be greatly assisted by a better theoretical understanding of the combustion process: the formation and development of the fuel jet, its interaction with the air motion in the chamber and with the walls of the chamber, the fuel-air mixing process, and the concurrent combustion process.

Exhaust emission control is a serious challenge to the future of the diesel engine. This technical challenge has strong economic overtones; the cost of effective emission control techniques must not prevent the diesel engine from competing with other power sources.

3.3 New Materials

There is much current interest (but as yet no full-scale production) in ceramic materials (e.g., silicon nitride, zirconia) for the walls of diesel engine combustion chambers. Since these materials have a lower thermal conductivity than metals conventionally used in engines, their use can substantially reduce the heat transfer from the combustion gases to the engine coolant. In this way the conventional cooling system can be reduced in size or, in the limit, eliminated. Since the net heat loss from the gases to the coolant is reduced, exhaust gas temperature is increased which provides extra energy in the exhaust stream. This additional energy can potentially be used to drive not only the turbocharger turbine but an additional power turbine geared to the engine crankshaft and by this means can increase engine power output without an increase in fuel consumption. The use of ceramics for this purpose is not without significant problems. Among these are high manufacturing cost, tendency to brittle fracture, problems in matching the thermal expansion of ceramics to that of contacting metal parts, and the selection of lubricating oil properties.

Ceramic materials have begun to be used in limited quantities for engine components subjected to high contact pressure (such as cam followers) or high-temperature corrosion (such as exhaust valves, piston crowns, and precombustion chambers).

GLOSSARY

Average Piston Speed: The product of twice the rotational speed of the crankshaft and the length of piston stroke.

Brake Efficiency: The dimensionless ratio of the power produced at the engine output shaft to the rate of fuel energy supplied to the engine.

Common-Rail Fuel Injection System: A fuel injection system in which a continuous supply of high-pressure fuel is provided to the injector nozzle, and fuel quantity and timing control is effected by the nozzle rather than by the pump.

Compression Ratio: The ratio of the maximum cylinder volume to the minimum cylinder volume.

Cylinder Displacement: The volume swept by the piston in one stroke.

Fuel-Air Ratio: The mass ratio of fuel to air. In diesel engine terminology, the unmodified term refers to conditions at a point within the combustion chamber. See Overall Fuel-Air Ratio.

Fuel Heating Value: The heat energy produced by the complete combustion of a unit mass of fuel.

Fuel Injection Pressure: The pressure of the fuel just upstream of the nozzle orifices.

Ignition Delay: The time between the start of fuel injection and fuel ignition.

Indicated Efficiency: The dimensionless ratio of the net power produced by the compression and expansion strokes of the engine to the rate of fuel energy supplied to the engine. The product of indicated efficiency and mechanical efficiency is brake efficiency.

Mechanical Efficiency: The ratio of the power produced by the engine output shaft to the net power produced by the compression and expansion strokes. Mechanical efficiency is less than 1 because of friction losses (mechanical friction as well as losses due to gas viscosity).

Naturally Aspirated: An engine without a turbocharger or other means for increasing inlet air pressure.

Overall Fuel-Air Ratio: The mass ratio of the total injected fuel quantity to the total air quantity trapped in the cylinder after the intake valve(s) or port(s) is closed.

Stoichiometric Fuel-Air Ratio: The fuel-air ratio that, under conditions of equilibrium, produces combustion products containing no unburned fuel or free oxygen.

Volumetric Efficiency: The mass of air inducted into the engine in one cycle divided by the mass of air that could be contained in the cylinder at the pressure and temperature of the air in the intake manifold.

INTRODUCTION

Diffusion, the transport of matter by random thermal motions, is one of nature's fundamental processes. If a few drops of ink are injected into the lower end of an unstirred glass of water, more ink diffuses upward than downward, simply because more randomly moving ink molecules are near the bottom of the glass than near the top. The ink gradually spreads from regions of higher to those of lower concentration. Eventually a uniform distribution is reached.

Despite instantaneous velocities of hundreds of meters per second, diffusing molecules make little headway in liquids because they travel only a fraction of a molecular diameter before being deflected by collisions with their neighbors. In fact, it takes about *10 years* for a molecule to diffuse through 1 m of unstirred liquid! For cold or viscous liquids, or macromolecules, diffusion can be orders of magnitude slower.

The slowness of diffusion has practical consequences for the dissolution and precipitation of crystals, gas absorption, mixing, and other mass transfer operations. Speeding up these processes requires mechanical convection, such as stirring, to reduce the distances over which molecules must diffuse. Even with efficient stirring, the rates of many chemical reactions are ultimately limited by how fast diffusion can bring the reactants together.

digital Encyclopedia of Applied Physics

Measured rates of diffusion provide information about the sizes and shapes of molecules, molecular aggregation, intermolecular forces, and the structure of solutions.

Thermal motion is not the only way to transport matter on the molecular level. If a voltage gradient is applied to an electrolyte (such as molten sodium chloride or sodium chloride dissolved in water), the positive and negative ions will begin to drift in opposite directions. Ion-solvent and ion-ion interactions can be investigated by measuring electrolytic conductivities. Ionic conduction is essential for the operation of batteries and fuel cells, the production of important industrial chemicals, electroplating, corrosion, the transmission of nerve impulses, and many other processes.

Surprisingly, the flow of heat through a mixture can also transport matter. If one region of a convection-free mixture is cooled and another heated, partial demixing occurs. In nonisothermal salt solutions, for example, the dissolved ions usually migrate with the flow of heat to the cooler parts of the solution, while the solvent migrates to the warmer parts. The relative diffusion of substances caused by a temperature gradient is called thermal diffusion. The reciprocal effect—the flow of heat caused by concentration gradients—is also observed.

Diffusion in a concentration gradient and heat conduction in a temperature gradient can be considered "first-order" processes. Thermal diffusion is a more subtle "cross-effect." Understanding thermal diffusion therefore provides a sensitive test of microscopic theories of liquids. In practice, thermal diffusion effects are usually too small to be important, though useful separation of mixtures can be achieved in some cases.

Section 1 of this article covers the principles of diffusion in isothermal liquids. After a summary of the major advances that have been made in diffusion studies, the different kinds of diffusion are discussed: chemical interdiffusion, self-diffusion, tracer diffusion, and Brownian motion. The section concludes with a brief description of experimental techniques for measuring diffusion coefficients.

Section 2 is devoted to ionic conduction in liquids. The discussion begins with historical developments, then moves to the relation between the electrical conductivity and the concentrations and mobilities of the charge-carrying ions. Techniques are outlined for measuring ionic mobilities, from which the drift speeds of ions can be deduced.

Thermal diffusion is the subject of the concluding section (Sec. 3). An empirical approach is taken, using coupled equations for the simultaneous flow of heat and diffusion of matter through mixtures. The Soret and Dufour effects, the thermal diffusion coefficient, Soret coefficient, and heat of transport are introduced.

1. DIFFUSION IN ISOTHERMAL LIQUIDS

1.1 Historical Background

Graham (1850) appears to have been the first to understand that the flux of a diffusing substance is directly proportional to its concentration gradient. A few years later Fick grasped the analogies between diffusion, the flow of heat in a temperature gradient (Fourier's law), and the flow of electric current in a voltage gradient (Ohm's law). He formulated the empirical laws of diffusion (Fick, 1855).

Progress was also being made along theoretical lines. Gibbs (1876) pointed out that gradients in chemical potential, rather than concentration gradients, are the fundamental driving forces for diffusion. This was one of the first steps toward the extension of classical thermodynamics to nonequilibrium systems. Onsager (1931) and others would later develop the thermodynamics of irreversible processes, providing a unified treatment of transport processes.

In the early years of this century the molecular-kinetic theory developed by Einstein (1905) accounted for the chaotic diffusion behavior of colloidal particles observed under a microscope. Visibly linking the molecular and macroscopic worlds, this crucial result helped establish the validity of molecular theory. A foundation had been laid for statistical mechanical treatments of liquid-phase diffusion.

The 1950s were exciting years for diffusion research (Tyrrell and Harris, 1984): accurate gradient techniques for measuring diffusion were developed; the difficult problem of measuring coupled diffusion in multicomponent mixtures was finally solved; radioactive isotopes became widely available for tracer diffusion studies; and molecular-dynamics simulations using digital computers opened a new window on diffusion. In recent years flow techniques and spectroscopic methods based on laser light scattering and nuclear magnetic resonance have become popular sources of diffusion data.

Largely because the forces between molecules in liquids are still not known in detail, a rigorous theory of liquid-phase diffusion is still under development.

1.2 Chemical Interdiffusion in Binary Liquids

Fick studied the interdiffusion of miscible liquids containing the same chemical substances, but at different concentrations. An example would be a solution containing 1.0 mol L^{-1} of heptane dissolved in benzene diffusing into a 0.5-mol-L^{-1} solution of heptane in benzene. Interdiffusion is by far the most common form of diffusion. For two-component systems, it is also called binary mutual diffusion or simply binary diffusion.

1.2.1 Fick's Laws. Suppose that substances *A* and *B* interdiffuse at constant temperature, without convection. Fick's law gives two diffusion equations:

$$J_A=-D_A\frac{\partial C_A}{\partial z}, \tag{1}$$

$$J_B=-D_B\frac{\partial C_B}{\partial z}. \tag{2}$$

C_A and C_B are the concentrations of *A* and *B* in moles per unit volume. J_A and J_B are the fluxes of the substances in moles per unit area per unit time in the *z* direction. The fluxes are measured in the volume-fixed (laboratory) frame of reference defined by

$$J_A V_A+J_B V_B=0. \tag{3}$$

V_A and V_B are the partial molar volumes of *A* and *B*.

Two substances are diffusing, yet only one flux is independent in view of Eq. (3). Moreover, it is easily shown that diffusion coefficients D_A and D_B are equal (Hartley and Crank, 1949):

$$D_A=D_B\,(=D). \tag{4}$$

D is the binary interdiffusion coefficient.

The differential equation for the binary interdiffusion of a substance is obtained by applying the principle of conservation of mass to the flux equation:

$$\frac{\partial C_A}{\partial t}=-\frac{\partial J_A}{\partial z}=\frac{\partial}{\partial z}\left(D\frac{\partial C_A}{\partial z}\right). \tag{5}$$

If *D* can be considered constant, which is a good approximation over small concentration intervals, Eq. (5) simplifies to

$$\frac{\partial C_A}{\partial t}=D\frac{\partial^2 C_A}{\partial z^2}. \tag{6}$$

Equation (6) has been solved for many initial and boundary conditions. Solutions in two and three dimensions are also available (Crank, 1975).

D is found to depend on the nature of the diffusing substances and their concentrations, as well as the temperature and pressure (Jost, 1960). For many liquids *D* is on the order of 10^{-9} m^2 s^{-1} (about one thousand times smaller than typical values for gases).

How fast, on average, is a diffusing substance moving? The flux of a substance equals its concentration times its diffusion velocity v_A,

$$J_A=C_A v_A, \tag{7}$$

so v_A is given by

$$v_A=-\left(\frac{D}{C_A}\right)\frac{\partial C_A}{\partial z}. \tag{8}$$

For a substance at concentration 1000 mol m^{-3} in a concentration gradient of 1000 mol m^{-4}, assuming the value 1×10^{-9} m^2 s^{-1} for *D* leads to a diffusion speed of 1 nm s^{-1}.

For substances of ill-defined molar mass, it is convenient to work with mass fluxes and mass concentrations (e.g., kg m^{-3}) rather than the corresponding molar quantities.

Diffusion fluxes and velocities relative to the center of mass or to the solvent are often used in theoretical treatments of diffusion. Procedures for transforming from the volume-fixed frame used here to other coordinate systems have been developed (Fitts, 1962).

1.2.2 Mobilities and Friction Coefficients. There are more fundamental ways to describe binary interdiffusion. According to the laws of nonequilibrium thermodynamics (de Groot and Mazur, 1962), the flux of a substance is proportional to the gradient in its chemical potential,

$$J_A = -L_{AA}\frac{\partial \mu_A}{\partial z}. \qquad (9)$$

L_{AA}, the Onsager transport coefficient of A, is related to the more familiar binary interdiffusion coefficient as

$$D = L_{AA}\frac{\partial \mu_A}{\partial C_A}. \qquad (10)$$

Both $\partial\mu_A/\partial C_A$ and D drop to zero for mixtures on the brink of phase separation at critical solution points (Haase and Siry, 1968).

When substances interdiffuse, the Gibbs free energy lost during the mixing process is dissipated against viscous frictional forces. For binary interdiffusion, the chemical potential gradient $-\partial\mu_A/\partial z$ can be regarded as a virtual force that propels A through the solution.

Pursuing the mechanical analogy further, the mobility per mole of A may be defined as the ratio of its diffusion speed to the driving force,

$$U_{Am} = -v_A\Big/\left(\frac{\partial \mu_A}{\partial z}\right) = L_{AA}/C_A. \qquad (11)$$

The reciprocal of U_{Am} is called the molar friction coefficient of A. The mobility of a single molecule of A is simply the molar mobility times the Avogadro constant,

$$U_A = N_A U_{Am}. \qquad (12)$$

The mobility is a kinetic quantity that depends on factors such as the size and shape of the diffusing molecules, the composition, and the viscosity of the surrounding medium.

For a better understanding of the meaning of the interdiffusion coefficient, Eqs. (10) and (11) may be combined to give

$$D = U_{Am}\frac{\partial \mu_A}{\partial \ln C_A} \qquad (13)$$

to show that D is the product of kinetic and thermodynamic factors. The latter is often overlooked.

1.2.3 Nonelectrolytes. The chemical potential of a nonelectrolyte relative to a suitable reference value can be expressed as

$$\mu_A = \mu_A^r + RT\ln(y_A C_A), \qquad (14)$$

and therefore

$$D = RTU_{Am}\left(1 + C_A\frac{\partial \ln y_A}{\partial C_A}\right), \qquad (15)$$

where R is the gas constant and T the temperature. The activity coefficient y_A is included to allow for the departures from ideal thermodynamic behavior shown by real solutions. For an infinitely dilute solution, however, the activity-coefficient term vanishes, leading to the limiting relation

$$D^0 = RTU_{Am}^0 \quad (C_A = 0). \qquad (16)$$

Stokes (1903) showed that the mobility of a spherical particle in a continuum fluid is given by

$$U = 1/6\pi\eta r, \qquad (17)$$

where r and η are the particle radius and the viscosity of the fluid. For molecules that are approximately spherical, Eqs. (16) and (17) can be used to estimate limiting interdiffusion coefficients:

$$D^0 = RT/6\pi N_A \eta r = kT/6\pi\eta r; \qquad (18)$$

k is the Boltzmann constant. The corresponding results for nonspherical molecules have been developed.

Equation (18), which is called the Stokes–Einstein equation, suggests that D^0 is proportional to T and inversely proportional to both the radius of the diffusing molecule and the viscosity of the surrounding solvent. These correlations hold reasonably well for molecules that are much larger than the solvent molecules. Since experimental values of the viscosity are invariably used, treatments of diffusion based on Eq.(18) are semiempirical.

1.2.4 Electrolytes. Fick's equations also describe the interdiffusion of a salt dissolved in a solvent, such as aqueous sodium chloride. Although there are two kinds of diffusing ions (the cations and anions), they must diffuse at the same rate to keep the solution electrically neutral. Only one flux is therefore independent, and the binary diffusion equations apply (Robinson and Stokes, 1959).

Because of long-range Coulombic interactions, the values of D for dilute salt solutions are sensitive to the concentration.

For a dissolved salt that dissociates into ν_+ cations and ν_- anions, the limiting interdiffusion coefficient and the ionic diffusion coefficients are related by Nernst's equation,

$$D^0=(\nu_++\nu_-)D^0_+D^0_-/(\nu_-D^0_++\nu_+D^0_-). \quad (19)$$

1.2.5 Interdiffusion with Fast Chemical Reactions. Fick's equations also apply to the diffusion of chemically reacting substances provided the reaction rates are rapid enough to maintain chemical equilibrium at each point along the diffusion path. Diffusion is usually slow enough to satisfy this requirement.

A good example is the diffusion of a partially dissociated electrolyte, $MX \leftrightarrow M^+ + X^-$ (Robinson and Stokes, 1959). There are three dissolved species: molecules MX and ions M^+ and X^-. But since electroneutrality and local chemical equilibrium provide two constraints, only one flux is independent. Fick's laws apply, with J_A and C_A representing the flux and concentration of total electrolyte (dissociated plus undissociated forms).

The diffusion of stepwise self-aggregating solutes ($A+A \leftrightarrow A_2$, $A+A_2 \leftrightarrow A_3$,...) has also been treated. In this case J_A and C_A are the flux and concentration of the total A molecules. It turns out that D is not the simple concentration-weighted average of the monomers, dimers, trimers, etc.

1.3 Multicomponent Interdiffusion

There are significant differences between interdiffusion in multicomponent solutions and the binary interdiffusion of the same components (Tyrrell and Harris, 1984). Not only do the rates of diffusion change, but a new feature appears: coupled diffusion, whereby the gradient in concentration of a substance leads to a flux of another substance. Diffusion can occur from regions of *lower to higher concentration*, opposite to the expected direction.

Diffusion tends to be strongly coupled for multicomponent mixtures that show large departures from ideal thermodynamic behavior. Suppose substance i lowers the chemical potential of substance k. Substance k, seeking regions of lower chemical potential, will diffuse "up" a gradient in the concentration of i. In associating mixtures, diffusing substances can bind and cotransport large amounts of other substances.

Mixed electrolytes provide some of the most striking examples of coupled diffusion. When an electrolyte diffuses, an electric field is generated which speeds up the less mobile ion and slows down the more mobile ion in order to prevent charge separation. The electric field produced by the diffusion of an electrolyte will in turn drive coupled flows of the ions belonging to the other electrolytes in the mixture. In extreme cases, one mole of a diffusing electrolyte has been found to cotransport hundreds of moles of other electrolytes.

If a solution contains $N+1$ independent chemical substances, there are N independent diffusional fluxes. The straightforward generalization of Fick's equations,

$$J_i=-\sum_{k=1}^{N} D_{ik}\frac{\partial C_k}{\partial z}, \quad (20)$$

$$\frac{\partial C_i}{\partial t}=\sum_{k=1}^{N} D_{ik}\frac{\partial^2 C_k}{\partial z^2} \quad (i=1,2,\ldots,N), \quad (21)$$

may be used to define multicomponent interdiffusion coefficients. Coefficient D_{ik} gives the flux of substance i caused by the gradient in the concentration of substance k. D_{ik} coefficients have been measured for a number of three-component systems and a handful of four-component systems.

In general, the matrix $\mathbf{D}$ of coefficients D_{ik} is not symmetric. It can be shown that the eigenvalues of $\mathbf{D}$ are positive, real numbers (Cullinan, Jr., 1965), which rules out damped oscillatory solutions of Eq. (21).

Using Onsager's approach, multicomponent diffusion fluxes may be expressed in terms of the gradients in the chemical potentials of the diffusing substances:

$$J_i=-\sum_{k=1}^{N} L_{ik}\frac{\partial \mu_k}{\partial z}. \quad (22)$$

Using the principle of microscopic reversibility, Onsager proved that the matrix of L_{ik} coefficients is symmetric: $L_{ik}=L_{ki}$ (Miller, 1960). It can also be shown that $L_{ii} \geqslant 0$ and $L_{ii}L_{kk} \geqslant L^2_{ik}$.

The two sets of multicomponent transport coefficients are related by

$$D_{ik}=\sum_{m=1}^{N} L_{im}\frac{\partial \mu_m}{\partial C_k}. \quad (23)$$

1.4 Intradiffusion in Chemically Uniform Liquids

Diffusion in liquids of uniform chemical composition is called "intradiffusion" (Tyrrell and Harris, 1984). It can be closely approximated by tagging diffusing species with isotopes. To measure the intradiffusion of heptane in heptane-benzene mixtures, for example, some of the heptane molecules could be tagged with ^{14}C, keeping the concentrations of benzene and total heptane (labeled + unlabeled) constant throughout the mixture. Intradiffusion can also be studied, without isotopic substitution, by orienting the magnetic moments of nuclei. "Tracer" diffusion is the intradiffusion of minute amounts of foreign species in otherwise uniform solutions.

The intradiffusion coefficient of species i, D_i^*, is defined by using Fick's equation to relate the flux and concentration gradient of the labeled species:

$$J_i^* = -D_i^* \frac{\partial C_i^*}{\partial z} . \tag{24}$$

Intradiffusion differs fundamentally from chemical interdiffusion: the former involves the interchange of labeled and unlabeled species under conditions of uniform chemical composition, while the latter involves the interchange of different chemical substances in composition gradients. Figure 1 illustrates the different coefficients for the heptane-benzene system.

There is no general relation between the interdiffusion and intradiffusion coefficients. For the special case of an infinitely dilute binary solution of nonelectrolyte i, however, the intradiffusion coefficient D_i^* and the interdiffusion coefficient D are identical.

Labeled and unlabeled species form thermodynamically ideal solutions. For this reason activity coefficients are not required to interpret intradiffusion. The intradiffusion coefficient of substance i and its mobility are therefore simply related:

$$D_i^* = RTU_{im}^* . \tag{25}$$

Except at infinite dilution, the mobilities derived from intradiffusion and interdiffusion experiments are different.

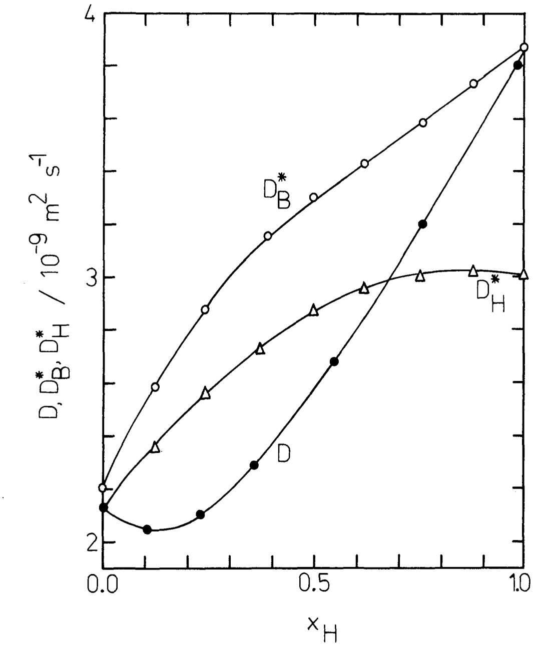

FIG. 1. Interdiffusion coefficient (D) and intradiffusion coefficients (D_H^* and D_B^*) of heptane (H)-benzene (B) mixtures at 25 °C (Harris *et al.*, 1970).

1.5 Self-Diffusion in Pure Liquids

Self-diffusion refers to intradiffusion in a liquid containing two distinguishable species having the same chemical composition. To measure the self-diffusion coefficient of liquid heptane, for example, some of the molecules in a sample of pure heptane could be tagged with ^{14}C.

1.6 Brownian Motion and the Random Walk

Analyzing the motion of a randomly jumping molecule leads to an extremely useful model of diffusion. The simplest case is the one-dimensional diffusion of a molecule at infinite dilution in a uniform solvent. To represent its chaotic thermal motion, the molecule is assumed to take v small steps of length λ per second. Steps are taken at random in the positive or negative directions.

Suppose the molecule is located at position $z=0$ at time $t=0$. Where is it at a later time t? Although its trajectory cannot be predicted, the probability $P(z,t)dz$ of finding the molecule between z and $z+dz$ can be derived for $t \gg v^{-1}$ (Einstein, 1905):

$$P(z,t)dz=(2\pi\lambda^2\nu t)^{-1/2}\exp(-z^2/2\nu\lambda^2 t)dz. \tag{26}$$

When this result is compared with the solution of Fick's equation for diffusion from a point source (Crank, 1975),

$$P(z,t)dz=(4\pi D^0 t)^{-1/2}\exp(-z^2/4D^0 t)dz, \tag{27}$$

a remarkably simple relation emerges between the diffusion coefficient, jump size, and jump frequency:

$$D^0=\nu\lambda^2/2. \tag{28}$$

Figure 2 shows probability distributions calculated with the value 1×10^{-9} m^2 s^{-1} for D^0. As time passes the chances of finding the molecule near the origin drop sharply; information on its position is lost.

The probability distributions shown in Fig. 1 are normal, with variance $2D^0t$. The same kind of distribution also arises in statistical sciences, underscoring the deep connection between diffusion and probability. The root mean square displacement of the molecule from the origin is

$$z_{\text{rms}}=(2D^0t)^{1/2}. \tag{29}$$

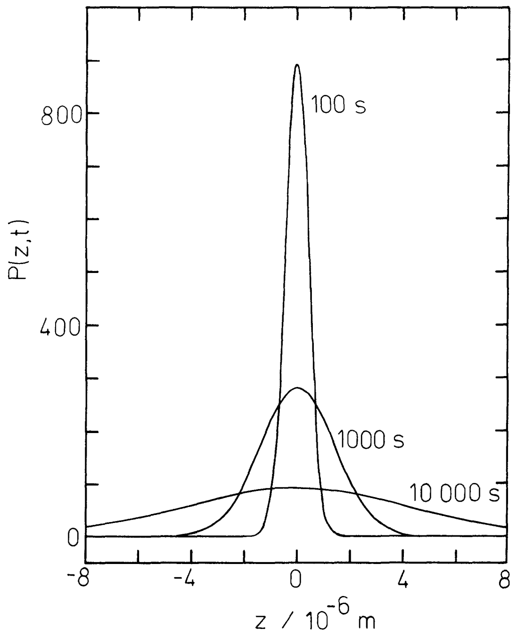

FIG. 2. Probability distributions at 100, 1000, and 10 000 s for a molecule with diffusion coefficient 1×10^{-9} m^2 s^{-1}.

Equation (29) is used to estimate the typical distances that molecules diffuse in one dimension in a given time interval. In two or three dimensions, the displacements are $(4D^0t)^{1/2}$ and $(6D^0t)^{1/2}$.

The diffusion of colloidal particles suspended in a liquid can be observed under a microscope. Bombarded on all sides by solvent molecules, such particles follow a truly chaotic path. This behavior is called Brownian motion.

1.7 Experimental Methods

Diffusion measurements pose two practical difficulties: following small changes in composition, and avoiding convection. Over the years a number of ingeneous diffusion experiments accurate to 1% or better have been developed (Dunlop *et al.*, 1989; Nagashima *et al.*, 1991; Tyrrell and Harris, 1984).

1.7.1 Optical Interferometry.

A sharp boundary between two solutions can be formed by layering the less dense solution over the denser one. When monochromatic light is directed horizontally through the solutions, the light passing near the boundary is bent downward by the sharp gradient in the refractive index. With suitable optics, the refracted light can be made to interfere with undeflected light passing at greater distances from the boundary. Interdiffusion coefficients are calculated from the time-dependent pattern of interference fringes. Two- and three-component liquids have been studied by interferometry. The accuracy of the results (0.1–0.2% of D) is unsurpassed.

1.7.2 Diaphragm Cells.

These simple but effective devices, the workhorses of diffusion experiments, have been used to measure interdiffusion in two-, three-, and four-component solutions, as well as intradiffusion. Diffusion occurs between two solution compartments through stagnant liquid held in the pores of a solution-soaked sintered-glass or sintered-metal frit. After a timed interval (usually several days), the solutions are retrieved and analyzed to determine the changes in concentrations of the diffusing species.

The rate of diffusion depends on the pore area and the effective thickness of the frit. Neither of these quantities is known accurately, so diaphragm cells are calibrated with solutions of known diffusivity, such as aqueous potassium chloride.

1.7.3 Taylor Dispersion. Flow techniques based on Taylor dispersion are a more convenient source of reliable diffusion data. The idea is to inject a narrow pulse of liquid into a laminar carrier stream of different composition confined within a long capillary tube. The injected sample spreads out into a Gaussian distribution as it flows along the tube. A detector, usually a differential refractometer, monitors the broadened distribution of the pulse as it flows out of the tube. Diffusion coefficients are calculated from the eluted pulse shapes.

Interdiffusion in two-, three-, and four-component solutions and intradiffusion have been measured by Taylor dispersion. The collection of data is easily automated using standard liquid-chromatography equipment.

1.7.4 Capillary Tubes. A short length of fine-bore capillary tubing, sealed at one end, is filled with isotopically labeled solution and then lowered into a slowly stirred bath of unlabeled solution. The labeled molecules begin to diffuse out of the tube into the surrounding solution. After a few hours or days, the tube is removed, and the amount of remaining labeled substance is determined, usually by counting of radioactive disintegrations.

1.7.5 Nuclear Magnetic Resonance. The solution is placed in a magnetic field gradient, and then, by use of radio-frequency pulses, the equilibrium distribution of nuclear magnetic moments is disturbed. From the measured decay of the magnetization, which depends in part on how fast the species move into regions of different magnetic field strength, intradiffusion coefficients are calculated.

Nuclear magnetic resonance (NMR) techniques are powerful because the intradiffusion of several different species within the same sample can be measured simultaneously, without isotopic substitution. Measurements can be made over a wide range of intradiffusion coefficient values, down to 10^{-14} m^2 s^{-1}.

2. IONIC CONDUCTION IN LIQUIDS

2.1 Historical Background

When the first electrolyte conductivities were measured, using direct currents, composition changes near the electrodes led to apparent departures from Ohm's law. Kohlrausch overcame this problem by using audio-frequency alternating currents. Electrolytes were found to obey Ohm's law after all (Robinson and Stokes, 1959).

Hittorf had already worked out how to measure the fraction of the total conductivity contributed by each ion. His results together with conductivity data meant that accurate mobilities of individual ions could be calculated. This was a breakthrough, a rare opportunity to determine unambiguous single-ion properties for electrochemical systems (Spiro, 1989).

Conductivity data for partially dissociated electrolytes helped Arrhenius develop the theory of electrolytic dissociation. He proposed that the ions and undissociated molecules of weak electrolytes exist in equilibrium. There was skepticism: Why, at room temperature, should molecules split into ions? It soon became clear that the solvent stabilizes dissolved ions by screening the Coulombic forces and surrounding the ions with a shell of tightly bound solvent molecules.

In the 1930s the general equations for ion transport were developed. Also, Coulombic interactions were shown to account for the strong variations in ionic mobilities at high dilutions (Onsager and Fuoss, 1932). A satisfactory theory for concentrated electrolytes is still elusive, and it is not yet possible to predict accurate ionic mobilities from first principles.

2.2 Molar Conductivities

Ohm's law states that the electric current passing through a conductor is proportional to the applied electric potential difference $\Delta\phi$,

$$I = -\Delta\phi/R\,, \qquad (30)$$

where R is the resistance. For a uniform conductor, the conductance $1/R$ is proportional to the cross-sectional area A and inversely proportional to the length l.

Dividing the current by the area gives the current density i:

$$i = I/A = -(l/AR)(\Delta\phi/l). \qquad (31)$$

Equation (30) may be rewritten as

$$i = \kappa E. \qquad (32)$$

E is the electric field strength $-\partial\phi/\partial z$. κ, an abbreviation for l/AR, is the conductivity. κ depends on the temperature, pressure, and the composition of the conductor, but not its dimensions.

The charge carriers in electrolyte solutions are ions, not electrons. By varying the concentration of ions, the conductivity can be changed over many orders of magnitude. It proves convenient therefore to define the molar conductivity Λ by dividing the conductivity by the concentration of the dissolved electrolyte:

$$\Lambda = \kappa/C. \qquad (33)$$

The molar conductivity of a partially ionized "weak" electrolyte [e.g., acetic acid in water: $CH_3COOH(aq) \leftrightarrow H^+(aq) + CHCOO^-(aq)$] is approximately proportional to its extent of dissociation.

For an electrolyte solution containing positive ions M^{z_M} at concentration c_M (in moles per unit volume) and negative ions N^{z_N} at concentration c_N, the molar conductivity of the electrolyte and the molar conductivities of the ions, λ_M and λ_N, are related by

$$\kappa = C\Lambda_m = c_M\lambda_M + c_N\lambda_N. \qquad (34)$$

Λ_m, λ_M, and λ_N have units S m^2 mol^{-1}.

If the ions moved independently, molar conductivities would be independent of concentration. But ions do, of course, interact, and so molar conductivities vary with concentration, even for very dilute solutions. The interactions are ion-specific. For example, the conductivity of Na^+ ions in 1.0-mol-L^{-1} aqueous NaCl solution differs from that for 1.0-mol-L^{-1} NaI solution. Only at infinite dilution do ions conduct current independently.

2.3 Ionic Mobilities and Transference Numbers

When an electric field is applied to an electrolyte solution, the ions accelerate almost instantaneously to their terminal velocities. The electric force acting on each ion is then balanced by the frictional force offered by the solvent. The mass of an ion plays no role in determining its conductivity. [This simple picture does, however, break down at high field strengths ($\gg$1 kV m^{-1}) or high frequencies ($\gg$10 kHz) (Harned and Owen, 1950).]

The electric mobility u_k of ion k is defined as the ion's terminal drift speed v_k divided by the electric field,

$$u_k = v_k/E. \qquad (35)$$

Taking the product of the drift speed and the concentration gives the flux of the ion, in moles per unit area per unit time:

$$j_k = c_k v_k. \qquad (36)$$

Each mole of ion k carries electric charge z_kF. z_k is called the charge number of ion k (e.g., -2 for $SO_4{}^{2-}$). F, the Faraday constant, is the charge per mole of protons: 96 485 C/mol.

Ion k contributes $c_k v_k F z_k$ to the electric current density. Summing over the different ions gives

$$i = \sum_k c_k z_k F u_k E = \sum_k c_k \lambda_k E \qquad (37)$$

for the total current density. The molar conductivity of an ion is therefore proportional to its mobility:

$$\lambda_k = F|z_k|u_k. \qquad (38)$$

(The equivalent ionic conductivity, $\lambda_{ke} = \lambda_k/|z_k|$, is occasionally used.)

The molar conductivities of many ions are on the order of 0.01 S m^2 mol^{-1}. For a 100-V-m^{-1} electric field, the corresponding ionic

Table 1. Molar ionic conductivities and electric mobilities of ions at infinite dilution in water at 25 °C (Robinson and Stokes, 1959).

Ion	$\lambda_i^0/10^{-4}$ S m^2 mol^{-1}	$u_i^0/10^{-8}$ m^2 s^{-1} V^{-1}
H^+	349.8	36.25
Li^+	38.6	4.00
Na^+	50.1	5.19
K^+	73.5	7.62
Ca^{2+}	119.0	6.17
La^{3+}	209.1	7.22
OH^-	198.3	20.55
F^-	55.4	5.74
Cl^-	76.4	7.91
Br^-	78.1	8.10
SO_4^{2-}	160.0	8.29
NO_3^-	71.5	7.41

speeds are about 10^{-4} m s^{-1}. Table 1 lists the conductivities and mobilities of selected ions in water. The mobilities of H^+ and OH^- are abnormally high because of proton jumps between the water molecules.

The transference number (or transport number) T_k of ion k is defined as the fraction of the total electric current carried by that ion,

$$T_k = c_k\lambda_k \Big/ \sum_i c_i\lambda_i. \tag{39}$$

If the conductivity and the transference numbers of an electrolyte solution have been measured, the ionic conductivities (and therefore the mobilities) can be calculated. For a salt $M_{\nu_M}N_{\nu_N}$ that dissociates to give ν_M cations M^{z_M} and ν_N anions N^{z_N}, the relations are

$$\lambda_M = T_M\Lambda/\nu_M, \tag{40}$$

$$\lambda_N = T_N\Lambda/\nu_N. \tag{41}$$

At very low concentrations (< 1 mol m^{-3}), the ions are far enough apart that the forces between them are essentially Coulombic. Coulombic interactions cause ionic conductivities to decrease linearly with the square root of the concentration (Onsager and Fuoss, 1932).

Although accurate ionic conductivities cannot be predicted, Stokes's law provides a useful qualitative guide for dilute solutions. The electrical force z_kFE per mole of ion k is assumed to be balanced by the frictional force calculated from Stokes's law for one mole of spherical particles of radius r_k:

$$z_kFE = N_A 6\pi\eta r_k v_k, \tag{42}$$

where η is the viscosity of the solvent. Combining Eqs. (35), (38), and (42) gives

$$\lambda_k = z_k^2F^2/6\pi N_A\eta r_k. \tag{43}$$

This result holds reasonably well for large ions, but only poorly for small ions. Ionic radii calculated from experimental conductivities using Stokes's law tend to exceed crystallographic radii, especially for ions with high charge densities (e.g., Li^+). Dissolved ions are effectively larger because they carry tightly bound solvent molecules held in place by ion-dipole forces.

Equation (43) suggests an inverse relation between ionic conductivities and the viscosity of the solvent. Since liquids become less viscous when heated, ionic conductivities *increase* with the temperature (unlike the electronic conductivities of metals).

2.4 Ion Transport Equations

Ionic conduction in electric fields and the diffusion of ions in concentration gradients often occur simultaneously. This more general case of ion migration is described by Onsager's equations (Onsager and Fuoss, 1932)

$$j_k = -\sum_q l_{kq}\frac{\partial\tilde{\mu}_q}{\partial z}, \tag{44}$$

which relate the ionic fluxes to the gradients in the electrochemical potentials of the ions. The matrix of ionic transport coefficients l_{kq} is symmetric.

The electrochemical potential of ion k is the sum of its chemical potential and its electric potential energy, $z_kF\phi$:

$$\tilde{\mu}_k = \mu_k^r + RT\ln(y_kc_k) + z_kF\phi. \tag{45}$$

For a single electrolyte dissolved in a solvent, the coefficients l_{kq} can be evaluated from measured values of D, Λ, and the transference numbers.

At infinite dilution, the ionic activity coefficients y_k are unity and the off-diagonal coefficients l_{kq} are negligible. In this limit Onsager's equations reduce to the Nernst-Planck equations (Newman, 1973):

$$j_k = -D_k^0\frac{\partial c_k}{\partial z} + \frac{z_kFD_k^0c_k}{RT}E, \tag{46}$$

where D_k^0 is the limiting diffusion coefficient of ion k,

$$D_k^0 = RT\lambda_k^0/z_k^2F^2 = RTu_k^0/|z_k|F. \tag{47}$$

Electrolytes show large departures from ideal behavior, even at very low concentrations. Quantitative applications of the Nernst–Planck equations are therefore limited.

2.5 Experimental Methods

2.5.1 Conductivity Measurements. The electrolyte solution is usually placed between two inert platinum electrodes (Robinson and Stokes, 1959). To minimize impedances due to electron transfer reactions, the electrode surfaces may be coated electrolytically with finely divided catalytic platinum.

Unless special cells are used, the length and cross-sectional area of the conducting solution between the electrodes are not accurately known. To determine l/A, so that resistances can be converted to conductivities, cells are calibrated with solutions of known conductivity, such as aqueous potassium chloride.

An ac Wheatstone bridge is suitable for measuring electrolyte conductivities. The bridge is energized with a 1–5-kHz sine-wave current from an audio-frequency oscillator. The ac impedance of the electrolyte consists of a resistance and a capacitance. A variable resistor and a variable capacitor are adjusted to balance the bridge.

Electrolyte conductivities can also be measured inductively, without electrodes contacting the solution, by using a loop of solution to link the cores of two transformers (Robinson and Stokes, 1959). This technique is useful in applications where metal electrodes would be corroded or fouled by adsorption.

2.5.2 Hittorf Experiment. Hittorf's procedure for measuring transference numbers relies on the changes in concentration near electrodes when direct current is passed through an electrolyte solution (Robinson and Stokes, 1959; Spiro, 1989). Figure 3 gives a sketch of a Hittorf cell. The composition of the electrolyte is initially uniform throughout the cell.

For purposes of illustration, suppose the cations are four times more mobile than the anions, and 5 F of charge are passed through the cell. During the experiment, 5 F of cations plate out onto the negative electrode, while 5 F of anions discharge at the positive electrode. Across any plane in the solution, 4 mol of cations are transferred for every mole of less mobile anions.

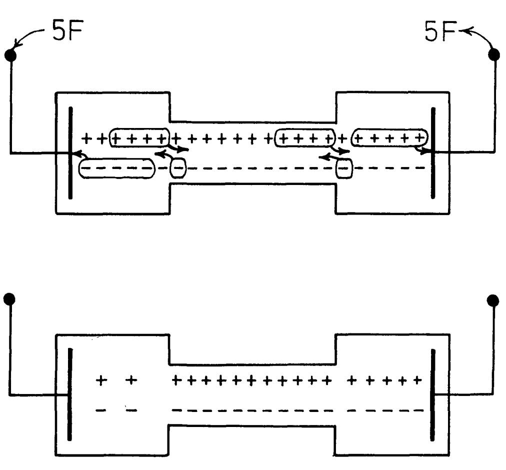

FIG. 3. Sketch of a Hittorf cell before and after the passage of 5 F of direct current. The cations are assumed to be 4 times more mobile than the anions.

After the current is turned off, the solution near the positive electrode is found to contain 4 mol less electrolyte, and the solution near the negative electrode contains 1 mol less electrolyte. The measured changes in concentration give $T_+ = \frac{4}{5}$ and $T_- = \frac{1}{5}$.

2.5.3 Moving-Boundary Experiment. In a moving-boundary cell, the solution is layered over a denser solution of a different electrolyte with an ion in common (e.g., aqueous HCl over aqueous $CdCl_2$). When a direct current is passed in series through the solutions, the boundary between them moves. Surprisingly, the boundary will remain sharp if certain concentrations are used.

By measuring the speed of the boundary, the transference numbers of the upper ion can be determined (Robinson and Stokes, 1959; Spiro, 1989). Suppose the boundary sweeps out volume V during the passage of a total of Q coulombs of charge. The fraction of the total charge carried by the upper ion (1) is $FVCz_1$, and hence $T_1 = FVCz_1/Q$.

3. THERMAL DIFFUSION

3.1 Historical Background

Ludwig was the first to notice diffusion caused by a temperature gradient. He filled a glass tube with a salt solution, heated one end of the tube, and chilled the other. Salt crystals grew in the cooler end, indicating migration of salt to lower temperatures. Soret verified that small but measurable concentration gradients do indeed develop when a temperature gradient is imposed on liquid mixtures. This behavior is called the Soret effect (Tyrrell, 1961; Agar, 1963).

The development of nonequilibrium thermodynamics rekindled interest in thermal diffusion; so did a practical development—the separation of mixtures in thermogravitational columns (Tyrrell, 1961). From the 1950s onward, experimental techniques for measuring the Soret effect were honed to higher accuracy. Reliable data have been obtained for binary electrolyte and nonelectrolyte solutions (Nagashima *et al.*, 1991).

The Dufour effect, the production of a temperature difference by a concentration gradient, is the reciprocal of the Soret effect. The Dufour effect had been measured for gases, but liquids, with their relatively large heat capacities, were not expected to show measurable Dufour effects. Recently, however, the Dufour effect has been measured for liquids (Rowley and Horne, 1980). This advance holds promise for studies of multicomponent liquids.

3.2 Diffusion and Heat Flow in Binary Liquids

When a temperature gradient is applied to a convection-free mixture, heat begins to flow, and the components begin to demix partially. There are many ways to describe such behavior (de Groot and Mazur, 1962; Fitts, 1962). The usual approach is to define first the "reduced" heat flux

$$J'_q = J_q - \sum_{i=1}^{2} J_i H_i, \tag{48}$$

by subtracting from the total heat flux J_q the heat flux arising from the diffusion of matter (Katchalsky and Curran, 1965). H_i is the partial molar enthalpy of substance i.

For thermal diffusion in binary mixtures (one independent diffusional flux of matter), irreversible thermodynamics suggests the coupled equations

$$J_A = -L_{AA}\frac{\partial \mu_A}{\partial z} - \left(\frac{L_{Aq}}{T}\right)\frac{\partial T}{\partial z}, \tag{49}$$

$$J'_q = -L_{qA}\frac{\partial \mu_A}{\partial z} - \left(\frac{L_{qq}}{T}\right)\frac{\partial T}{\partial z} \tag{50}$$

for diffusion, the reduced flow of heat, and their interactions. L_{AA} is the Onsager coefficient for the isothermal interdiffusion of A (Sec. 1.2.2). L_{qq}/T is the thermal conductivity of the solution.

The magnitudes of the Soret and Dufour effects depend on the cross-coefficients L_{Aq} and L_{qA}, respectively. Onsager's reciprocal relation theory holds that $L_{Aq} = L_{qA}$.

The flux of substance A caused by a temperature gradient is roughly proportional to the concentration of that substance. To define a practical transport coefficient that is less sensitive to composition, it is convenient to replace L_{Aq}/T with $C_A D_T$. D_T is called the thermal diffusion coefficient. The flux of substance A can then be expressed as

$$J_A = -D\frac{\partial C_A}{\partial z} - D_T C_A \frac{\partial T}{\partial z}. \tag{51}$$

3.3 Soret Steady State

If convection can be avoided, the concentration gradients induced by thermal diffusion slowly grow in magnitude until they are balanced by interdiffusion in the opposite direction. Heat continues to flow once the steady state is reached, but the diffusional flux of each component is zero.

When the condition $J_A = 0$ is applied to Eq. (51), the result,

$$-\left(\frac{\partial \ln C_A}{\partial T}\right)_{ss} = \frac{D_T}{D} = \sigma, \tag{52}$$

shows that the fractional change in the concentration of A at steady state equals the ratio of the thermal diffusion coefficient to the binary interdiffusion coefficient. The ratio D_T/D is known as the Soret coefficient, σ. (The related quantity $\alpha = T\sigma$ is also used.)

Soret coefficient values lie in the range 0.001 to 0.01 for many liquid mixtures. A 10-K temperature difference typically produces a 1–10% change in concentration. σ does, however, rise to infinity at critical solution points (Haase and Siry, 1968).

3.4 Heat of Transport

To understand thermal diffusion, it is helpful to introduce the heat of transport Q^*, the reduced heat flow per mole of diffusing substance under isothermal conditions:

$$Q^*_A = (J'_q/J_A)_{T\ \mathrm{const}} = L_{qA}/L_{AA}. \tag{53}$$

The heat of transport may be calculated from measured Soret coefficients as

$$Q^*_A = \sigma T C_A \frac{\partial \mu_A}{\partial C_A}. \tag{54}$$

When A diffuses out of a volume element of solution, Q^*_A is the heat that must be absorbed per mole of A to maintain isothermal conditions (Tyrrell, 1961).

3.5 Experimental Methods

Thermal diffusion is usually studied by placing a short column of uniform solution between two metal plates maintained at different temperatures, and then following the subsequent changes in composition induced by the temperature gradient (Tyrrell, 1961; Nagashima, *et al.* 1991). Optical methods can provide accurate results. For electrolytes, thermal diffusion can also be studied by measuring the changes in conductance or potential along the column.

Even small amounts of convection can produce significant errors. One way to minimize this problem is to use a diaphragm cell with a warm upper compartment and a cool lower compartment. Convection can be eliminated by confining diffusion to sufficiently small pores (<15 μm).

Flow cells have also been used to measure thermal diffusion. The liquid mixture is pumped under laminar conditions through a thin (<0.001 m) duct sandwiched between two horizontal metal plates held at different temperatures. A horizontal knife edge bisects the stream into lower and upper portions as it emerges from between the plates. The Soret coefficient is evaluated from the difference in composition between the two streams.

Thermogravitational columns can also be used to measure Soret coefficients, but the analysis is more difficult. A thin layer of solution is sandwiched between two *vertical* surfaces, one of which is cooled and the other heated. Convection causes the denser solution near the cold surface to sink, while the solution near the warm surface rises. Substances that migrate to the warm plate are lofted to the top of the column, while the components that migrate to the cold plate are enriched at the bottom of the cell.

GLOSSARY

Brownian Motion: Random thermal motion of molecules or suspended particles in fluids.

Chemical Potential: Partial molar Gibbs free energy (J mol^{-1}).

Colloidal Particle: Small particle ($\lesssim 0.5$ μm) suspended in a fluid.

Conductance: Reciprocal of the electrical resistance of a conductor (S).

Conductivity: Conductance of a uniform conductor of unit length and unit cross-sectional area (S m^{-1}).

Dufour Effect: Flow of heat caused by concentration gradients.

Electric Mobility: Drift speed of an ion per unit applied electric field strength (m^2 s^{-1} V^{-1}).

Electrochemical Potential: Sum of the chemical and electrical potential energies per mole of an ionic species (J mol^{-1}).

Electrolyte Solution: Liquid or solid that contains mobile ions.

Faraday: Electrical charge per mole of protons (C mol^{-1}).

Flux: Quantity of substance, heat, etc., passing through unit cross-sectional area per unit time (amount m^{-2} s^{-1}).

Interdiffusion: Diffusion between solutions of different chemical composition.

Intradiffusion: Diffusion of labeled (by isotopic substitution or nuclear magnetization) species in systems of uniform chemical composition.

Mobility: Terminal speed of a particle or molecule developed per unit of applied force (s kg^{-1}).

Self-Diffusion: Intradiffusion in systems containing only one form of chemical species.

Soret Effect: Diffusion of matter caused by a temperature gradient.

Thermal Diffusion: See Soret Effect.

Thermogravitational Cell: Device containing a nonisothermal mixture in which both thermally driven diffusion and convection occur.

Tracer Diffusion: Diffusion of a minute amount of species in an otherwise uniform solution.

Transference Number: Fraction of the total electrical current carried by an ion.

INTRODUCTION

During the last three decades or so, thin films have become essential to advanced technology in a variety of ways. Their use is well known to the scientists and engineers involved in the microelectronic industry. In other industries as well, thin films are used extensively as coatings to control corrosion, wear, friction, hardness, etc. Their applications are very cost effective since specific performance objectives can be met with the use of small amounts of material on relatively cheap substrates. From the microelectronic applications point of view, thin films can be divided into three functional groups.

Electrically conducting film packages are used in Si chip personalization (interconnection) schemes or in subsequent packaging technology (Fried *et al.* 1982; Blodgett and Barbour, 1982). Thin films in these packages invariably have polycrystalline structures and may consist of pure metals, alloys, or intermetallic compounds. To preserve the electrical and chemical characteristics of the thin-film package, thin-film diffusion barriers may be interposed, consisting of either refractory metals or intermetallic compounds. In some recent applications, amorphous thin films have also been considered (Kattelus and Nicolet, 1988). The degradation of the thin-film package takes place by interdiffusion between films or the formation of discontinuities by diffusion-controlled processes such as electromigration, thermomigration, creep and fatigue, etc. (d'Heurle, 1989). Interdiffusion between films may also promote formation of phases with an attendant loss of adhesion.

Dielectric films are also needed in microelectronic thin-film packages between lines used for electrical power distribution and signal propagation. The dielectrics used may be either inorganic compounds, principally the oxides and nitrides of Si (SiO_2, Si_3N_4), or polymeric films such as polyimides that generally have lower dielectric constants and hence are beneficial to prevent noise in dense circuits operating at high speeds (Small and Pearson, 1990; Feigl, 1986). Since dielectric films are always in contact with the conducting lines, control of metallic diffusion and solubility in these films is important to prevent signal shorting and degradation of the dielectric properties.

Finally, semiconducting films are used in Ohmic contacts and Schottky barriers on the

digital Encyclopedia of Applied Physics

Si chip itself during the device fabrication process (Katz *et al.* 1990; Wittmer *et al.*, 1986). These films are commonly epitaxial in character. Here, only high-temperature dopant diffusion is relevant, and may be neglected once the transistors have been formed in the Si wafers. In the thin-film applications other than microelectronics, diffusion still plays an important role in developing adhesion and other desirable properties in contact with the substrate. Once again the degradation of the structure involves the formation of undesirable phases, and the development of stresses is controlled by diffusion.

Since diffusion in thin films is highly structure sensitive, the most convenient classification is the one based on the structure itself. As will be seen, such a classification adequately describes the thermal aspects of fabrication and reliability of the thin-film package. In this article, we will describe a hierarchy of diffusion rates due to the various possible defects in polycrystalline thin films and the principles of their modification by alterations of structure or chemistry. Some examples of metallic epitaxial and textured thin films are included to illustrate the role of special boundaries. A brief discussion of diffusion in amorphous conducting and insulating films is provided because they are gaining importance in VLSI (very large scale integration of microelectronic devices) applications. Inclusion of a discussion on amorphous films is appropriate as it is another variation of microstructure of thin films. Comprehensive tabulated lists of diffusion data for the commonly used thin films are provided using the functional classification discussed above. Our discussions will assume largely invariant chemistry during diffusion in thin films with the exception of the presence of small additions of solutes. Consequently, the thin-film systems involving large chemical composition changes such as the ones encountered in heterostructures have not been included. Also, as mentioned earlier, semiconducting films have not been included because of their epitaxial character and freedom from fast diffusion paths such as grain boundaries and dislocations. In view of the limited scope of this article, it has not been possible to cover atomistic aspects of diffusion in thin films, but the interested reader is referred to several publications on this subject (Gupta and Ho, 1988; Nowick and Burton, 1975; Murch and Nowick, 1984).

1. GENERAL ASPECTS OF DIFFUSION

Under the condition of an instantaneous thin-film source of the diffusing species into a semi-infinite solid, the diffusion profile that follows from Fick's second law has a Gaussian mathematical form given by (Shewmon, 1989)

$$c(x,t) = (M/2\sqrt{\pi D t})\exp(-x^2/4Dt), \qquad (1)$$

where M is the total amount of the diffusant per unit area, D is the diffusion coefficient, t is time for diffusion, and $c(x,t)$ is the concentration of diffusant at distance x and time t such that

$$\left(\frac{\partial c}{\partial x}\right)_{(0,t)} = 0.$$

The diffusion profiles are therefore typically linear in plots of ln c versus the penetration distance squared. If diffusion occurs from an infinite source, the profiles are best described by a complementary error function, and the procedure for evaluation of the diffusion coefficient is discussed by Shewmon (1989).

From Eq. (1), the diffusion length $\bar{x}$, which may be defined as that for which $c/M = 1/e = 0.37$,

$$\bar{x}^2 = 4Dt, \qquad (2)$$

is commonly used as a measure of the extent of diffusion in solids.

The temperature dependence of the diffusion coefficient is generally expressed by the Arrhenius relationship:

$$D = D^0 \exp(-Q/kT), \qquad (3)$$

where D^0 is the preexponential factor, Q is the activation energy for diffusion, k is Boltzmann's constant, and T is the temperature in kelvins. The diffusion parameters D^0 and Q implicitly contain a large amount of information on the thermodynamic and kinetic properties of the defects responsible for diffusion. For example, the magnitude of enthalpy and the preexponential term provide clues as to whether vacancies, divacancies, or interstitial atoms are responsible for diffusion. Discussions on the thermodynamic and atomic theories of the diffusion parameters may be found in several references (Nowick and Burton, 1975; Murch and Nowick, 1984). We will use the subscripts a, b, and l on D, D^0, and Q

to denote amorphous, grain-boundary, and bulk lattice diffusion, respectively.

2. DIFFUSION IN POLYCRYSTALLINE THIN FILMS

2.1 Diffusion Kinetics

In polycrystalline thin films, diffusion in the lattice and in grain boundaries generally occurs simultaneously and complicates the kinetics. The coupling of these processes takes place at the grain boundaries, which have an effective thickness δ of the order of the atomic spacing ($\sim 5\times 10^{-8}$ cm). The temperature dependence of the lattice diffusion D_l and that of the grain-boundary diffusion (D_b), together with their respective dimensions—L, the grain size, and δ, the grain-boundary width—determine the overall diffusion profile. It will be seen later on in this section that diffusion processes in general are related to the absolute melting temperature of the host (T_m). Hence, the temperature dependence of diffusion profiles may be described using homologous temperatures (T/T_m) in various materials. We also note here that the problem of diffusion in polycrystalline thin films is identical to the measurement of grain-boundary diffusion in polycrystalline specimens in general. Hence, in the following discussion they have been used in an interchangeable manner.

The interplay of the two atomic diffusion processes in thin films is best described by the three kinetic regimes A, B, and C due to Harrison (1961) that are shown schematically in Fig. 1. Figure 1(a) illustrates A-type kinetics that involves extensive lattice diffusion together with grain-boundary diffusion and mixing across the grains. This regime is typical of diffusion at temperatures above $0.5T_m$ in thin films. Since the diffusion activity is large in both the regions, the diffusion front becomes nearly planar. The diffusion kinetics may resemble that of lattice diffusion, i.e., the diffusion front would advance as a Gaussian with respect to the annealing time t. The measurements would show enhanced apparent diffusivities (D_{app}) with lower activation energies that can be described by Hart's equation (1957):

$$D_{\mathrm{app}}=D_l+fD_b, \qquad (4)$$

where f is the fraction of atoms at the grain boundaries with respect to the grains so that $f=4\delta/L$.

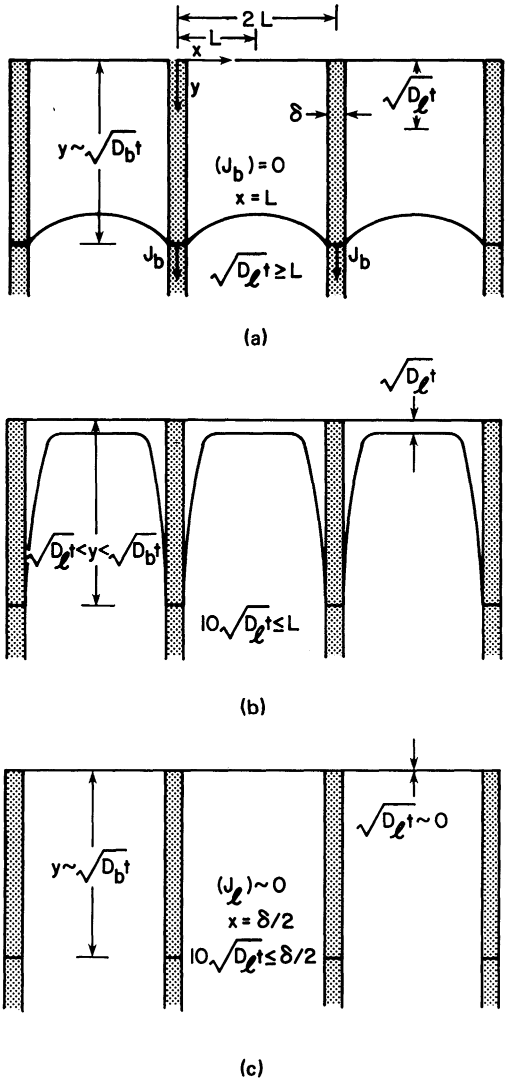

FIG. 1. Schematic representation of (a) type-A, (b) type-B, and (c) type-C kinetics for grain-boundary diffusion after Harrison (1961). The vertical lines indicate the individual grain boundaries of width δ that are perpendicular to the sample surface. The curved lines are isoconcentration contours. The diffusion source coincides for each kinetic regime with the horizontal line.

In the temperature range of $0.3T_m<T<0.5T_m$, B-type kinetics are operative as shown in Fig. 1(b). Here, each boundary is assumed to be isolated, and fast diffusion along the grain boundaries is accompanied by leakage of the diffusant into the grains where lattice diffusion in the *y* direction away from the grain boundaries [Fig. 1(b)] approaches zero.

In the past, almost all experiments on grain-boundary diffusion in metals, alloys, and oxides have been carried out in this regime. It will not be possible to discuss them in detail in this publication. The most commonly used solution is the asymptotic solution due to Whipple (1954) and Suzuoka (1961) and is expressed as

$$P=\delta D_b=0.661\left(\frac{\partial \ln c}{\partial x^{6/5}}\right)^{-5/3}\left(\frac{4D_l}{t}\right)^{1/2}. \quad (5)$$

For metals the grain-boundary width δ is assumed to have a constant value of $\delta=0.5$ nm. Therefore D_b can be determined by plotting the logarithm of the mean tracer concentration c in a thin section parallel to the surface versus $x^{6/5}$. This plot generally contains a straight-line segment in the region where grain-boundary diffusion is dominant and atoms have diffused via grain boundaries into the adjoining grains; for example, see Fig. 2(a) for ^{67}Cu diffusion in polycrystalline W thin films in the range 800–898 °C (Vieregge and Gupta, 1991). To evaluate *P*, a necessary requirement is the knowledge of the bulk diffusion coefficient D_l. In addition, there is a critical parameter $\beta=\delta D_b/2D_l\sqrt{D_l t}$ that must be maintained larger than 30 for Eq. (5) to be valid; otherwise an erroneous activation energy will result (LeClaire, 1963).

Finally, below $0.3T_m$, lattice diffusion is almost frozen out so that only grain-boundary diffusion prevails. This regime is characterized by *C*-type kinetics, shown in Fig. 1(c). This is the only type of kinetic regime offering a straightforward access to D_b. It requires

$$2\sqrt{D_l t}\ll\delta, \quad (6)$$

implying that the diffusing atoms move only inside grain boundaries and lattice diffusion is absent. Analytically, the system can be described in a manner similar to volume diffusion by replacing *D* with D_b in Eq. (1). Therefore, a plot of the logarithm of *c* vs x^2 should yield a straight line the reciprocal slope of which gives D_b:

$$D_b=-\frac{1}{4t}\left(\frac{\partial x^2}{\partial \ln c}\right). \quad (7)$$

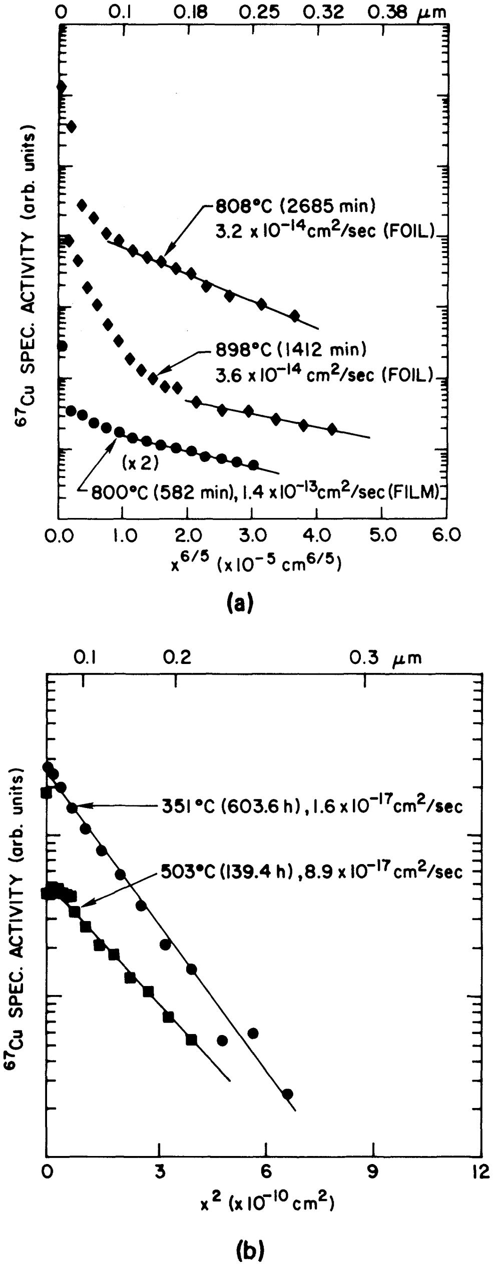

FIG. 2. (a) Penetration profiles for ^{67}Cu diffusion in W films formed by chemical vapor deposition and in sintered W foils. For clarification the profile at 800 °C is multiplied by a factor of 2. The slopes of the linear parts of the profiles are used to calculate *P* in Eq. (5) for type-*B* grain-boundary diffusion regime [after Vieregge and Gupta (1991)]. (b) Penetration profiles of ^{67}Cu diffusion in W films formed by chemical vapor deposition and in W foils at 351 and 503 °C plotted in the penetration distance squared (x^2). The linear plots are strong evidences for the existence of type-*C* kinetics of grain-boundary diffusion in W at temperatures below $0.2T_m$ [after Vieregge and Gupta (1991)].

Because of the constraint imposed by Eq. (6) on the lattice diffusion that must essentially vanish, efforts to study type-*C* kinetics have been largely unsuccessful in the past. Only in recent years has it been possible to investigate type-*C* kinetics unequivocally in fine-grained refractory metals and oxides at temperatures below $0.3T_m$ (Atkinson and Taylor, 1986) by the use of microsectioning techniques. The *C*-type diffusion kinetics is generally encountered only in thin films that have very fine grains. We have recently shown that it is possible to measure grain-boundary diffusion of Cu in the *C* regime in W films formed by the chemical vapor deposition technique at temperatures below $0.3T_m$ (Vieregge and Gupta, 1991). In Fig. 2(b), ^{67}Cu diffusion profiles in polycrystalline W films at 351 and 503 °C are plotted according to Eq. (7). The profiles clearly are linear in the x^2 plots indicating that *C*-type kinetics is, indeed, operative.

At this point, we wish to note that in the case of solute diffusion, the tendency for solute segregation at the grain boundaries has to be taken into account as well. This results in a replacement of the term δ with $s\delta$ in Eqs. (5) and (6), where s is the solute to grain-boundary segregation factor defined by the partitioning of the solute concentration between the lattice, c_l, and the grain boundary, c_b, so that $c_b = sc_l$. The factor s has an inverse Arrhenius temperature dependence compared to the diffusion processes, and it increases as temperature is lowered.

2.2 Hierarchy of Diffusion and Diffusion Data in Polycrystalline Thin Films

In polycrystalline thin films or bulk samples, there are three kinds of defects present that contribute to diffusion: vacancies, dislocations, and grain boundaries. There is actually a hierarchy of diffusion rates along these paths that was first proposed by Gjostein (1973). The lattice diffusion rates due to atom-vacancy exchanges are the slowest, dissociated dislocations have intermediate rates, and high-angle grain boundaries (where the misfit between the adjoining lattices is large) have the fastest diffusion rates. The activation energies for the three kinds of defects can be described, respectively, by $(34, 25, \text{and } 17)T_m$ in calories/mole and the corresponding values for the preexponential terms are of the order of 0.5, 3, and 0.3 cm^2/s. Although the uncertainty is ±20% in the activation energy and an order of magnitude in the preexponential factor, these rules provide reasonable estimates of diffusion rates in systems where no measurements are available. In practice, these parameters lead to measurable diffusion contributions from structural defects even at temperatures below $0.5T_m$ where the normal lattice diffusion is considered to be negligible. In fact, grain boundaries become the dominant diffusion paths in thin films at the temperature of their deposition and subsequent use.

In Table 1, we have compiled diffusion data in thin films of commonly used metals and alloys obtained by various techniques in many laboratories. As mentioned above, in most cases these data are similar to grain-boundary diffusion coefficients measured in the bulk samples. Hence, some bulk materials have also been included. It is not possible to compile all the diffusion data in thin films available in the literature since it is voluminous. For specific systems, the reader is referred to *Defect and Diffusion Forum*, where the results of many diffusion investigations are abstracted on a continuing basis.

Arrhenius plots of some selected systems from Table 1 are shown in Fig. 3. The diffusion coefficients among the various systems are seen to vary by many orders of magnitude. Hence, refractory metals films such as oxygen stabilized β-Ta, prepared by cathodic sputtering (Schwartz and Feit, 1977), and CVD-W may be considered for diffusion barriers against Cu migration from conducting metallizations such as Al-Cu and Cu themselves.

2.3 Principles of Modification of Diffusion

In thin-film technology, diffusion is often detrimental to devices during their fabrication and operation. For example, hillock growth and electromigration failures in thin films have continued to be serious problems in microelectronics (d'Heurle, 1989; Kwok and Ho, 1988). However, ingenious solutions have been found by

1. altering the microstructure of films,
2. addition of solutes,
3. interposing diffusion barriers, and
4. formation of sandwich structures.

These are briefly discussed below.

Table 1. Grain-boundary diffusion parameters in conducting polycrystalline thin films and some bulk specimens.[a]

Matrix solute (wt %)	Diffusant	D_b^0 (cm^2 s^{-1})	Q_b (eV)	Remarks (Poly. films/bulk)

[b] Vieregge *et al.* (1992a).
[c] Vieregge and Gupta (1991).

2.3.1 Modification of Film Microstructure. It is seen in Table 1 that (100) and (111) epitaxial Au films show a significantly higher activation energy for diffusion compared to the polycrystalline films. This is attributed to the presence of special grain-boundary structure consisting of dissociated dislocations, which is commonly observed in Au. Similarly, films having (111) preferred orientation also have a tendency to show higher activation energy for diffusion compared to the randomly oriented films, due to the preponderance of special boundaries. However, it is almost impossible to produce epitaxy on the substrates commonly employed in devices and other applications. Even films having preferred orientation can only be fabricated in very special circumstances. Therefore, modification of film structure to reduce diffusion has rightly received little attention. Only in the electromigration in submicron-width lines has some success been achieved by producing a bamboo-shaped grain structure. The enhancements in electromigration lifetimes have been possible largely through the elimination of the flux divergence at the triple points of grain boundaries, which are less probable in the bamboo structure (Kwok and Ho, 1988).

2.3.2 Additions of Solutes. Additions of small amounts of solutes to polycrystalline thin films have sometimes resulted in remarkable improvements in performance. For ex-

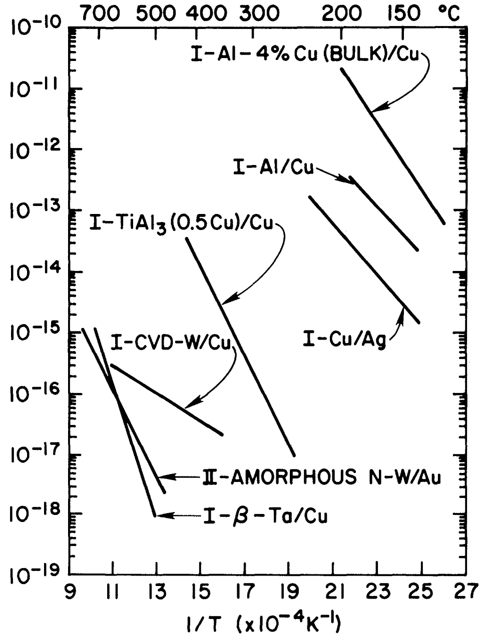

FIG. 3. Arrhenius plots of Au and Cu diffusion in a variety of conducting polycrystalline or amorphous thin films. The large differences in the diffusion coefficients are due to the variable melting temperatures, chemistry, and microstructure of the thin films that may be used as guidance for materials selections for applications such as diffusion barriers. I and II refer to Tables 1 and 2, respectively.

ample, in the Al thin-film interconnects used in VLSI, significant reduction in electromigration damage has been accomplished through additions of 4 wt. % Cu (Ames *et al.* 1970; Rosenberg, 1972). The beneficial effect is attributed to reduction of grain-boundary diffusion through segregation of Cu and formation of an Al-Cu intermetallic compound at the host Al grain boundaries. However, such improvements cannot always be expected as binary alloy systems show all the possible trends, namely enhancement, reduction, and no change of grain-boundary diffusion. In this regard, an empirical correlation between the tendency toward solute segregation and hence grain-boundary diffusion reduction and the shape of the binary phase diagram has been shown to exist (Gupta, 1978). Generally the phase diagrams showing sharp lowering of the liquidus temperature with increasing solute concentration are also prone to solute segregation at the grain boundaries. The data listed in Table 1 seem to substantiate this rule.

2.3.3 Polycrystalline Thin-Film Barriers. The primary purpose of polycrystalline pure metal, alloy, or intermetallic compound films intended for use as diffusion barriers is to block atomic transport in all the possible diffusion paths, namely by vacancies, grain boundaries, and dislocations. Since these processes scale with the melting temperature, the chosen metallization should have a sufficiently high melting point so that even the fastest diffusion process, namely grain-boundary diffusion, is negligible at the device fabrication or performance temperatures. Intuitively, these metals turn out to be transition refractory metals such as Cr, Ni, Ta, Ti, Hf, etc., which also fulfill the above considerations. There are, however, additional requirements for the barrier metals; notably, good adhesion with the adjoining films without excessive stress buildup and, of course, without significant loss of physical properties such as electrical and thermal conductivity. Generally a good compromise can be reached. Pure nickel films are commonly employed in electronic packaging because of inherently low stresses compared to refractory metal thin films. A multilayer low-stress Ti-Cu-Ni-Au thin-film package has been discussed by Morabito *et al.* (1975). Diffusion in pure metal thin-film barriers can be further reduced by incorporating small amounts of solutes to give what have been termed "stuffed barriers" (Kattelus and Nicolet, 1988). As discussed above, in the stuffed barriers the solute tends to segregate at the grain boundaries, thereby blocking the active paths for grain-boundary diffusion.

2.3.4 Sandwich Structures. Howard *et al.* (1978) have investigated Cr, Hf, and Ti intermetallic-compound barriers in Al first-level interconnects to prevent Ohmic and Schottky contact degradation. The Cr, Hf, or Ti metal films of ~1000 Å thickness are deposited as a sandwich with an Al film in between. When heated to 400 °C, CrAl, $HfAl_3$, or $TiAl_3$ compounds are formed depending on the choice of the metal used. These intermetallic-compound barriers are superior to the Cr elemental barrier, and also form structurally coherent electrical contacts without generating excessive stresses. In particular, $HfAl_3$ appears to be an ideal barrier whose effectiveness is not thickness dependent but rather in the fact that diffusion approaches zero. The concept of transition-metal (Cr, Ti, Ta, Hf) intermetallic sandwich structures has been extended to the Al thin-film electromigration problem as well. In the case of 2-μm-wide Al–4% Cu conductors, the Al–intermetallic compound–Al sandwich structures showed improvements of 100-fold in the electromigration lifetimes compared to the Al-Cu system. Again, the $HfAl_3$ and to a lesser extent $TaAl_3$ is the best barrier to prevent electromigration void growth. Diffusion of the radiotracer ^{67}Cu through $TiAl_3$ containing 0.5 wt. % Cu has been recently measured (Vieregge *et al.*, 1992b) and the data are listed in Table 1 and displayed in Fig. 3. The Cu diffusion rates between Al-Cu and $TiAl_3$ (0.5Cu) are seen to differ by a factor of $\sim 10^4$ which directly shows the manner in which transition-metal aluminides are likely to reduce diffusion and improve electromigration lifetimes.

3. DIFFUSION IN AMORPHOUS THIN FILMS

3.1 General Aspects of Diffusion in Amorphous Phases

Amorphous thin films are beginning to receive wider attention for applications in modern technologies because of their unusual properties. Amorphous films, despite their metastable state, have many useful properties below the crystallization temperature. Ionic diffusion in oxide glasses has been studied extensively in the past (Frischat, 1975), and diffusion in organic glasses has also begun to be studied in recent years (Frisch and Stern, 1983). Long-range diffusion in metallic amorphous solids was earlier considered incompatible with the noncrystalline structure due to the onset of crystallization. Measurable amounts of long-range diffusion in amorphous PdSi were first reported by Gupta *et al.* (1975) up to the glass transition temperature without crystallization. Diffusion in metallic amorphous systems has since been investigated extensively in recent years (Mehrer and Dönner, 1989; Kronmüller and Frank, 1989). The thermal energy needed to transform an amorphous structure into a periodic one turns out to be a lot larger than that required for long-range atomic motion of many species.

Because of the absence of periodicity in amorphous phases, it is not possible to have diffusion from defects such as vacancies, grain boundaries, and dislocations in amorphous structure. For diffusion of heavy atoms, the only possible "defect" is the free volume that is generally smaller than vacancy or the atomic volume. Lighter atomic species such as H, however, can diffuse as interstitials. The thermal fluctuation of free volume and the cooperative atomic motion are now considered responsible for diffusion in a disordered structure. Full understanding of the diffusion mechanism, however, is still lacking. In view of the absence of extended defects such as grain boundaries and a single mode of diffusion, amorphous structures are very attractive. Diffusion kinetics in most amorphous phases turn out to lie between those for single crystals and grain boundaries. Hence, attractively small diffusion coefficients can be obtained in some amorphous systems comparable to those in refractory metals for use as diffusion barriers. This may possibly minimize complications due to either high internal stresses or the development of undesirable phases. Amorphous thin films are attractive for VLSI applications as they can be used as dielectrics, Ohmic contacts, and Schottky barriers. Diffusion in these two groups of amorphous films is discussed below.

3.2 Diffusion in Insulating Amorphous Thin Films

The use of glassy or amorphous SiO_2 dielectric films in the microelectronic industry is well known. In recent years, as microelectronic devices have become denser and faster, the need to reduce the dielectric constants in the insulating films has become urgent (Small and Pearson, 1990). Hence other alternatives, both inorganic and organic, are being considered. For example, Si_3N_4, PMDA-ODA (pyromellitic dianhydride-oxydianiline), and BPDA-PDA (biphenyldianhydride-paraphenyldianiline) are being investigated, which also have amorphous structures. Polyimide films, in addition to having smaller dielectric constants, also offer the advantages of ease of fabrication and planarization by spinning and curing. Since the dielectric films always have buried conductors, there is a possibility of metallic dissolution and diffusion. Both processes can be detrimental to the device performance since dissolution would decrease the conductivity and diffusion would impair the dielectric constant leading to shorts if the

Table 2. Diffusion data in amorphous thin films.

Matrix	Diffusant	D_a^0 ($\mathrm{cm^2\,s^{-1}}$)	Q_a (eV)	Remarks (film/foil)
		Insulating amorphous films		
4% PSG	^{67}Cu	4.0×10^{-11}	0.50	Films[a]
PMDA-ODA	^{67}Cu	4.8×10^{-11}	0.42	Films[a]
BPDA-PDA	^{67}Cu	3.4×10^{-10}	0.58	Films[a]
		Conducting amorphous films		
N-W	^{195}Au	5.8×10^{-5}	2.02	18–38 at. % N films[b]
Pd-Si	^{195}Au	—	1.90	20 at. % Si films[c]
Pd-Si	^{110}Ag	2×10^{-6}	1.3	19 at. % Si unrelaxed foils[d]
$PdCu_6Si_{16.5}$	Au	1.5×10^{-4}	1.67	Relaxed films[e]
Gd-Co	^{57}Co	10^{-7}	1.2	16 at. % Gd films[c]

distance of line separation is comparable to the diffusion length.

It has been possible to measure diffusion of ^{67}Cu and ^{110}Ag radiotracers in 4 wt % phosphosilicate glass (PSG), PMDA-ODA, and BPDA-PDA dielectric films (Faupel *et al.*, 1989; Faupel *et al.*, 1990; Vieregge and Gupta, 1992b). The measured diffusion coefficients are listed in Table 2. Sizable diffusion of both Ag and Cu is seen to take place. Although the Cu solubility in the dielectric films has not yet been measured, the Cu concentration in the diffusion profiles does indicate that the polyimide films may dissolve an order of magnitude more Cu in comparison to the PSG films. Furthermore, diffusion in the BPDA-PDA and PSG films is comparable, while in the PMDA-ODA films it is substantially larger.

3.3 Diffusion in Conducting Amorphous Films

As mentioned above, amorphous structures are free from extended defects such as grain boundaries and dislocations and hence are attractive as diffusion barriers in Ohmic contacts as well as Schottky barriers. The current status of this class of barriers in semiconductor contacts has been recently reviewed by Kattelus and Nicolet (1988). Amorphous films are deposited by any one of the familiar thin-film techniques, such as electron-gun coevaporation, sputtering, and CVD where vapor quenching is possible. In cases where vapor quenching is not possible, amorphization by ion beam or laser glazing may provide an alternative approach. Recent investigations of solid-state amorphization by gentle annealing of interlaced ultrathin transition-metal films with amorphous Si layers (Herd *et al.*, 1983; Anderson *et al.*, 1983) have added another dimension to this technology. The list of the amorphous films used on semiconductor contacts contains both metal-metal and metal-metalloid systems. The metal-metal systems are typified by the refractory-metal–based alloys, namely $Nb_{53}Ni_{47}$, $W_{35}Zr_{65}$, $Ir_{58}Ta_{42}$, etc. The typical metal-metalloid systems include $N_{21}Ni_{30}W_{49}$, $N_{23}W_{77}$, $Si_{10}W_{90}$, $Si_{10}W_{80}$, etc. These barriers are generally used in thicknesses of ~1000 Å on Si or GaAs substrates against migration of Al and Au conductors.

Because the use of amorphous conducting films in VLSI is rather recent, diffusion measurements of the conductor-metal species are sparse. Most diffusion investigations are in the melt-spun ribbon specimens that have been reviewed by Mehrer and Dönner (1989) and Kronmüller and Frank (1989). Direct diffusion measurements of ^{95}Au radiotracer in amorphous N-W thin films have been carried out by Dörner *et al.* (1991) to elucidate its possible use as a diffusion barrier. The data are listed in Table 2 along with the earlier results of Au and Co radiotracer diffusion in amorphous PdSi and GdCo films by Gupta *et al.* (1975). The Au diffusion data in the N-W thin films are also plotted in Fig. 3. It is seen that they compare favorably with Cu diffusion in β-Ta (Vieregge *et al.*, 1992a), which is considered to be the best diffusion barrier.

4. SUMMARY

In this article diffusion in polycrystalline, epitaxial, and amorphous thin films has been reviewed in conducting and insulating systems. Diffusion in polycrystalline thin films is controlled by their microstructure, and involves fast atomic transport along grain boundaries, and to a lesser extent along dislocations, whereas lattice diffusion due to vacancies within the grains is vanishingly small. Based on the understanding gained of the diffusion processes, it is now possible to provide guidelines for modification and reduction of diffusion in thin films. These involve solute additions that tend to segregate and precipitate at the grain boundaries. In some cases, structure refinement by producing epitaxial and textured films may be possible. An alternative approach is the interposition of thin-film diffusion barriers for which the rules for material selection are discussed. Diffusion data in a large number of polycrystalline metallic systems are compiled in Table 1. Diffusion in several amorphous conducting and dielectric thin-film systems is examined for the first time and the available diffusion data are listed in Table 2. Despite the progress in production of amorphous thin films by many novel techniques, their applications remain largely unexplored with respect to use as diffusion barriers and contacts of various sorts. Direct diffusion measurements in this class of material are much needed to aid in their evaluation for such applications.

ACKNOWLEDGMENT

The author is grateful to Dr. B. S. Berry for valuable suggestions on the manuscript before publication.

GLOSSARY

Activation Energy: Thermal energy needed to accomplish a kinetic process.

Amorphization: A process of producing amorphous structure.

Arrhenius Relationship: A linear semilog plot of a kinetic parameter versus reciprocal of the absolute temperature.

Bamboo Structure: One-dimensional structure where grain boundaries are arranged perpendicular to its length.

Diffusion Barrier: A thin film of metal or an alloy interposed between two conducting films to prevent interdiffusion.

Diffusion Profile: A plot of concentration of the diffusing material versus depth in the specimen.

Electromigration: Diffusion under an electrical field.

Epitaxial Film: A film deposited on a single-crystalline substrate with its orientation related to that of the substrate.

Extended Defects: Defects in solids other than point defects, such as dislocations and grain boundaries.

Intermetallic Compound: A phase formed by two or more metals in specified proportions.

Laser Glazing: Heating of a thin film by a laser with the objective of melting at the surface only to produce an amorphous structure.

Melt Spinning: Quenching of a liquid on a spinning drum to produce amorphous ribbons.

Microelectronic Devices: Microscopic electronic devices consisting of wires, transistors, and resistors.

Ohmic Contact: An electrical contact on a transistor in a Si chip that follows Ohm's law.

Personalization of Si Chip: A scheme of wiring transistors in a Si chip to produce microelectronic devices.

Preexponential Factor: A temperature-independent factor in the Arrhenius relationship.

Preferred Orientation: Grain structure where a certain crystallographic axis is aligned preferentially.

Refractory Metals: Metals having very high melting temperature, in excess of 2500 K.

Sandwich Structure: A scheme in which a film is formed between two films to obtain a specific property.

Schottky Barrier: A *p-n* junction formed with a semiconducting film to prevent electrical and thermal transients.

Solute Segregation: Segregation of impurities at surface of a specimen or at grain boundaries.

Stuffed Barriers: Diffusion barriers containing impurities that segregate at the grain boundaries and prevent diffusion.

Thermomigration: Diffusion under a temperature gradient.

Thin-Film Package: A scheme in which several films are formed to achieve specific objectives.

Vapor Quenching: A method of vapor deposition of amorphous films onto cold substrates.

INTRODUCTION

Disperse systems are quite common in nature and in various industries. Examples are aerosols, cement, dyestuffs, emulsions, foams, ink, paint, alloys, paste, paper, plastics, rubber, soil, and dust. Examples of colloidal processes include grinding, fuel carburetion, ion exchange, lubrication, food processing, and pharmaceutical and cosmetic preparation.

Simple disperse systems are two-phase systems, composed of a dispersed phase (small particles or the like), and a continuous dispersion medium. The particles may also be called colloids. The International Union of Pure and Applied Chemistry defines a colloid as any material with at least one of its three dimensions in the range of a nanometer (nm) to a micrometer (μm).

Before the turn of this century, the study of disperse systems did not appear to be more than a descriptive subject. The turning point was the demonstration, made by Sientopf and Zsigmondy in 1903, that particles of certain gold sols were definitely revealed in the ultramicroscope.

In 1923, Svedberg invented an ultracentrifuge for finding particle sizes and molecular weights. Langmuir's concept of adsorption, Einstein's clarification of diffusion of particles in medium, and the ideas of dispersion forces and electric double layers, etc., all contributed to the quantitative understanding of colloids.

The recent development of laser and computer technologies has promoted dynamic methods of investigation for these systems,

covering a wide particle-size range, dynamic behavior, and the commercial development of various user-friendly devices for monitoring sizes in industry, as well as improved resolution.

In this article, discussion starts with examples of disperse systems. In addition to classical methods of size determination, a new, powerful approach of dynamic light scattering (photon correlation spectroscopy) is discussed. Subsequent sections deal with various important physical properties of emulsions, foams, sols, gels, and aerosols. We note that aerosols are discussed in more detail in a separate article (see AEROSOLS). In the present article, we have omitted detailed experimental procedures and some important topics, such as biological and environmental suspensions.

1. TYPICAL DISPERSE SYSTEMS

1.1 Classification of Two-Phase Disperse Systems

The main two-phase colloidal dispersions are listed in Table 1.

1.2 Importance of the Surface for Small Particles

A characteristic feature of colloidal dispersions is the large ratio of surface area to volume for the particles involved. As a result, the surface energy is relatively large compared to that of the bulk, making the two-phase disperse system thermodynamically unstable with respect to separation into two bulk phases.

If the dispersion medium wets the particle, the colloid is called lyophilic (solvent loving) and behaves like a solute in solvent; otherwise the colloid is called lyophobic (solvent fearing). Lyophobic colloids may form an unstable disperse system. For instance, oil and water can be vigorously mixed to form a nontransparent, heterogeneous mass; but, on standing, the mixture will separate into two clear, homogeneous layers.

There are surface-active substances that can change a lyophilic to a lyophobic interface or vice versa. Such molecules are called surfactants. An example is a soap. Soap molecules have two active parts: the hydrophilic (water-loving) part, which is an ionic group with a strong electrostatic attraction to water molecules, and another part (hydrocarbon), which is hydrophobic (water fearing) but is lyophilic and wets oil. Thus, if soap molecules cover the surface of an oil drop in water, the hydrophobic colloidal system becomes a hydrophilic colloidal system. If colloidal particles are solvated, then the solvent, immobilized at the surface, must be treated as a part of the particle.

2. DETERMINATION OF PARTICLE SIZES

2.1 Microscopy, Chromatography, and Sedimentation

The particle size is often defined by the radius. However, there are other ways to represent the particle size, such as molecular weight and particle mass. We must note that particles are in general nonspherical, that the definition of size is sometimes conventional,

Table 1. Examples of two-phase systems

Dispersed phase/ medium	Name	Examples
Liquid/gas	Liquid aerosol	Fog, liquid spray, mist
Solid/gas	Solid aerosol	Smoke, dust
Gas/liquid	Foam	Soap foam
Liquid/liquid	Emulsion	Milk, mayonnaise
Solid/liquid	Sol, suspension	Au sol, paste, gel
Gas/solid	Solid foam	Expanded polystyrene
Liquid/solid	Solid emulsion	Opal, pearl
Solid/solid	Solid suspension	Alloy, pigmented plastics

and that the word "molecule" is used here loosely, implying sometimes an aggregate of molecules. A few examples are given in the following.

Optical and electron microscopes are useful for determining geometrical sizes and shapes of particles and the size distribution. Because of diffraction, however, optical microscopes cannot be used for particles smaller than about 1 μm. Thus an electron microscope (transmission or scanning) is important for particle imaging, provided particles have a small vapor pressure and can be put in vacuum without changing their characteristics. In some cases, a colloidal suspension may be freeze-fractured and a surface replica is then used for observation.

Lyophilic colloids form a stable solution, and so one of the methods available for the size determination is chromatography (Yau *et al.*, 1979). When a solution is injected into a stream of liquid flowing through a column packed with small solid spheres, the particles separate according to size, with the largest particles eluting first. The size is calibrated with a colloidal solute of known molecular weight, or measured optically. Thus, some colloids are characterized by molecular weight, which can be easily converted to their geometrical sizes if the density is known. Chromatography provides a rapid method for fractionating polydisperse systems and is capable of size separation of particles between 20 nm and 1 μm (see CHROMATOGRAPHY).

Sedimentation is another useful method for determining molecular weights, but the densities, ρ_1 and ρ_2, of the dispersion medium and colloidal particles, respectively, must differ. In a steady state, the force **F** of buoyancy acting on the particle under gravity or in a centrifugal field is given by

$$\mathbf{F}=V(\rho_2-\rho_1)\mathbf{a}. \qquad (1)$$

This force is balanced by the frictional force against the particle moving in the medium if particles are electrically neutral. Here V is the volume and **a** is the acceleration of the particle. If the experiment is made under the force of gravity, **a** is the gravitational acceleration. When a centrifuge is used with an angular velocity ω, the magnitude a of **a** is ω^2R for a particle at a distance R from the axis of rotation.

The frictional force is proportional to the velocity **v**. The proportionality constant is usually assumed to obey Stokes's law,

$$f=6\pi\eta r_0, \qquad (2)$$

where η is the viscosity of the medium and r_0 is the radius of the particle. If Eq. (2) is assumed for nonspherical particles, then r_0 is called an equivalent radius.

Equation (2) must be modified for aerosols. When a small particle moves in a gas, its collision with gas molecules is intermittent and discontinuous, and the value of the frictional proportionality constant f is reduced (Vold and Vold, 1983). Historically, this effect was first noted in the rate of fall of the colloidal drops in the famous Millikan experiment on the electronic charge.

Because of this friction, a particle under force **F** almost instantaneously reaches a terminal speed v. Since the mass of the particle $m = \rho_2V$, we can then write

$$m(\rho_2-\rho_1)a=\rho_2fv. \qquad (3)$$

This equation still holds for aerosols if the corrected f is used.

The speed v in Eq. (3) may be measured by using a laser Doppler velocimeter or anemometer to estimate the mass m. Alternatively, the speed may be measured under an ultramicroscope with a timer.

Gravity sedimentation is not feasible for particles below a few micrometers, because of disturbances of Brownian motion and thermal gradient. It is easy to overcome this difficulty by using a centrifuge, since the acceleration can be easily increased by a factor of 10^5. From Eq. (3), since $a = \omega^2R$ and $v = dR/dt$, the time for the particle to travel radially from R_0 to R is given by

$$t=\frac{f\ \ln(R/R_0)}{m(1-\rho_1/\rho_2)\omega^2}. \qquad (4)$$

The symbol ln stands for the natural logarithm. The equation may be used to obtain the value of m, provided the effect of diffusion is small.

Experimentally, a suspension is injected at R_0 into a centrifuge while it is spinning with the medium. Assuming that the dispersed particles instantly attain the terminal velocity, the time t is then measured by optically detecting them at $R > R_0$. Thus the rotor is usually made transparent.

In some cases, the frictional coefficient f is not known. Then the method of sedimentation equilibrium may be useful. With a centrifuge, before equilibrium sets in, the particles move outward and build up a radially outward gradient of the particle concentration. The gradient, on the other hand, causes inward diffusion of particles. When equilibrium sets in between them, the particle concentration is constant in time and is given by

$$\ln\frac{c_2}{c_1}=\frac{m}{2k_BT}\left(1-\frac{\rho_1}{\rho_2}\right)\omega^2(R_2^2-R_1^2), \tag{5}$$

where c_i is the concentration at R_i $(i=1,2)$. The symbols k_B and T are respectively Boltzmann's constant and the absolute temperature. The concentration can be measured by attenuation of transmitted light. For this purpose, a transparent, hollow, plastic disk is conveniently used as a rotor.

Recently, sedimentation field-flow fractionation techniques have been developed for high-resolution studies (Caldwell, 1984). They combine the technique of flow separation used in hydrodynamic chromatography with the technique of size separation in centrifugation.

2.2 Light Scattering

There are many other methods applicable for size observation (Provder, 1987; Barth, 1984; Ross and Morrison, 1988). One of them employs scattering of light by colloidal particles and is useful for emulsions, aerosols, air pollution, and microbiological research, sensing the onset of precipitation or nucleation, etc. If particles do not absorb incident light, but have refractive indices distinct from the medium, they scatter incident light into various directions and accordingly reduce the transmitted intensity. The time-averaged attenuation obeys the exponential law

$$I(x)=I_0\exp(-\tau x), \tag{6}$$

where the x axis is in the direction of the incident light and I_0 is the intensity of light at $x=0$. In the exponent, τ is called the turbidity or attenuation.

An exact expression for τ can be derived from a general theory of light scattering. It is not simple, but its limiting cases of Rayleigh scattering and diffraction are easy to handle. The limiting cases can be classified in terms of the particle size r_0 and the wavelength λ of the light as

$r_0<\lambda/20$, Rayleigh scattering;

$r_0>2\lambda$, diffraction theory.

Rayleigh scattering has been widely applied to liquid and solid aerosols in the atmosphere. Brownian motion of the particles causes the particle concentration to fluctuate locally in time, generating local fluctuations in the index of refraction of the solution. On taking the statistical average, the turbidity is given by (Hiemenz, 1986)

$$\tau=\frac{32\pi^3n_0}{3N_A\lambda_0^4}\left(\frac{dn}{dc}\right)^2\frac{1}{(1/cm)+2B'} \tag{7}$$

where c, m, and B are, respectively, the concentration, the mass of solute particle, and the second virial coefficient of the osmotic pressure of the solution. N_A is Avogadro's number, n_0 is the refractive index of the solvent, n is that of the solution, and λ_0 is the wavelength *in vacuo* ($\lambda_0 = n\lambda$). Equation (7) gives a particle mass irrespective of the shape for small particles. For a polydisperse systems, Eq. (7) provides a weight-averaged mass.

If the particle size increases and is larger than $\lambda/20$, scattering into a certain direction from different points of a single particle is out of phase, causing destructive interference and reduced intensity, but phase differences are small for small scattering angles, causing a greater intensity of scattered light at low angles. The overall effect gives rise to maxima and minima in the scattered intensity depending on the scattering angle, with greatest intensity in the forward direction. This behavior depends on the particle size, and the scattering for sizing of spherical particles can be treated with help of the rigorous Mie theory, which was developed in 1809 (Garcia-Rubio, 1987). With the advent of high-speed computers, the treatment has advanced rapidly. Later Kerker (1969) extended the theory to include cylinders and stratified spheres. These theories must be used whenever the particle size is large.

However, if the particle size is larger than about 2λ, the light scattered with large angles becomes very weak because of destructive interference and only the forward scattering is pronounced. This type of scattering is customarily called diffraction.

For this diffraction regime ($r_0 > 2\lambda$), a method has been described by Weiner (1984) to cover observations of spherical particles larger than 1 μm. Since the diffraction pattern spreads more for smaller particles but is narrower in the forward direction for larger particles, the intensity distribution in the diffraction pattern can be used to measure particle sizes in either monodisperse or polydisperse systems.

2.3 Frequency Broadening and Photon Correlation in Light Scattering

Another technique, which has recently attracted widespread attention, is to use temporal fluctuations of scattered intensity by particles in Brownian motion directly (Pecora, 1985). It has also been applied to measurements of interfacial tension (Wielebinski and Findenegg, 1988).

If particles are spherical, the electric field of the light scattered by them behaves, at the detector, as

$$E(t)=E_0 \sum_j \exp\left(i \int_0^t \mathbf{q}\cdot\mathbf{v}_j(t)dt - i\omega t\right), \quad (8)$$

where $i = (-1)^{1/2}$ and $\mathbf{v}_j(t)$ is the velocity of the jth particle at time t. The vector $\mathbf{q}$ is the scattering vector, $\mathbf{q} = \mathbf{k}_0 - \mathbf{k}$, where $\mathbf{k}_0$ and $\mathbf{k}$ are wave vectors of incident and scattered light. In Eq. (8), $\mathbf{v}_j$ is constantly changing in time for all j, because particles are undergoing thermal motion and colliding both with molecules of the medium and with other particles. At a collision, $\mathbf{v}_j$ abruptly changes in its direction and/or magnitude, and so $\mathbf{q}\cdot\mathbf{v}_j$ does also. The phase of the oscillation of the jth term in Eq. (8) accordingly shifts abruptly.

The phase shift at a single collision is sometimes large compared with unity. However, it is usually small, but adds up to unity or even more after many collisions. When a large phase shift occurs or the phase shift accumulates to about unity, the incident long wave train is divided into two incoherent shorter wave trains (Ch'en and Takeo, 1957). If this collisional effect occurs continuously, the scattered light is composed of many wave trains of random length. The shortening of the wave trains results in frequency broadening in the frequency domain, and the unpredictable redistribution of incident photons among the divided wave trains results in a temporally fluctuating scattered intensity.

There is a contribution to the intensity fluctuation from the interference of light scattered by Brownian particles. But it is small if they are randomly distributed or the solution is dilute.

The intensity of light $I(t)$ at the detector is the squared absolute value of Eq. (8). Its fluctuation is handled statistically in terms of the autocorrelation function,

$$G(\tau) = \lim_{T\to\infty} \frac{1}{2T} \int_{-T}^{T} I(t)I(t+\tau)dt. \quad (9)$$

For a monodisperse system, we have

$$G(\tau) = e^{-2Dq^2\tau}, \quad (10)$$

where the normalization is so chosen that the coefficient is unity. D is the diffusion coefficient, given, for a sphere, by

$$D = k_B T/6\pi\eta r_0, \quad (11)$$

and q is the magnitude of the scattering vector $\mathbf{q}$, given by

$$q = \frac{4\pi}{\lambda} \sin\frac{\theta}{2}, \quad (12)$$

where θ is the scattering angle. Since molecules of the medium also scatter the incident light with no correlation, the autocorrelation function contains an additional constant term. Interactions among particles affect the fluctuation of the scattered intensity, so that the interactions can be observed by this method (Pusey and Tough, 1985).

For a polydisperse system,

$$G(\tau) = \int_0^\infty F(\Gamma)e^{-\Gamma\tau}d\Gamma, \quad \Gamma = 2Dq^2, \quad (13)$$

where $F(\Gamma)$ is the normalized distribution function of the particle size parameter Γ. Thus, the autocorrelation function is a Laplace transform of the distribution function.

Experimentally, the intensity fluctuation is measured by counting the number of photons arriving at the detector per unit time. Then Eq. (9) is used to calculate the autocorrelation function on a computer. The result is compared with either Eq. (10) or Eq. (13). We note that, if Eq. (13) is expanded into a power series in τ, the coefficients are the moments of the size distribution function. However, since particles that strongly scatter light contribute more to the observed intensity, the distribution function obtained from the experimental $G(\tau)$ is intensity-weighted. Mie theory may be used to correct the effect, since it gives the scattered intensity as a function of the particle size.

Instead of intensity fluctuation, collisional frequency broadening may be observed by using a spectrometer or an interferometer. In the observed power spectrum, the full width at the half height of the peak intensity is $2Dq^2$ for monodisperse systems of spherical particles. Then Eq. (11) gives r_0.

We note that the power spectrum is the Fourier transform of the autocorrelation function of the fluctuating electric field of the scattered light, instead of the fluctuating light intensity.

If a particle is anisotropic, the particle rotation due to collisions is important, since it causes reorientations of the polarizability tensor and depolarization of the scattered light. The effect is also an intensity fluctuation in the time domain and a frequency broadening in the frequency domain (Pecora, 1985).

Microscopic observations of Brownian motion of the particles reveal an ever-increasing irregularity with reduction of the time interval of observation. A Brownian pathway obtained by joining, with straight lines, successive positions of a particle marked at a given time interval forms a random zig-zagged pattern. Although the scale of the time interval changes, the general feature of the pattern remains the same. This suggests a fractal behavior (see FRACTAL GEOMETRY). In fact, the concept of a fractal dimension has proved to be useful in studying colloids (Zrinyi *et al.*, 1988).

3. EMULSIONS

3.1 Coarse Emulsions and Microemulsions

An emulsion is a disperse system in which the phases are immiscible or partially miscible liquids. The dispersed particles are usually between 0.1 and 10 μm in diameter. If they are between 0.01 and 0.1 μm, the systems are called microemulsions. There is a visual distinction: microemulsions are clear and coarse emulsions are cloudy, because of difference in light scattering.

The practical application of emulsions is very active and important in dairy products, pharmaceutical preparations, cosmetics, the petroleum industry, etc. In many cases, oil will be the dispersed phase and water the continuous phase, designated O/W, or water may be dispersed in oil (W/O). An example of an O/W emulsion is milk, and for a W/O emulsion is butter. Compatibility with either oil or water upon dilution is an easy way of identifying which phase is continuous. Another test for emulsion type is the electrical conductivity—O/W emulsions almost always have high conductivity compared to W/O emulsions.

3.2 Stability of Coarse Emulsions and Microemulsions

The most important physical property of an emulsion is its stability. The state of emulsions can change in various ways; for example, an emulsion may change its type from W/O to O/W or vice versa (inversion). It may also separate into its two constituent phases by coalescence (breaking). Because a density difference may exist between the two phases, the dispersed phase may rise or sink within the medium due to gravity or centrifugation (creaming or settling). The rates of such changes are influenced by various parameters, such as temperature, size distribution of droplets, and the phase volume ratio. Additional factors are described below.

Collisions among droplets, often leading to coalescence, result in emulsion breaking. Consequently, a reduction in collision frequency is effective in promoting stability. This reduction is accomplished by repulsion if droplets are electrically charged with the same sign or by attenuated motion if the viscosity of the medium is high. Droplets covered by mechanically strong and elastic films do not coalesce during collisions.

The free energy (Helmholtz) for the process of coalescence of droplets at constant volume, temperature, and composition is

$$\Delta F=\gamma(A_{\text{final}}-A_{\text{initial}}), \tag{14}$$

where γ is the surface tension and A is the total surface area. Since A in general decreases with coalescence, ΔF is negative, in favor of spontaneous coalescence. For good stability, ΔF must be positive upon coalescence, requiring additional positive terms in Eq. (14).

If an emulsion is prepared by homogenizing two pure liquid components, phase separation (breaking) will usually be rapid. To prepare reasonably stable emulsions, a third component—an emulsifying agent (emulsifier)—is needed in the process of homogenizing. The emulsifier must itself have a negative free energy of adsorption, so that it spontaneously arrives at the interface of droplets. Then if droplets coalesce, A decreases and some of the adsorbed emulsifier is desorbed or removed from the interface at the expense of positive energy, leading to a positive change in ΔF.

Assessment of the stability of an emulsion against coalescence involves droplet counting by means of, say, a microscope or a Coulter counter. In the latter, a dilute solution is made to flow through a small orifice in which electrodes are placed. An electric pulse occurs each time a particle passes between the electrodes. The counting of the pulses gives the particle number, provided there is no "coincidence" (Vold and Vold, 1983). The pulse height depends on the particle size, and if a pulse height discriminator is added, the apparatus can yield a size distribution. However, this technique cannot be used for particles smaller than 0.7 μm.

Although more important in sols, we must note here another mechanism for reducing the particle number density. It is the process called flocculation, aggregation, or coagulation, in which small particles clump together, like a bunch of grapes, due to interaction forces among particles. This phenomenon has been treated, for quantitative discussion of colloidal stability, by the DLVO theory, developed by Deryagin and Landau and by Verwey and Overbeek (and named by their initials), and by improved theories (Tadros and Vincent, 1983). They calculated the energy changes that take place when particles approach one another under mutual interactions between them, and successfully applied the model calculation to the study of stability. Flocculation has been experimentally observed by photon correlation spectroscopy with help of the Mie theory.

Suppose we add a fourth component to an emulsified system. The fourth component is called a coemulsifier, generally an alcohol of short chain length, such as hexanol. Then a transparent and stable microemulsion forms spontaneously in the region where the ratio of components satisfies a certain condition that has been experimentally determined. The coemulsifier, by combining with the emulsifier, achieves a large energy of desorption and a small interfacial tension, which may result in spontaneous formation of smaller droplets. It is also known that certain hydrophobic emulsifiers (nonionic surfactants) may require no coemulsifier for producing microemulsions (Friberg and Venable, 1983). On the other hand, coarse emulsions usually do not form spontaneously. Thus, whether microemulsions should be regarded as true emulsions or as swollen aggregates of surfactant ions (swollen micelles) is a matter of controversy (Hiemenz, 1986). Nevertheless, this technology has opened new applications in countless areas, such as oil recovery from porous rocks and floor waxes.

3.3 Factors Determining Types of Emulsions

In coarse emulsions, what makes W/O or O/W emulsions when two liquids are emulsified? Clearly, the favorable configuration must be that in which the largest amount of emulsifier is accommodated at the interface. In other words (Bancroft's rule), the phase in which the emulsifying agent is more soluble tends to be the continuous dispersion medium. For instance, a water-soluble substance such as sodium oleate emulsifies oil in water. The rule, however, may break down for higher concentrations of the phase that is expected by the rule to form droplets. Emulsifiers are usually soaps or nonionic surfactants.

In addition to surfactants, effective resistance to coalescence of emulsion droplets is conferred by certain finely divided solids. If the solid is preferentially wetted by one phase, then more particles can be found at the interface if that phase forms a continuous medium surrounding drops of the other phase. The moist surfaces of inorganic salts are predominantly hydrophilic and so tend to promote O/W emulsions, while the surfaces of carbon black and resins are predominantly lipophilic and promote W/O emulsions.

It is desirable, in practice, to be able not only to predict the type of an emulsion but also to suggest which surfactant gives maximum stability in emulsification. An attempt at prediction was initiated in 1949 by using Bancroft's rule. This rule assigns a semiempirical scale, called HLB (hydrophile–lipophile balance) numbers, to surfactants. A value of 1 was assigned arbitrarily to oleic acid (predominantly lipophilic) and a value of 20 to sodium oleate (predominantly hydrophilic). The scale (HLB) is constructed for their mixture by

$$\mathrm{HLB}=1\ W_{\text{oleic acid}}+20\ W_{\text{sodium oleate}}, \qquad (15)$$

where W is the weight fraction. This mixture is used as a reference for assigning the HLB number to other emulsifiers by comparing the abilities in forming a W/O or O/W emulsion out of a 50/50 mixture of white oil and water. The HLB numbers have been tabulated (Shinoda and Kunieda, 1983). Those that form W/O emulsions have a low HLB number (3.5–6), and those that form O/W emulsions have a high number (8–18). A good detergent has an HLB number between 13 and 15 and a solubilizer between 15 and 18. The HLB number of a molecule can also be calculated by referring to hydrophilic and lipophilic groups that the molecule carries (Vold and Vold, 1983).

Determination of HLB numbers is usually tedious. But there are various empirical formulas that may be available for nonionic surfactants (Shinoda and Friberg, 1986). One of them is

$$\mathrm{HLB}=20\ W_h/(W_h+W_l), \qquad (16)$$

where W_h and W_l are molecular weights of the hydrophilic and lipophilic moieties of the nonionic surfactant. The HLB number of a nonionic surfactant depends on temperature, although that of an ionic surfactant alone does not change appreciably with temperature around 25 °C.

The HLB concept is fairly satisfactory, but its major disadvantage is that it makes no allowance for temperature, in particular, for ionic surfactants. In fact, an emulsifier can, if nonionic, change at a certain temperature from an O/W to a W/O stabilizer or vice versa. The temperature is called the phase inversion temperature (PIT). The HLB number and the PIT are correlated (Shinoda and Friberg, 1986).

In some practical cases, processes for emulsion instability are desirable. Examples are the creaming, breaking, and inversion of milk to obtain butter and the breaking of W/O oil-field emulsions. Techniques to accelerate breaking include centrifugal separation, freezing, distillation, and filtration. The addition of O/W-promoting emulsifiers may be used to break W/O emulsions, and vice versa.

3.4 Electrical Conductivity of an Emulsion

The electrical conductivity of an emulsion can be used to follow changes in emulsion composition and emulsion type, including inversion. The electrical conductivity of a two-phase system, in which the conductivity of the continuous medium is σ_1 and that of the dispersed phase is σ_2, is given by

$$\sigma=\sigma_1\frac{2\sigma_1+\sigma_2-2(\sigma_1-\sigma_2)V}{2\sigma_1+\sigma_2+(\sigma_1-\sigma_2)V}, \qquad (17)$$

where V is the volume fraction of the dispersed medium. This equation was used to identify experimentally the emulsion inversion as the volume fraction was increased (Manegold, 1952)—an exception to the HLB rule.

4. FOAMS

4.1 Bubble Foams and Concentrated Foams

A foam is a coarse dispersion of gas in liquid (or solid). There are two types: bubble foams and concentrated foams. The former consist of nearly spherical bubbles separated by a bulk liquid, while the latter are mostly polyhedral gas cells partitioned by thin liquid films (exceptions include foam rubber, where the cells are spherical).

4.2 Stability of Foams

Pure liquids do not form stable foams. Thus, certain solutes (foaming agents) are necessary to achieve stability by retarding foam rupture. Good emulsifiers are usually also good foaming agents.

When a large number of spherical bubbles are produced in a medium, a foam is eventually produced, as in a glass of beer. Liquid between the bubbles is drained by gravity, as they rise, and their shapes become polyhedral when in contact through a continuous thin liquid film. In the polyhedron, some portions of the film are flat, where two bubbles meet, and others are curved, where more than two bubbles meet (plateau borders). The pressure of the liquid inside the film is higher at the flat portion than at the curved portion, due to the surface tension. Thus, liquid in the flat portion of the film tends to flow to the curved portion. The flow drags some of the surface layer along with it, so that it locally creates a surface with less foaming agent and hence higher surface tension (Gibbs's effect). The diffusion of a foaming agent is slow if the concentration (gradient) is not high, and then this higher tension promotes a counter flow. Namely, the higher tension exerts a pull on the adjoining areas of lower tension, causing the surface to flow toward the region of higher tension, and the viscous drag of the moving surface carries liquid in the film with it (Marangoni effect). Of course, these effects occur almost simultaneously as complements to each other and thus affect foam stability by opposing the thinning process. However, the film may be ultimately so thinned that its thickness is of molecular-level size, and molecules in the film lose the properties of bulk liquid. It may eventually rupture, or attain an equilibrium thickness, depending on the amount and type of foaming agents and electrolytes. If electric double layers are present at both of the surfaces of the film, the DLVO theory (see Sec. 3.2) predicts the stability of the film. If evaporation occurs, the film is disturbed, affecting the foam stability.

4.3 Antifoamers and Foam Inhibitors

The prevention of foaming and the destruction of existing foams are often matters of practical importance. Antifoamers act against various factors that promote foaming, impairing the ability to foam. For instance, certain substances of low molecular weight may render the surface-active solute more soluble and hence less surface active. Foam inhibitors, on the other hand, totally inhibit the formation of foam. They are always insoluble materials that can spread on the surface of the solution.

A very effective form of antifoam is an emulsion of hydrophobized silica particles in silicone oil, dispersed in water.

5. COLLOIDAL SOLS AND SUSPENSIONS

5.1 Preparation of Colloidal Sols and Suspensions

There are many practically important sols and colloidal suspensions, such as silver halides, oxides and hydrous oxides, clays, carbon black, rubber latex, polystyrene, and paste. In general, the preparation of these systems for any purpose can proceed either by comminution of macroscopic material or by aggregation of smaller molecular units. The mechanical force required to break up crystalline solids into particles of colloidal size is enormous and not practical, unless the solid has glide planes. If rolling mills, ball mills, crushers, ultrasonic irradiation, etc., are not effective, chemical reactions as well as nucleation by vapor condensation may be used to create atomic or molecular aggregation, such as smoke, fume, etc., similar to preparations of aerosols (see Sec. 7.2). The term *sol* is used to distinguish colloidal suspensions from macroscopic suspensions.

5.2 Colloidal Stability, Flocculation, and Ionic Charges

An important cause of colloidal instability is aggregation and flocculation, which is due to dispersion forces, ionic interactions, the overlap of electric double layers, etc. Flocculation has a kinetic analogy with polymerization, which involves, however, covalent bonding. These tendencies are overridden if particles are electrically charged to repel each other to a larger separation. Lyophobic sols are stabilized mainly by electric-double-layer interactions. In hydrophilic sols, if the aqueous medium releases ions from the particles, as in silica, and so confers ionic charges on the surface, then an electric double layer extends into the solution, stabilizing the suspension. A quantitative discussion of these aspects has been successfully developed in terms of the DLVO theory (see Sec. 3.2) (Vold and Vold, 1983).

Usually nonelectrolytes have no effect on sols and suspensions. But when an electrolyte is added, coagulation may be the result. For example, when rivers reach salt water, deltas tend to be formed. For each electrolyte there is a threshold concentration that depends strongly on the charge number of the colloid and has to be exceeded for noticeable coagulation. The DLVO theory provides the theoretical rationale. Here, particular ions are effective, especially those of highest valency and of opposite charge from the colloidal particles. Among monovalent ions, the hydrogen ion and those of high molecular weight, such as alkaloids and dyes, are especially effective (McBain, 1950).

5.3 Zeta Potential

The physical properties of colloidal dispersions in electrolytes depend on the ionic charge on the particles. The amount of electric charge can be best determined by means of measurement of the zeta potential by electrophoresis (Hunter, 1981). When a charged particle is made to move in the electrolyte medium, the ion atmosphere around it is disturbed. Remote ions are left behind, and ions adjacent to its surface are dragged along with it. The concept of a shear plane has arisen, which is a dividing surface, in the mathematical sense, and separates the kinetic unit (colloidal particle plus those ions that move with it) from the medium. The potential due to the ionic charge at this surface is called the zeta potential. The zeta potential by itself is useful to predict the resistance to flocculation by electrolytes.

In solution electrophoresis, let us denote by v the speed of a charged particle moving in an external electric field E. Then the zeta potential is given by

$$\zeta=\eta v/\epsilon DEf\,, \tag{18}$$

where η and ϵ are respectively the viscosity and the dielectric constant of the bulk solution. The parameter f varies between 0.65 and 1.5, depending on the particle size and the ionic strength. Several commercial instruments are available for measurements of the zeta potential (Hiemenz, 1986).

6. GELS

6.1 Structure of Gels

Colloidal particles in sols are very often solvated to a thickness of about one molecule. Sometimes much greater amounts of solvent can be entrapped within particle aggregates or flocculent precipitates. In solutions of long threadlike molecules the polymer chains may cross-link and become mechanically entangled to such an extent that a continuous network is formed. If all of the solvent is trapped within this network, the system as a whole takes on a solid appearance and is called a gel. The solvent within the structure may be immobilized. Jellies are considered as one type of gel and have similar structures. In these, the units of the aggregates are primarily spherical or linear, but these are sufficiently linked so that the whole liquid is enmeshed into a loose framework. Thus, in gels or jellies both the solid and the fluid components are in a highly dispersed state. The entrapped water or ions behave in nearly the same way as in bulk water (Alexander and Johnson, 1949).

In order to form a three-dimensional structure, at least some particles must be joined to three or more others. Heat-reversible gels have junction points that are destroyed on heating and reformed on cooling. Cooling a sol produces eventual gelation at a temperature that seems to be reproducible. Once gelation has occurred, the gel can be maintained at higher temperatures up to some limit. This hysteresis permits holding the systems as either sol or gel within ranges of temperature characteristic of the material and depending also on its concentration and on the presence of other substances.

In some gels, the junction points are permanent. Such gels will come to an equilibrium volume when immersed in a given solvent. Of course, the junction points can move around in thermal motion. If the gels are placed in a suitable solvent, the amount of liquid absorbed can be very large. This is swelling. The theory of swelling can be developed by calculating the chemical potential of the solvent in the gel (Vold and Vold, 1983).

6.2 Applications of Gels

There are wide applications of gel states. It is necessary to maintain agricultural soil in a gel state in order to achieve good aeration and drainage. Treatment with coagulants is common practice. In oil-well drilling, removing the cuttings and sealing the bore wall are made effective if a drilling mud (a bentonite clay suspension) is converted to a gel by a peptizing agent, such as a polyphosphate. A paint should be designed to brush easily and yet not flow on a vertical surface; this is achieved by making the paint thixotropic.

Some gels behave like ultrafilter membranes of very large pore sizes of 100 Å or as large as 8000 Å (cellulose membranes). One application is gel permeation chromatography, which is of great value in biochemical and medical research.

7. AEROSOLS

See AEROSOLS for more details.

7.1 Nature and Characteristics of Aerosols

Liquid or solid colloidal dispersion in a gas, such as dust, fumes, smoke, fog, mist, and clouds, has enormous practical importance. The behavior is quite different from sols, suspensions, and emulsions. The reasons are that the gaseous medium is not as dense as a solvent so that the dispersed particles in aerosols collide easily with each other, and that the stability of the system cannot be readily modified by adding any agent to the gaseous medium. Thus aerosols are always unstable and tend to aggregate and precipitate, unless particles are protected by certain films against aggregation. If particles are volatile, they may disappear by evaporation, depending on temperature.

7.2 Preparation of Aerosols

Dust, fog, clouds, etc. have natural sources. However, the chief methods of preparing aerosols may utilize nucleation or dispersion processes.

Highly supersaturated vapor tends to condense to form large clusters, and if these are larger than a critical size, they grow spontaneously and form droplets. Classical nucleation theory treats the condensation and successfully predicts the nucleation rate (Zettlemoyer, 1969). If ions are present, stable condensation occurs around them at a lower supersaturation value than it would without them. If a liquid droplet forms by condensation on a solid surface with a certain contact angle, which determines the critical size, it grows also at a lower supersaturation value.

Dispersion processes include fuel injection, spray painting, and air humidifiers. Aerosols can also be made by using a nebulizer on solutions of the material in a volatile solvent such as a Freon or a hydrosol. Mechanical disintegration of liquid jets and high-voltage disruption of liquid droplets at the tip of a capillary are also useful.

GLOSSARY

Aggregate: A group of particles joined at their surfaces, with a specific surface area significantly less than the sum of the areas of their constituents.

Coagulation: Joining of primary particles at their faces, making the resulting total surfaces much smaller than the total surface area of their constituents.

Coalescence: The merging of small drops or bubbles into a single large drop or bubble.

Colloidal Particle: Usually a submicrometer particle, but defined academically as any material with at least one of its three dimensions between 10^{-9} and 10^{-6} m.

Dispersion: A finely divided solid, liquid, or gas in a medium.

Dispersion Forces: A long-range, usually attractive force between molecules or particles.

Electric Double Layer: Two parallel sheets of oppositely charged layers, formed by an ionic surface (layer) in contact with an electrolyte. Oppositely charged ions in the electrolyte are attracted to the surface, forming a diffuse layer of opposite charge, very close to the surface.

Electrophoresis: Electrokinetic effect resulting from migration of ions and charged particles relative to the medium, under the influence of an electric field.

Emulsion: A dispersion of an immiscible liquid in another.

Floc: A loose structure formed of primary particles, aggregates.

Flocculate: To create flocs by adding a chemical agent or by changing physical conditions.

Foam: A coarse dispersion of gas in a liquid.

Gel: A sol with strong viscoelastic properties.

Hydrophile: A hydrogen-bonding moiety.

Inversion: The process of reversing the continuous and discontinuous phases of an emulsion.

Lamella: An extended sheet of liquid.

Lipophile: A non-hydrogen-bonding moiety.

Lyophilic: Having an affinity for the medium.

Lyophobic: Lacking affinity for the medium.

Micelle: An organized aggregate of surfactant ions in which the lipophilic hydrocarbon chains are oriented towards the interior of the aggregate, leaving the hydrophilic groups in contact with the aqueous medium, or with reversed orientation of surfactant as well as medium.

Microemulsion: A thermodynamically stable, transparent solution of droplets of sizes between 0.01 and 0.1 μm.

Monodisperse: Dispersed with particles of identical size.

Number Density: Number of particles per unit volume.

Particle Texture: Particle surface characteristics and microstructure.

Peptize: To deflocculate, to disperse, to change a sol to a gel.

Plateau Border: The thin vein of liquid at the intersection of three liquid lamellae.

Polydisperse: Dispersed with particles of various sizes.

Sol: A transparent colloidal suspension.

Solvate: To immobilize solvent by mechanical entrapment at a particle surface or within particle aggregates.

Surfactant: A surface-active agent.

Suspension: Finely divided solid in a liquid medium.

Thixotropy: The time dependence of reforming an internal structure after its dispersion by shear.

Turbidity: The attenuation of transmitted light by scattering.

Ultramicroscope: An instrument to detect light scattered by ultramicroscopic objects when they are lit from the side and against a dark background.

Wet: A liquid wets a solid when it has a contact angle of 0° or less than 90°.

INTRODUCTION

The Earth's deep interior is largely inaccessible (the deepest hole at Kola peninsula in Russia is ~12 km, only ~0.2% of the Earth's radius), and consequently most of our understanding is based on indirect inferences. These include the average chemical composition of the solar system, the chemical composition of rocks near the Earth's surface, geophysical observations of the Earth's density and of seismic wave-velocity distribution, and laboratory studies of the state and properties of materials at high pressures and temperatures. Recent progress has also been made to increase the resolution in inversion of the Earth's structure through seismic tomography and developments in high-pressure and high-temperature experimental studies.

Section 1 of this article discusses the gross Earth structure, i.e., the major constituent materials of the crust, mantle, and core. Section 2 discusses the Earth's temperature distribution, which is determined by the heat

digital Encyclopedia of Applied Physics

generation and heat transfer processes. The temperature distribution determines the Earth's rheological stratification and has a significant effect on dynamics (see Sec. 4). Section 3 summarizes experimental observations on the melting of silicates. Finally, Sec. 4 gives a brief summary of rheological properties of rocks and the dynamics of the Earth's interior.

1. EARTH'S GROSS STRUCTURE

1.1 Geophysical and Geochemical Observations

1.1.1 Seismology and the Earth's Interior (see also SEISMOLOGY). Table 1 summarizes some of the important parameters of the Earth. Note that the Earth's average density, 5.52×10^3 kg/m^3, is significantly higher than the densities of rocks found on the Earth's surface [$(2.7\text{–}3.4)\times10^3$ kg/m^3]. Another observation is that the ratio $C/MR^2=0.331$ (C, moment of inertia; M, mass; R, radius) is significantly smaller than the theoretical value for a homogeneous body (0.40). These observations show that the density of the Earth must increase significantly with depth. This density increase is due to two factors: the existence of a dense iron-rich core and the increase in density due to hydrostatic compression within the Earth.

The most detailed information on the variation of physical properties or composition of the Earth with depth comes from seismological observations of elastic-wave propagation in the Earth. Various types of elastic waves are used to probe the Earth, including body waves, surface waves, and the free oscillation of the Earth.

The vibrations of the Earth due to natural earthquakes or artificial explosions are recorded on seismograms. Seismic waves recorded at a long distance from the focal point of an earthquake pass through deeper portions of the Earth's interior than waves recorded at a nearby station. Similarly, the surface waves and the free oscillation of the Earth with a longer period reflect the properties of deeper portions of the Earth than those with a shorter period. Thus using the seismograms at different stations, or the surface-wave or free-oscillation records with different periods, one can estimate the depth variation of elastic properties and density. The information used includes the travel times of body waves, the frequency dependence of surface-wave velocities, and the frequencies of various modes of free oscillation.

In an isotropic elastic body, there are two different modes of elastic waves: compressional and shear waves. The velocities of these waves (V_P, velocity of compressional wave; V_S, velocity of shear wave) are related to the physical properties by

$$V_P=\sqrt{(K+\tfrac{4}{3}\mu)/\rho} \qquad (1)$$

and

$$V_S=\sqrt{\mu/\rho}, \qquad (2)$$

respectively, where K is incompressibility, μ is rigidity, and ρ is density. These relations are exact only for an isotropic material, but will be sufficient for the purpose of the present section. However, when the fine details of seismic wave propagation are used to discuss the dynamics of the Earth's interior, the consideration of anisotropy becomes important (see Sec. 4.3.2).

An Earth model (depth variation of seismic wave velocities and densities) based on seismological data is shown in Fig. 1. This model (called PREM, for preliminary reference earth model; see Anderson, 1989) incorporates such details as the frequency dependence of seismic-wave velocities and attenuation but neglects the lateral variation and the azimuthal anisotropy (variation of seismic-wave velocities with the orientation of wave propagation; see Sec. 4.3.2). The gross Earth structure discussed in Sec. 1 is mainly based on the laterally averaged model (except for the crust).

Such an Earth model indicates that the Earth's interior is divided into three layers; the crust, the mantle, and the core. Once an Earth model is obtained, one can infer the internal constitution of the Earth by comparing the model with laboratory data on density

Table 1. Earth parameters.

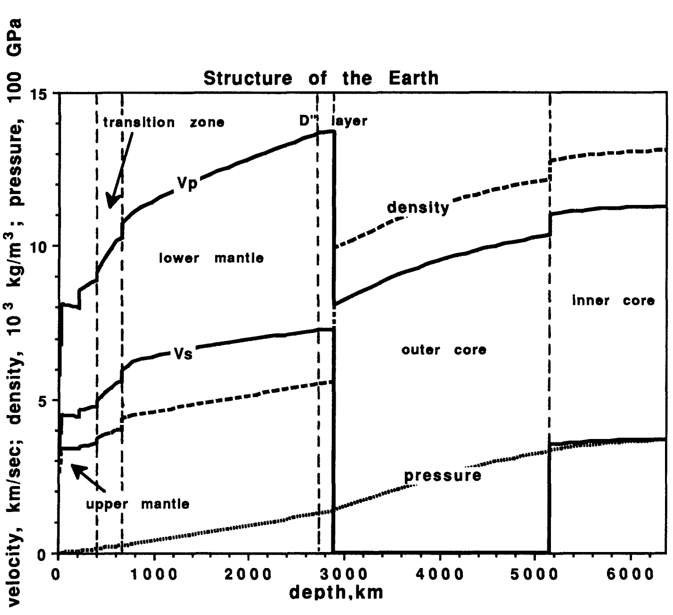

FIG. 1. The depth variation of the average seismic-wave velocities, densities, and pressure according to the PREM model.

and elastic properties with the help of physics of materials under high pressures and temperatures. Such studies indicate that these three layers have quite different chemical composition: The crust is mainly composed of silica-rich minerals such as quartz (SiO_2) and feldspars [$CaAl_2Si_2O_8$, $(K,Na)AlSi_3O_8$], while the mantle is composed of magnesium- and iron-rich minerals such as olivine [$(Mg,Fe)_2SiO_4$] and pyroxenes [$(Mg,Fe,Ca)SiO_3$] and their high-pressure polymorphs. The core is composed mainly of iron and some other alloying elements. The details of compositions of each layer will be discussed in Sec. 1.2.

The Earth structure thus inferred may be compared with a theoretical prediction of depth variation of density and of seismic-wave velocities for an ideal situation, that is, the depth variation of these properties in an adiabatically compressed homogeneous body (a situation corresponding to a vigorously convecting layer without phase transformations). The density change in a homogeneous body due to adiabatic compression is given by

$$\frac{d\rho(r)}{dr}=\left(\frac{\partial\rho}{\partial P}\right)_S\frac{dP(r)}{dr},\tag{3}$$

where r is the distance from the center of the Earth, $(\partial\rho/\partial P)_S$ indicates the pressure dependence of density at adiabatic conditions, and P is the pressure. Now, as we shall see (Secs. 2 and 4), the temperature in the Earth is high enough to make rocks soft, and therefore no significant nonhydrostatic stresses can be maintained over geological time scales. Thus

Table 2. Density and elastic properties of typical minerals (at room temperature and room pressure).

Mineral	Density, ρ (10^3 kg/m^3)	Incompressibility, K (GPa)	Rigidity, μ (GPa)
Quartz, SiO_2	2.65	38	44
Feldspar (anorthite), $CaAl_2Si_2O_8$	2.76	90	40
Olivine, Mg_2SiO_4	3.22	129	82
Modified spinel, Mg_2SiO_4	3.47	174	114
Spinel, Mg_2SiO_4	3.55	184	119
Pyroxene (enstatite), $MgSiO_3$	3.20	104	77
Garnet (majorite), $MgSiO_3$	3.52	175	90
Perovskite, $MgSiO_3$	4.10	246	184
Magnesiowüstite, MgO	3.58	163	131
Iron, Fe	7.87	172	83

the hydrostatic equilibrium is a very good approximation. Hence, we get

$$\frac{dP(r)}{dr} = -g(r)\rho(r) = -\frac{GM(r)\rho(r)}{r^2}, \tag{4}$$

where $g(r)$ is the gravitational acceleration at r, G is the gravitation constant, and $M(r)$ is the mass of a sphere within the radius r, which is given by

$$M(r) = 4\pi \int_0^r \xi^2 \rho(\xi) d\xi. \tag{5}$$

The change in density with pressure is given by the incompressibility $K(r)$ which is related to the observed seismic-wave velocities through

$$\begin{aligned} K(r) &= \rho(r)\left(\frac{\partial P}{\partial \rho}\right)_S \\ &= \rho(r)\left(V_P^2(r) - \frac{4}{3} V_S^2(r)\right) \\ &= \rho(r)\Phi(r), \end{aligned} \tag{6}$$

where $\Phi(r)$ is the seismic parameter defined by $\Phi = V_P^2 - \frac{4}{3}V_S^2$. Combining Eqs. (3)–(6) one gets the Adams–Williamson equation that describes the depth variation of density due to adiabatic compression of a homogeneous body,

$$\frac{d\rho(r)}{dr} = -\frac{\rho(r)g(r)}{\Phi(r)} = -\frac{4\pi G\rho(r)}{\Phi(r)r^2} \int_0^r \xi^2 \rho(\xi) d\xi. \tag{7}$$

The pressure in the Earth can also be calculated from the estimated densities using Eq. (4).

A useful application of the Adams–Williamson equation is to examine how the real Earth structure is different from the idealized state of adiabatic compression of a homogeneous body. This can be done by calculating the inhomogeneity parameter, defined as

$$\eta_B(r) = -\frac{d\rho(r)}{dr} \frac{\Phi(r)}{\rho(r)g(r)}, \tag{8}$$

from the inferred density and seismic-wave velocity distributions. For a homogeneous body compressed adiabatically, $\eta_B = 1$. Here $\eta_B > 1$ implies that the density increases with depth more than in an adiabatically compressed homogeneous body. A typical example includes the density increase due to phase transformations. In contrast, $\eta_B < 1$ implies that density does not increase with depth as much as in an adiabatically compressed homogeneous body. A typical example is the case where the temperature gradient is higher than the adiabatic gradient. Changes in chemical composition with depth can also cause the deviation of η_B from 1. Figure 2 shows the inhomogeneity parameter in the Earth. It is seen that the core and the lower mantle are very close to an adiabatically compressed homogeneous body, but significant deviations are observed in the shallow upper mantle

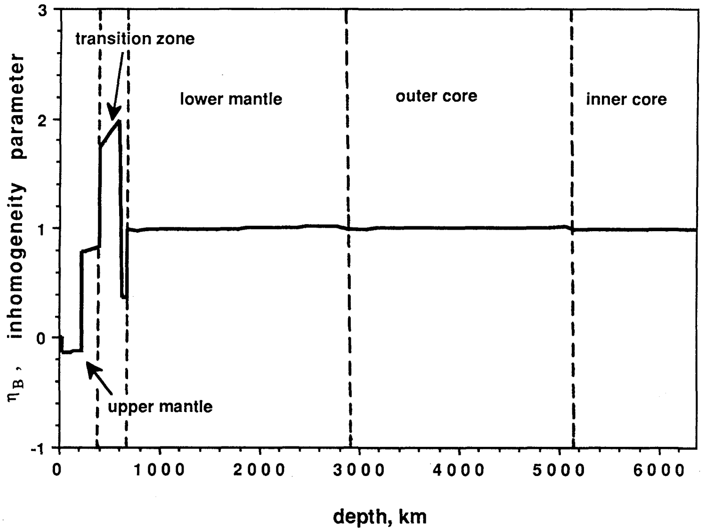

FIG. 2. The depth variation of the inhomogeneity parameter. The deviation from homogeneity ($\eta_B = 1$) is significant in the upper mantle and in the transition zone.

(down to ~200 km) and in the transition zone (400–670 km). We shall discuss possible implications of these observations in the following sections.

A layered Earth model such as shown in Fig. 1 is an idealization. Deviations from a simplified layered model are sometimes important in the discussion of the Earth's structure and dynamics. First, significant lateral variations occur in both the crust and the mantle, reflecting the lateral variation of temperature and/or composition. Second, the structure of the Earth is sometimes anisotropic (anisotropy in the upper mantle is taken into account in a simplified way in the PREM). Studies of fine structure of the Earth (lateral heterogeneity and anisotropy) have made significant progress during the past few years as a result of the development of digital broad-band seismic networks and powerful computers. The results and their implications for the Earth's dynamics are discussed in Sec. 4.3.

1.1.2 Solar Abundance and the Bulk Composition of Silicate Earth. The Earth's internal constitution may also be studied by analysis of the chemical composition of rocks (geochemistry). Unfortunately, we only have access to rocks presently at the surface of the Earth. Rocks are there as a result of complicated processes of differentiation and tectonics and do not represent the average composition of the Earth. To get some insight into the composition of the deep interior of the Earth, we need some understanding of the source materials from which the Earth was formed and the differentiation processes that have occurred throughout its history.

The Earth was formed in the solar nebula at ~4.5 billion years ago. The Earth's present chemical structure is a result of differentiation processes that have occurred in the solar nebula and in the Earth's interior. Therefore, a starting point of understanding the chemical composition and the differentiation processes in the Earth (and in the solar nebula) is the chemical composition of the solar system ("solar abundance"). There are two ways of estimating solar abundance. The first way is through analysis of the chemistry of the outer layer of the sun where convection is vigorous and therefore the chemistry of the outer layer is believed to be representative of the average chemistry of the sun and of the solar system-.The second way is examination of the chemical composition of the "primitive" (meaning undifferentiated) meteorites such as (type I) carbonaceous chondrites. These two estimates agree well, except for some volatile elements which are depleted from chondrites. The average chemical composition of the nonvolatile components of the solar system is given by the "solar abundance" in Fig. 3.

Basaltic magma is generated by partial melting of the upper mantle (see Secs. 1.2.1 and 3.2.1). Ringwood (1979) considered that upper mantle rocks or peridotites (composed mainly of olivine and pyroxenes) sampled as xenoliths by some volcanoes represent a residue of partial melting that generates basaltic magma. Therefore, the composition of the source material from which both basaltic magma and peridotite xenoliths are formed is considered to be some average of the two. This hypothetical source material is called "pyrolite" (see Fig. 3).

The chemical composition of upper-mantle rocks shows a large diversity due to variations in the degree of differentiation by partial melting. Rocks that show evidence of minimum differentiation may be representative of the primitive mantle. The composition of these primitive rocks is similar to that of pyrolite and has the following characteristics (Fig. 3):

1. Most of the refractory elements (except for elements with strong affinity to Fe, called siderophile elements) have abundances similar to the "solar abundance," although the Mg/Si ratio of the mantle (about 1.27 in atomic ratio) is slightly higher than that of the solar abundance (about 1.05);
2. Fe and siderophile elements are depleted; and
3. volatile elements are depleted.

Among the above compositional characteristics of the primitive upper mantle, 2 and 3 are readily explained by differentiation due to the formation of the Earth's core and by differentiation in the solar nebula, respectively. However, the origin of the high Mg/Si ratio [item (1)] has been a controversial matter. Three alternative explanations are possible:

1. The chemical composition of the Earth is different from the "solar abundance," possibly because of the differentiation processes in the solar nebula,

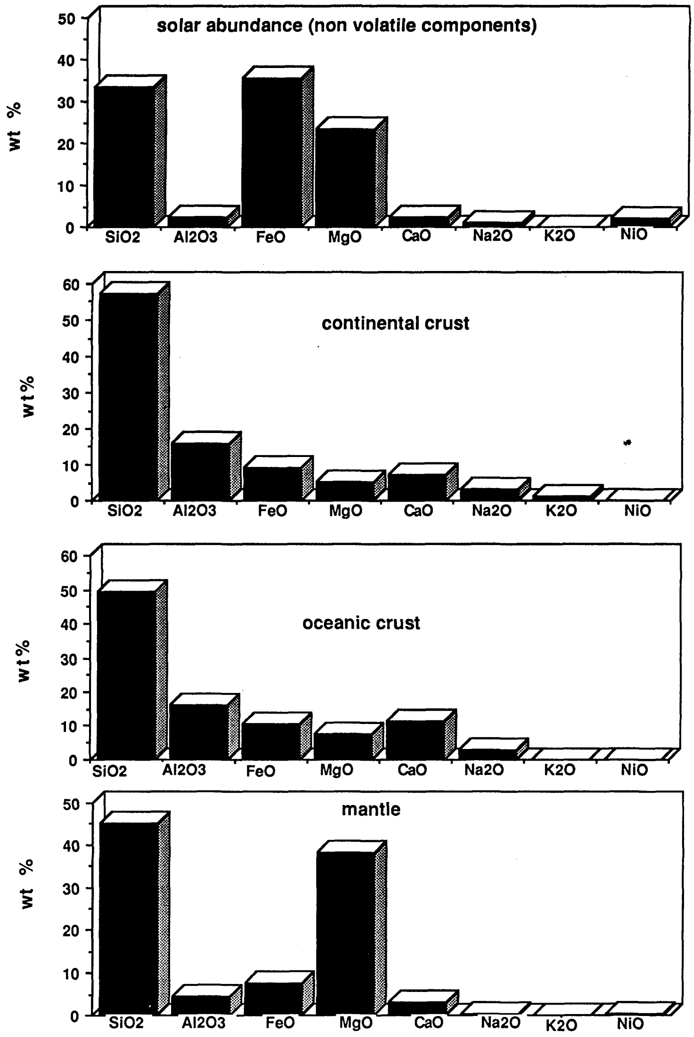

FIG. 3. The chemical composition of the solar system, the mantle (the pyrolite model), and the oceanic and continental crust.

2. the lower mantle (and/or the transition zone) is more enriched with Si than the upper mantle, and
3. a significant amount of silicon is dissolved in the core.

1.2 The Composition of the Earth

(See also VOLCANICS; PLATE TECTONICS; GEOLOGY)

1.2.1 The Crust. The crust is the near-surface layer with variable thickness (~5–50 km). The crust in the oceanic region is considerably thinner than the crust in the continental region and is remarkably homogeneous with ~6-km thickness. In contrast, the thickness of continental crust is highly heterogeneous. It is 10–20 km in the Basin and Range province in the U.S.A., but it is ~50 km in Tibet.

The oceanic crust is made of sediments (major chemical composition being $CaCO_3$ and SiO_2) and an underlying basaltic layer {basalt is a fine-grained rock composed mostly of calcium-rich feldspar ($CaAl_2Si_2O_8$) and pyroxenes [$(Mg,Fe,Ca)SiO_3$]}. The basaltic layer is created at mid-oceanic ridges by the partial melting of upper mantle rocks (see Sec. 3.2.1). The oceanic crust subducts together with the underlying uppermost mantle (together they constitute the oceanic lithosphere) into the deeper mantle at ocean trenches.

The continental crust is more heterogeneous than the oceanic crust, reflecting its complicated history of metamorphism and deformation. A simplified model divides it into two layers: the upper and the lower continental crust. The upper continental crust is mainly composed of silica-rich rocks such as granitoids, the major constituent minerals being quartz (SiO_2), potassium/sodium-rich feldspars [$(K,Na)AlSi_3O_8$], biotite [$K(Mg,Fe)_3(AlSi_3O_{10})(OH)_2$] and hornblende [$Ca_2(Mg,Fe,Al)_5(Si,Al)_8O_{22}(OH)_2$]. The lower crust is composed of more mafic (meaning MgO- and FeO-rich) rocks such as basalt, gabbro, or amphibolite, the major constituent minerals being calcium-rich feldspar, pyroxenes, hornblende, and amphibole [$(Mg,Fe,Ca,Na)_{2\text{-}3}(Mg,Fe,Al)_5(Si,Al)_8O_{22}(OH)_2$].

1.2.2 The Mantle. The crust-mantle boundary is referred to as the Mohorovičić (or Moho) discontinuity. The velocity of compressional waves changes from 6–7 to 8 km/s at this discontinuity. The presence of clear reflection at this discontinuity indicates that this is a sharp boundary: The width must be significantly smaller than the wavelength of seismic waves ($\sim$5 km).

The mantle may be divided into three layers: the upper mantle ($<$400 km), the transition zone (400–670 km), and the lower mantle (670–2900 km).

1.2.2.1 The Upper Mantle. The layer below the Moho discontinuity down to $\sim$400 km is referred to as the upper mantle. The comparison of inferred velocities with laboratory measurements shows that the major constituent minerals are olivine, pyroxenes, and garnets [$(Mg,Fe,Ca)_3Al_2Si_3O_{12}$]. Olivine is the most abundant mineral in the uppermost mantle. It has highly anisotropic elastic properties and the observed anisotropy of seismic waves in the upper mantle (see Sec. 4.3.2) can be explained by the anisotropic alignment of olivine. However, the relative amounts of these minerals may change with depth.

The inhomogeneity parameter defined by Eq. (8) has low values in the upper mantle, indicating that the temperature gradient is much higher than the adiabatic gradient. This is consistent with the temperature gradients estimated from other geophysical and petrological observations (see Sec. 2.1).

The high temperature gradient causes a mechanical stratification of the upper mantle (see also Sec. 4.2). The top cold part is the lithosphere which is characterized by high velocity and low attenuation of seismic waves, low electrical conductivity, and high creep strength (viscosity). A layer beneath the lithosphere is characterized by relatively low velocity and high attenuation of seismic waves, high electric conductivity, and low creep strength, all of which are indicative of high temperatures (temperatures close to the melting temperature). This layer is called the asthenosphere. The lithosphere/asthenosphere boundary is well defined by a sharp change in physical properties, but the bottom of the asthenosphere is not well defined. The depth of the lithosphere/asthenosphere boundary varies from place to place. In the oceanic mantle, the lithosphere thickness increases with age: the lithosphere is very thin near the ocean ridges where new oceanic lithosphere is formed, but its thickness increases up to 50–100 km at the age of $\sim$100 million years.

An important issue about the asthenosphere is whether it represents a layer of partial melting or not. It was often postulated that the geophysical anomalies (low velocity and high attenuation of seismic waves, high electrical conductivity, low viscosity) in the asthenosphere are due mainly to the presence of a small amount of melt. But recent experimental studies on elasticity (and anelasticity), electrical conductivity, and rheology of upper-mantle rocks show that high temperature (and/or the presence of hydrogen) is sufficient to cause these anomalies. Partial melting may not be required throughout the asthenosphere but may be a localized phenomenon beneath volcanoes rather than a global phenomenon.

1.2.2.2 The Transition Zone. Laboratory studies under high pressures and temperatures show that silicate minerals undergo several series of phase transformations at the pressure and temperature conditions corresponding to those in the transition zone (400–670 km). Most of these phase transformations are of the first order and are associated with the increase in density and in seismic-wave velocities (see Table 2). The observed high gradients or discontinuities in density and in seismic-wave velocities (and the resultant high inhomogeneity parameter) in the transition zone is mostly attributed to these phase transformations.

Olivine [$(Mg,Fe)_2SiO_4$] with $Fe/(Fe+Mg) \sim 0.1$ transforms to the modified spinel structure at $\sim$400 km and then to the spinel structure at ~500 km and finally to the perovskite [(Mg,Fe)SiO$_3$]+magnesiowüstite [(Mg,Fe)O] at ~670 km (see Fig. 4). In these cases, the packing of atoms changes significantly in a narrow pressure (or depth) interval (see Fig. 4). The sharp increases in density and in seismic-wave velocities at ~400 and ~670 km are considered to be due mainly to the transitions from olivine to modified spinel and from spinel to perovskite + magnesiowüstite, respectively (the modified-spinel to spinel transformation does not change the density or velocity very much; see Table 2). In the case of the spinel to perovskite + magnesiowustite transformation, the number of oxygen ions surrounding the silicon ions changes with the transformation: Silicon ions are surrounded by four oxygen ions in spinel, while they are surrounded by six oxygen ions in perovskite.

The other example is the transformation of pyroxene [(Mg,Fe)SiO$_3$] into the garnet structure. In this case, the mutual solubility of pyroxenes and alumino-silicate garnet [(Mg,Fe)$_3$Al$_2$Si$_3$O$_{12}$] increases with pressure. Thus the transformation is gradual and this phase transformation is considered to be responsible for the observed gradual increase in density and velocities in the depth range of 400–670 km. In a silica-rich garnet, some lattice sites which are normally occupied with aluminum ions are occupied with silicon and magnesium ions, and therefore those silicon ions are surrounded by six oxygen ions. Garnets which have silicons surrounded by six oxygens are called majorite.

The transformation pressure P_{tr} varies with temperature through the Clausius–Clapeyron relation, viz;

$$\frac{dP_{\mathrm{tr}}}{dT}=\frac{\Delta S}{\Delta V}, \tag{9}$$

where $\Delta S = S_{\mathrm{hpp}} - S_{\mathrm{lpp}}$ (S_{hpp}, entropy of the high-pressure phase; S_{lpp}, entropy of the low-pressure phase) and $\Delta V = V_{\mathrm{hpp}} - V_{\mathrm{lpp}}$ (V_{hpp}, volume of high-pressure phase; V_{lpp}, volume of low-pressure phase). In all cases, ΔV is negative, but the sign of ΔS depends on specific transformations. In the case of the olivine to modified spinel transformation, ΔS is negative, that is, the modified spinel has smaller entropy than olivine, and hence dP_{tr}/dT is positive. In contrast, the phase transformation from spinel to perovskite + magnesiowüstite has negative dP_{tr}/dT, because the

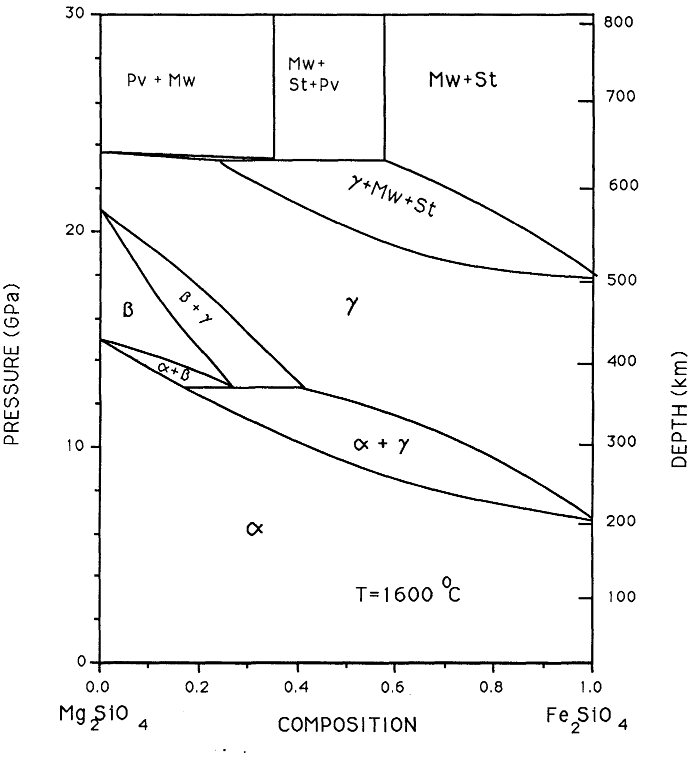

FIG. 4. The phase diagram of (Mg,Fe)$_2$SiO$_4$. α, olivine; β, modified spinel; γ, spinel; Pv, Perovskite; Mw, magnesiowüstite; St, stishovite. For a typical chemical composition appropriate to the Earth's interior [Fe/(Mg+Fe)~0.1], (Mg,Fe)$_2$SiO$_4$ transforms from olivine (α) to modified spinel (β) at ~400 km, to spinel (γ) at ~500 km, and finally to perovskite (Pv) +magnesiowüstite (Mw) at ~670 km at T~1600° C. T~1600° C is the temperature estimated at 670 km on the basis of the comparison of the phase diagram with the seismological observations (see Sec. 2).

perovskite (+ magnesiowüstite) has higher entropy than spinel. Since the transformation pressure (depth) depends on temperature, by measuring the exact depth of phase transformations from seismological observations, one can estimate the temperature at these depths (see Sec. 2.3).

Although the major cause for high velocity gradients and velocity discontinuities in the transition zone is now known to be phase transformations in silicates, it is not well established whether the observed density and velocity changes in this region are solely due to phase transformations or partly due to some chemical stratifications as well. Seismological and petrological observations are also consistent with chemical stratification involving enrichments in pyroxenes and/or garnet in the transition zone.

Major seismic discontinuities in the mantle occur at ~400 and 670 km on the global scale. However, these depths may vary laterally because of heterogeneity in temperature and/or chemistry (or mineralogy). In particular, large variation in these depths is expected in and around subducting slabs where a large lateral variation in temperature and/or chemistry (mineralogy) occurs. High-resolution seismological studies are under way to detect these fine details, which contain important information as to lateral variation in temperature and/or chemistry (or mineralogy) and hence have important clues as to the dynamics of the Earth's interior.

1.2.2.3 The Lower Mantle. The lower mantle is mostly composed of (Mg,Fe)SiO_3 perovskite and magnesiowüstite. The amount of magnesiowüstite is not well constrained and ranges from 0% to 20% depending on the models. Thus the (Mg,Fe)SiO_3 perovskite is the most abundant mineral in the Earth (it constitutes ~40%–50% of the Earth). The velocity and density variations in the lower mantle are smooth, and are compatible with a homogeneous composition without major phase transformations except near the topmost lower mantle (~670–1000 km)where relatively high gradients of these properties are observed. The phase transformation of majorite garnet into perovskite structure, or formation of some aluminous high-pressure minerals, may be responsible for the anomalous density and velocity gradient of the topmost part of the lower mantle.

1.2.2.4 The D'' Layer and the Core–Mantle Boundary. The very bottom of the Earth's mantle (100–200 km thick), which is called the D'' layer, has unusual physical properties: the velocity gradient is low and lateral variation is very large (Lay, 1989).

Two hypotheses have been proposed to explain this layer. One is that the D'' layer corresponds to the bottom thermal boundary layer of a convecting mantle where the temperature gradient is high. The other alternative is that the D'' layer is chemically different from the rest of the mantle. A high temperature gradient is also suggested by the comparison of estimated temperatures in the mantle with the melting temperatures of the core materials (see Secs. 2.3 and 3.3). Both high temperature gradient and large chemical heterogeneities may cause the unusual properties of the D'' layer.

The core–mantle boundary is not smooth but has some topography with amplitude ~0.5 to ~5 km. Such topography may be a result of upwelling and downgoing convection current in the Earth's mantle and may also reflect the density variations due to chemical heterogeneities. The topography at the core–mantle boundary enhances the mechanical interaction of the core and mantle.

1.2.3 The Core. The core is divided into two parts: the outer core and the inner core. The densities of these two layers are much higher than those of silicates, and the major constituent of the Earth's core is believed to be metallic iron (Fig. 5). This conclusion is supported by the comparison of chemical compositions of the mantle (and the crust) with the solar abundance (Fig. 2). The inspection of Fig. 2 shows that the mantle (and the crust) is significantly depleted in iron compared to the solar abundance, suggesting an iron-rich layer in the deep portion of the Earth.

The absence of shear-wave propagation in the outer core indicates that it is largely in a molten state. This metallic liquid outer core may generate the geomagnetic field by convection. The observed density of the outer core indicates that the outer core is less dense than molten iron. Some light elements are needed to explain the observed density. Candidates include sulfur, oxygen, hydrogen, silicon, and carbon. High-pressure experiments show that all of these elements can be dissolved into iron at high pressures and high

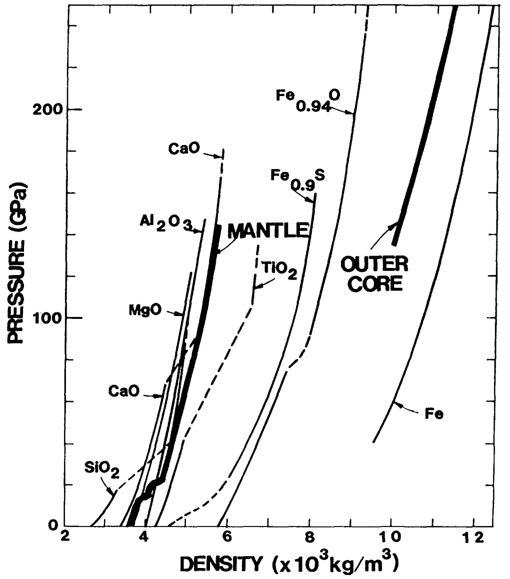

FIG. 5. Density–pressure relationships for various materials. Thin solid lines are those determined by laboratory experiments by shock waves. Thick solid lines are those inferred from seismological observations. The comparison shows that the mantle is composed of silicates or oxides but the core is composed mainly of iron.

temperatures. No consensus has been reached as to which of these elements are dominant. An important effect of light-element alloying is that it significantly reduces the melting temperature.

Shear waves pass through the inner core, and therefore it must be largely in a solid state. The density of the inner core is close to that of pure iron (+ nickel). Thus the Earth's core appears to be chemically layered: a relatively pure, solid inner core, and a liquid outer core containing a significant amount of light elements. An interesting hypothesis is that the inner core may have resulted from the solidification of the outer core as a result of secular cooling. On the basis of the seismologically determined density jump at the outer–inner core boundary and the assumption that the inner core has grown throughout the Earth's history, one can estimate the rate of energy release upon the solidification of the inner core. It is shown that the gravitational energy released by the growth of the inner core can provide sufficient energy to generate the geomagnetic field.

2. EARTH'S THERMAL REGIMES

2.1 Introduction

The temperature profile $T(z)$ of the Earth's interior is determined by the heat generation and heat transfer processes through the energy conservation equation, viz;

$$\frac{\partial T}{\partial t}=\left(\frac{k}{\rho C_p}\right)\nabla^2 T+\frac{H}{\rho C_p}-\mathbf{v}\cdot\nabla T, \tag{10}$$

where k is thermal conductivity, C_p the specific heat, H the heat generation per unit volume, and $\mathbf{v}$ the velocity. The first term in the rhs of Eq. (10) indicates the heat loss due to thermal conduction, the second term the heat generation, and the third term the energy transfer due to convection. The relative importance of each term depends on specific geological settings. For example, the heat production due to radioactive elements is important in the continental crust, but is less important in the oceanic crust and in the mantle. The relative importance of convective and conductive heat transfer depends on the rheology (viscosity) of Earth material (see Sec. 4). Convection becomes important when the Rayleigh number exceeds a critical value ($\sim 10^3$). The Rayleigh number for a fluid layer heated from below is given by

$$Ra=\alpha\rho\Delta T g L^3/\kappa\eta, \tag{11}$$

where α is the thermal expansion, ΔT the temperature difference between the top and bottom of the layer, L the thickness of the layer, κ the thermal diffusivity ($\kappa=k/\rho C_p$), and η the viscosity. Among these parameters, the most critical is the viscosity, which changes significantly with temperature (and pressure) (see Sec. 4). The parameters in the equation are presented in Table 3 which shows that the Rayleigh number of the mantle (below the asthenosphere) is 10^5–10^7 and therefore vigorous convection should occur in most of the mantle (and the core).

When convective heat transfer is not important, the temperature profile is determined by heat generation within a layer and by the boundary conditions [T and the heat flux $J=k(dT/dz)$ at the boundary]. The amount of heat flux varies from place to place and ranges from (20 to 300)$\times 10^{-3}$ W m^{-2}, and the total heat loss from the Earth is estimated to be $\sim 4\times 10^{13}$ W. Since the thermal conductivities

Table 3. Physical constants and parameters relevant to mass and heat transfer in the Earth.

Thermal expansion α^a	3×10^{-5}/K
Acceleration of gravity g^b	10 m^2/s
Density ρ^c	$(3–5)\times10^3$ kg/m^3
Thermal diffusivity κ	10^{-6} m^2/s
Thickness of the layer L^d	400–2900 km
Viscosity η^e	
(asthenosphere and below)	10^{20}–10^{22} Pa s
(lithosphere)	10^{24} Pa s or higher
Temperature difference ΔT^f	1500–4000 K

[a] Thermal expansion in minerals depends on temperature and pressure. This value is for olivine at high T ($T\sim1000$–1500 K) and at 0.1 MPa.

[b] The acceleration of gravity is nearly constant throughout the Earth's mantle.

[c] See the Earth model in Fig. 1.

[d] For the upper mantle, $L=400$ km; for the whole mantle, $L=2900$ km.

[e] The viscosity of mantle materials is a strong function of temperature (and pressure) and varies significantly with depth (see Sec. 4; Fig. 9).

[f] See Sec. 2.

of rocks are generally small (0.1–0.5 W/m K), steep temperature gradients (10–500 K/km) will be formed in a layer where only conductive heat transfer occurs. In contrast, when convective heat transfer becomes important, the temperature profile within a convection cell becomes close to adiabatic ($dT/dz=\alpha gT/C_p$), leading to a much smaller gradient (0.3–0.5 K/km for the upper mantle). One expects therefore that the temperature gradient near the surface (i.e., the lithosphere) is much higher than in the deep mantle.

The temperature profile also varies laterally because the amount of convective heat transport and of heat generation varies from place to place. A large amount of heat is carried to the surface near ocean ridges by an upwelling convective current, but the downgoing current related to subducting slabs at ocean trenches will cool the mantle. The lateral variation in temperatures therefore reflects the convective pattern and provides useful constraints as to the dynamics of the deep interior of the Earth (see Sec. 4.3).

The Earth's temperature profile has also changed through geological time. Current understanding of temporal variation of the Earth's temperature is discussed in Sec. 2.4.

2.2 Heat Flow and Near-Surface Temperature Profile

The processes that determine the temperature profiles are quite different between the oceanic and the continental lithosphere. The oceanic lithosphere contains only a small amount of radiogenic elements and the temperature profiles are mainly determined by the heat flux carried by the underlying convective current. This heat flux is large near ocean ridges and decreases with the distance from ridges. Thus the temperature of the oceanic lithosphere decreases with the distance from ocean ridges. The temperatures near ocean ridges exceed the solidus of upper mantle rocks and partial melting occurs to create a basaltic layer.

In the continental lithosphere, the heat transported by the underlying convective current is relatively small [$(30–50)\times10^{-3}$ W m^{-2}] compared to the oceanic lithosphere. However, the contribution from radiogenic heat (H) in the continental crust is significant and compensates the effects of relatively small heat flux. Thus the temperature profiles of the continental lithosphere are similar to those of old oceanic lithosphere, and the heat flux from the old oceanic lithosphere is similar to that from the continental lithosphere. In total, the heat flux from the Earth amounts to $\sim4\times10^{13}$ W.

The temperature gradient measured in this way ranges from ~10 K/km in the stable continent to more than 500 K/km near volcanic regions (such as ocean ridges). When extrapolated to deeper portions, temperatures would exceed the melting temperatures of most of rocks at the depth of 100–200 km. However, seismological observations indicate that most of the Earth's mantle is solid. The implication is that the temperature gradients at the deeper portions must be significantly smaller than the near-surface gradients.

2.3 Temperature Profiles of the Earth's Deep Interior

Melting temperatures of Earth materials (see Sec. 3) provide important constraints on the temperature profiles. First, the temperatures in the inner core and the mantle must be lower than the melting temperatures of the relevant materials. Second, the temperatures in the outer core must be higher than the melting temperature of iron (plus some light elements).

Melting temperatures of iron (and its alloys) have been determined up to pressures corresponding to the core pressures, using shock waves as well as static compression experiments. The melting temperature of iron increases with pressure and reaches ~7000 K at the pressure of the outer–inner core boundary. If the core were made of pure iron, this temperature would be the temperature at the outer–inner core boundary. However, the outer core contains a significant amount of secondary components such as sulfur, oxygen, and hydrogen (see Sec. 1.2.3) which, in most cases, reduce the melting temperature. For example, if the light element is sulfur, the melting temperature for the eutectic composition will be ~ 4500 K at the outer–inner core boundary and ~3500 K at the core–mantle boundary (Jeanloz, 1990).

In addition to these broad constraints, more detailed estimates of temperature profiles can be made using petrological studies of mantle xenoliths (fragments of rocks carried up by volcanoes) and from the phase diagrams determined by high-pressure experiments (see Sec. 1.2.2.2). Also, some physical properties such as electrical conductivity or seismic-wave velocities (see Sec. 1.1.1, Fig. 2) can be used to estimate the temperature profiles in the deep interior of the Earth. The temperatures in the upper mantle and the transition zone have been estimated using these techniques (Fig. 6) (Jeanloz and Morris, 1986). The following points can be noted.

1. The temperature gradient changes from steep in the upper portion of the mantle to gradual in the deeper portion. The temperature gradient in the deeper mantle (400–670 km and below) thus estimated is close to the adiabatic gradient (0.3–0.5 K/km).
2. The temperature in the upper mantle be-

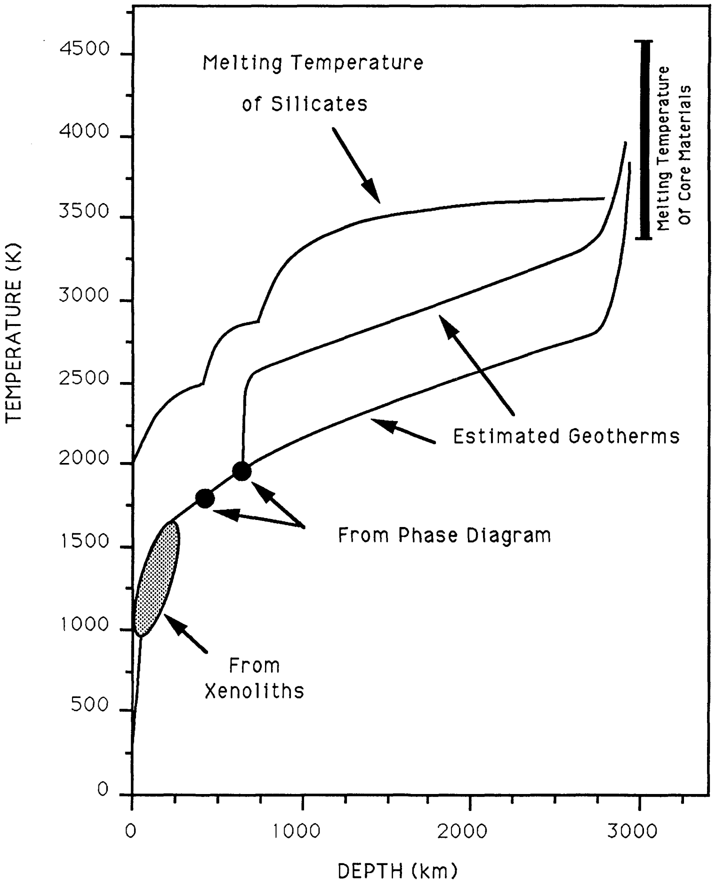

FIG. 6. Average temperature profiles for the Earth's interior. Shown together are the depth variation of melting temperatures of silicates and the melting temperature of iron at the core–mantle boundary determined by laboratory experiments. The two curves in the lower mantle show two possible temperature profiles, one (colder one) corresponding to whole-mantle convection, the other (hotter one) corresponding to layered convection with a thermal boundary layer at ~670 km.

low young ocean is higher than the temperature in a stable continent, but they are indistinguishable when the age of the ocean exceeds ~100 millions years.

When the temperature at ~670 km (~2000 K) is extrapolated to the core–mantle boundary assuming an adiabatic gradient (as suggested by the seismic-wave velocities in the greatest part of the lower mantle), one gets the temperature of ~2500–3000 K, which is lower than the melting temperature of the core materials (4000±500 K). The implication is that there must be some layers in the Earth below 670 km where the temperature gradient is significantly higher than the adiabatic gradient. Possibilities include thermal boundary layers near 670 km and/or at the bottom of the mantle (D'' layer).

The uncertainties in estimated temperatures become larger as we go deeper in the Earth. The uncertainties in the estimated temperatures in the upper mantle and transition zone are ~ ±100 K. The major uncertainty in the temperatures in the lower mantle concerns the presence or absence of thermal boundary layers in the transition zone and this yields ~ ±500-K uncertainties in the estimated temperatures. The uncertainties in the temperatures in the core come from the uncertainties in the melting temperature of core materials and are more than ±1000 K.

2.4 Thermal History

The previous discussions are concerned mainly with the Earth's present temperature profiles. The Earth's temperatures, however, have changed with time since the rates both of heat generation and of heat loss change with time. The major energy sources for the Earth's dynamics are gravitational energy and the heat produced by radiogenic elements. A significant amount of gravitational energy was released during the early stage of evolution of the Earth (during accretion and core formation) and probably throughout geological history as a result of growth of the inner core. The amount of gravitational energy released during accretion is proportional to R^5 (R is the radius of the planet), and therefore the bigger the planet, the larger this effect. The net temperature increase due to gravitational energy depends also on the rate of energy release and the efficiency of heat loss. When a planet is formed quickly, the heat is largely retained in the planet and a significant temperature increase will occur. Also, when a planet has a thick atmosphere, it will reduce the efficiency of energy loss and increase the temperature. Current theoretical studies on the formation processes of Earth suggest that a significant melting leading to the formation of a magma ocean may have occurred during the accretion and the core-formation processes.

The heat production due to radiogenic elements is determined by their concentration and the half-life times. Important radiogenic elements include ^{235}U, ^{238}U, ^{232}Th, ^{40}K and possibly ^{26}Al. ^{26}Al has a short half-life (0.74 million years) and it may have been important in the early stage of the solar nebula. All of other elements have half-lives on the order of a billion years and their activity has been decaying slowly.

The time variation of the Earth's average temperature T is determined by the balance of heat generation and heat loss as

$$\rho C_p V \frac{dT}{dt} = H^+(t) - H^-(t), \qquad (12)$$

where ρ is the density, C_p the specific heat, V the volume of the Earth, and H^+ and H^- the rates of heat generation and heat loss, respectively. The present-day energy loss rate can be estimated from the heat-flow measurements (see Sec. 2.2) to be $\sim 4\times10^{13}$ W. The heat generation due to radioactivity at present can be estimated if the bulk composition of the Earth is assumed to be the same as a primitive chondrite (see Sec. 1.1.2), which yields $\sim 2\times10^{13}$ W. The imbalance between the two indicates that the Earth has been cooling through time. Both the release of gravitational energy and the heat production due to radiogenic elements were more significant in the early stage than they are today. Thus the temperature in the past should have been higher than it is now. However, the rate of temperature change is also controlled by the energy loss mechanisms. The most important energy loss mechanism is the convective heat transfer through the mantle (see Sec. 4). The efficiency of heat loss due to this mechanism depends on temperature because the viscosity of rocks depends strongly on temperature (see Sec. 4.2): the higher (lower) the temperature, the higher (lower) the rate of cooling.

In this way, the temperature-dependent viscosity of rocks tends to stabilize the temperatures in the Earth. Thus a rather moderate temperature drop of ~100–300 K is estimated from the Archean (<2.5 billion years) to the present.

3. MELTING OF SILICATES AND MAGMATISM

(See also VOLCANICS)

3.1 Melting and Chemical Stratification

Melting is a very efficient way to create chemical stratification of the Earth. The major chemical boundaries of the Earth, namely the crust–mantle boundary, the mantle–core boundary, and the outer-inner core boundary, are considered to have been formed through some processes involving melting. Melting can create chemical stratification in two different ways. First, when partial melting occurs, melt may migrate up or down depending on its density relative to the host solid rock. Second, when total melting occurs, fractional crystallization in a melt will create a chemical stratification. The former process is believed to be responsible for the major volcanic activity near the surface, including that at mid-ocean ridges. The latter is believed to occur at the inner and outer core boundary and in magma chambers (or the hypothetical magma ocean).

When partial melting (or fractional crystallization from melt) occurs, selective enrichment or depletion of some elements occurs in the melt (or the solid phases). The nature of element partitioning between melt and solid phases depends strongly on the crystal structure of the solid phases and the degree of partial melting (or crystallization). Thus the measurements of abundance patterns of various elements in rocks provides important information as to the degree of melting (or crystallization) and the crystal structure of solid phases involved (and hence the depth of melting).

The melting temperatures of most Earth materials increase with pressure (Fig. 6). However, the rate of increase in melting temperature within the stability field of a given phase becomes small at high pressures because of the large increase in density of melt relative to solid (melts are more compressible than solids). Secondary components sometimes have important effects on melting. An example is the effect of water on the melting of silicates: Water dramatically reduces the melting temperature and changes the chemical composition of the melt.

3.2 Magmatism and Melting of the Earth's Interior

3.2.1 Mafic Magmas. Magmas enriched in (Mg,Fe)O are called mafic magmas, and the typical one is basaltic magma. The most important igneous rock formed by the solidification of this type of magma is mid-ocean ridge basalt (MORB), and its production rate is approximately ~4.5 km^3/year. MORB comprises a major part of the oceanic crust that descends into the deep interior of the Earth at a subduction zone.

Some ocean islands such as Hawaii are composed of a somewhat different igneous rock called ocean island basalt (OIB), which shows enrichment in incompatible elements (elements that are selectively concentrated into the liquid phase upon partial melting). These rocks are thought to have originated in relatively undepleted regions (or mantle enriched in incompatible elements). In most cases, the volcanoes which supply these basalts remain at the same position for a geologically long period of time, while the surface plates move a significant distance. Thus these volcanoes are often referred to as "hot spots." The production rate of this type of magma is ~0.1 km^3/year.

3.2.2 Silicic and Intermediate Magmas. Magmas enriched with silica (e.g., granite) are called silicic, and magmas with a composition between silicic and mafic are called intermediate. Andesite is a typical igneous rock formed by an intermediate magma. These magmas are formed in the island arcs or the active continental margins, and they are generated by partial melting of the crust or the mantle in the presence of water. Silicic and intermediate magmatism is responsible for the growth of continents and island arcs. The production rate is ~1 km^3/year.

3.2.3 Ultramafic Magmas and Melting in the Deep Mantle. Komatiite is a unique igneous rock formed by the solidification of magmas which are extremely enriched in

(Mg,Fe)O (ultramafic magma). They occur mainly in the Archean period (more than ~2.5 billion years ago). Magmas with this composition indicate a high degree of partial melting and therefore high temperatures in the Archean period.

Theoretical studies of thermal history (see Sec. 2.4) strongly suggest extensive melting in the early stage of the Earth. Large-scale melting in the early stage of Earth's history could have generated a thick layer of ultramafic magmas (magma ocean). The consequences of such extensive melting can be inferred from experimental studies on melting at high pressures, and the results can be compared with geochemical and geophysical observations to shed some light on the degree of chemical differentiation in the Earth.

Melting experiments under ultrahigh pressure indicate that the chemical composition of the upper mantle is similar to the composition of partial melt that is formed at high pressures (13–15 GPa) and that the solidus phase (a solid phase that crystallizes first from the melt upon cooling) changes from olivine at low pressure to majorite at ~15 GPa, and finally to perovskite at ~25 GPa. Partial melting or crystallization involving majorite or perovskite results in quite different (trace) element partitioning than those involving upper mantle minerals (such as olivine or pyroxenes). Therefore some stratification, in both trace- and major-element chemistry, might have been formed in the mantle if large-scale melting had occurred in the early stage of Earth's history.

Another important observation in ultrahigh-pressure melting is that the density differences between melt and solid become smaller at high pressures. This eventually leads to density crossover: Melts will become denser than solids. If this density crossover occurs in the Earth, the transport of magmas from deep interior of the Earth would become difficult.

The consequences of large-scale melting (such as magma ocean) for chemical stratification depend on the processes of melt crystal separation as well as on the density contrasts and the partitioning of elements between melts and crystals. It has often been assumed that large-scale melting inevitably results in chemical stratification, but recent theoretical studies suggest that very limited chemical stratification might result because of a stirring effect of vigorous convection in the magma ocean.

4. EARTH'S RHEOLOGICAL STRUCTURE AND DYNAMICS OF THE EARTH'S INTERIOR

(See also PLATE TECTONICS)

4.1 Time-Dependent Deformation of the Earth

The Earth's dynamics is governed by the balance of the driving force determined by the density heterogeneity and the resistance force determined by rock rheology. The Earth's rheological properties depend on time scales and on the stress magnitude. At short time scales and for small deviatoric stresses, Earth materials behave like an elastic solid (with minor energy dissipation). When the time scale and/or the stress magnitude are large, nonelastic deformation will result, leading to permanent deformation that causes tectonic activities such as mountain building and earthquakes. The transition conditions from elastic to nonelastic therefore involve two criteria, the time-scale criterion and the stress criterion (Fig. 7).

To understand this, we must first understand the two contrasting mechanisms of nonelastic deformation. The first one is brittle deformation, that is, fracture. Fracture occurs mostly along a fault, and therefore the fracture strength of rocks is determined by the resistance for sliding along a fault. The strength σ of a rock in the brittle regime is given by

$$\sigma=\sigma_0+\mu_f\sigma_n, \tag{13}$$

where σ_0 is the cohesive strength, μ_f the friction coefficient, and σ_n the normal stress on the fault. Laboratory studies show that both σ_0 and μ_f are relatively independent of rock type, temperature, pressure, and strain rate. However, the strength in a brittle regime increases with pressure, since σ_n is proportional to pressure.

The second mechanism is ductile deformation. Ductile deformation occurs, in most cases, through the motion of crystalline defects in minerals. The motion of these defects is thermally activated, and therefore ductile deformation is important only at high temperatures. The easiness of the motion of defects depends on the strength of chemical bonds and crystal structure, and therefore the ductile strength depends on the rock type. To a first approximation, the dependence on rock

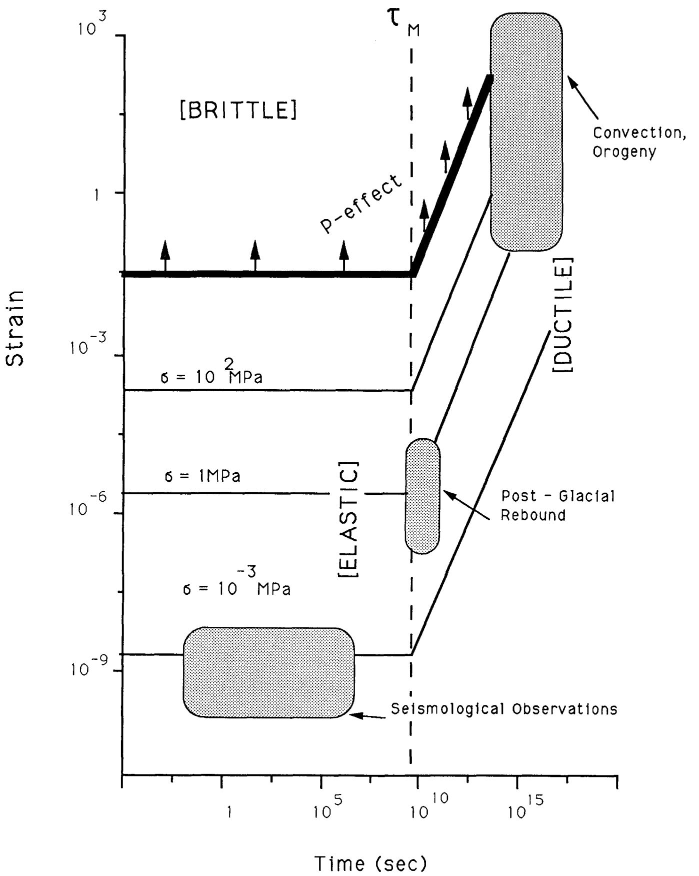

FIG. 7. Mechanical behavior of rocks as a function of time scales and strain (stress) magnitude. Constant stress contours are also shown for both elastic and ductile regimes. When the stress magnitude exceeds a critical value, a material will deform in the brittle manner (fracture), and this critical stress increases with pressure ("*P*-effect"); the critical stress shown in this figure corresponds to the stress in the continental lower crust and the uppermost mantle. Ductile deformation is important compared to elastic deformation when the Maxwell time $\tau_M=\eta/\mu$ (η, viscosity; μ, rigidity) is smaller than the time scale of the relevant process. The Maxwell time depends on temperature and pressure and the value shown in this figure is for the typical asthenosphere. Shown together are the strain magnitudes and time scales of typical deformation processes in the Earth.

type is through the melting temperature, and the flow law is given by

$$\dot{\epsilon}=A\sigma^n \exp[-\beta T_m(P)/RT], \tag{14}$$

where $\dot{\epsilon}$ is the strain rate, σ the differential stress, A a constant preexponential factor, n the stress exponent ($n=1$–5), $T_m(P)$ the melting temperature which depends on pressure, and β a nondimensional constant. The effective viscosity η is defined by

$$\eta=\sigma/\dot{\epsilon}. \tag{15}$$

For Newtonian rheology (i.e., $n=1$), the effective viscosity is independent of stress, whereas for non-Newtonian rheology ($n>1$), the effective viscosity decreases with the stress magnitude. Ductile deformation is important compared to elastic deformation when the Maxwell time

$$\tau_M=\eta/\mu \tag{16}$$

is smaller than the time scale of deformation, where μ is the rigidity. Thus ductile deformation is important in slow processes and/or at high temperatures (see Fig. 7).

Ductile deformation results in changes in rocks' microstructures reflecting deformation conditions. They include the formation of preferential alignment (preferred orientation) of minerals and the creation of crystal dislocations. The preferential alignment of minerals can be observed as an anisotropy in seismic-wave velocities as well as in thin sections of rocks under a microscope. The density of crystal dislocations and some other microstructures can be observed by the analysis of rock specimens and provide an estimate for the magnitude of differential stress in the Earth.

Brittle and ductile deformation are largely independent, and the lower of the strengths associated with these processes will determine the real strength. Thus the mechanical properties of rocks can be summarized as in Fig. 7. At low stresses and short time scale (or low temperatures), rock behaves as an elastic solid. At high stress and short time scales (or low temperatures), rocks deform in a brittle manner. Finally, at long time scales (or high temperatures), rocks deform in a ductile fashion.

4.2 Earth's Rheological Stratification

The Earth's rheological stratification can be predicted on the basis of temperature profiles (Fig. 6) and the constitution and the mechanical properties of rocks [Eq. (14)]. The temperature is low in the near-surface regions of the Earth, and therefore rocks are elastic or brittle depending on the stress levels. The strength of rocks in the near-surface layer increases with depth as a result of increases in pressure. As one goes to deeper portions, temperatures will increase, and this enhances ductile deformation. The depth of onset of ductile deformation depends on the rock type and the temperature profile. In the continental lithosphere, the lower crust will be a ductile layer with strength significantly smaller than that of the upper crust and the uppermost mantle. In the oceanic region, the crust is mostly a brittle layer and ductile deformation occurs only in the upper mantle. The ductile strength of the upper mantle first decreases with depth because of the rapid increase in temperature in near surface regions (Fig. 6). However, the temperature gradient becomes small at the deeper portions, and then the pressure effect (through the pressure dependence of melting temperature) becomes more important, which increases the ductile strength with depth. Thus one expects a strength minimum at depths where the temperature gradient changes from a near-surface high gradient to a low gradient at the deeper portions (this depth depends on the temperature profile and is ~50–200 km in the oceanic mantle; see Fig. 6). At even deeper portions where a series of phase transformations occur in major constituent minerals, rheological properties will also change. Recent laboratory studies suggest that the garnet and spinel-rich transition zone (400–670 km) presumably has a larger viscosity than the olivine-rich upper mantle or the perovskite-rich lower mantle. Thus a rheological stratification of the Earth is a natural consequence of temperature and pressure distribution and of the phase transformations in the Earth.

The Earth's rheological properties can be inferred from some geological and geophysical observations. Attenuation of seismic waves provides information as to the Earth's non-elastic properties at relatively short time scales ($1\text{–}10^3$ s). The attenuation of seismic energy is measured by a quality factor Q defined as

$$Q^{-1}=\Delta E/2\pi E, \tag{17}$$

where ΔE is the energy dissipated per unit cycle, and E is the energy stored per unit cycle. Figure 8 shows the depth variation of Q in the mantle which is characterized by a high-Q (low-loss) lithosphere (0–100 km), low-Q (high-loss) asthenosphere (100–200 km), and a moderate-Q lower mantle.

Time-dependent deformation after the last deglaciation provides the most detailed information as to Earth's rheological stratification. The melting of polar ice sheets ~10 000 years ago changed the distribution of surface load,

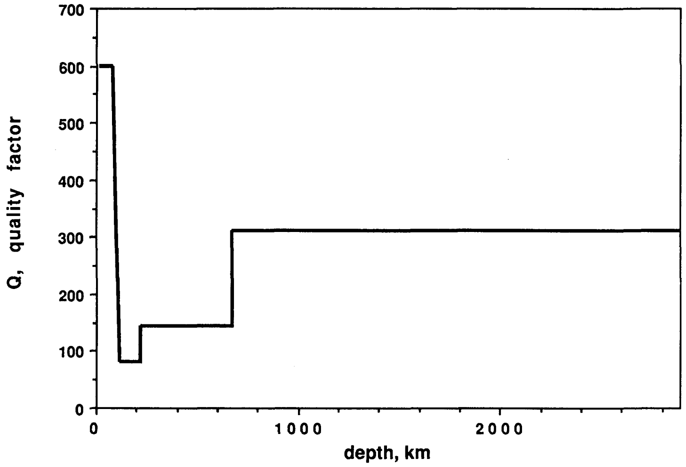

FIG. 8. Depth variation of seismic wave attenuation (Q, quality factor).

which induced plastic flow in the Earth. The resultant deformation is still going on today as observed by the change in sea levels at the coast or by the change in the spin rate of the Earth (as a result of change in the moment of inertia due to internal mass redistribution). Theoretical analyses of such deformation show that the near-surface layer of the Earth behaves like a thin elastic shell (the lithosphere), whereas the deeper portions behave like a viscous fluid.

Another observation related to mantle rheology is the geoid anomalies (anomalies of the height of equipotential surface of the Earth's gravity field). Such anomalies reflect the anomalies of mass distribution in the Earth. Mass anomalies with a long wavelength are supported by viscous flow and therefore provide a clue as to the rheological properties of the Earth's interior. Theoretical analysis of the geoid anomalies associated with subduction of the oceanic lithosphere suggests a significant increase in viscosity in the deep part of the mantle.

Most of these studies assume Newtonian rheology [linear relationship between strain rate and stress, i.e., $n=1$ in Eq. (14)]. The viscosity of the mantle thus inferred is shown in Fig. 9. The average viscosity of the Earth's mantle is well constrained from these studies ($\sim 10^{21}$ Pa s), but the depth variation is poorly resolved. There are some indications that the asthenosphere has lower viscosity and the transition zone and the lower mantle have higher viscosity than the average.

4.3 Dynamics of the Earth's Interior

4.3.1 Plate Tectonics (see also PLATE TECTONICS). The estimation of the Rayleigh number defined by Eq. (11) for the Earth's mantle shows that it significantly exceeds the critical number ($\sim 10^3$), for both the upper (or the lower) and the whole mantle (see Sec. 2.1). Thus the Earth's mantle must convect vigorously. The relative motion of the near-surface layer (lithospheric plates) is the manifestation of mantle convection. Several geophysical or geological observations indicate that Earth's surface is divided into several plates which move relative to each other with the speed of 1–10 cm/year. A lithospheric plate has a large creep strength at the Earth's surface, and deformation within a plate is minor except for continental collision zones such as Tibet. Most of the geological or geophysical processes such as earthquakes, volcanism, and mountain building occur at the boundaries of plates.

Plates that carry mostly oceans (such as the Pacific plate) are created at ocean ridges and subduct into the Earth's deep interior at ocean trenches. Subducting plates are marked by the planar zone of high seismic activity called the Wadati–Benioff zone which extends to ~ 700 km in some areas (e.g., beneath the Japan, Tonga, and Kermadic trenches).

4.3.2 Seismic Tomography and Deep-Mantle Dynamics. Although the surface motion of plates is well established, the relation between plate motion and mantle convection is

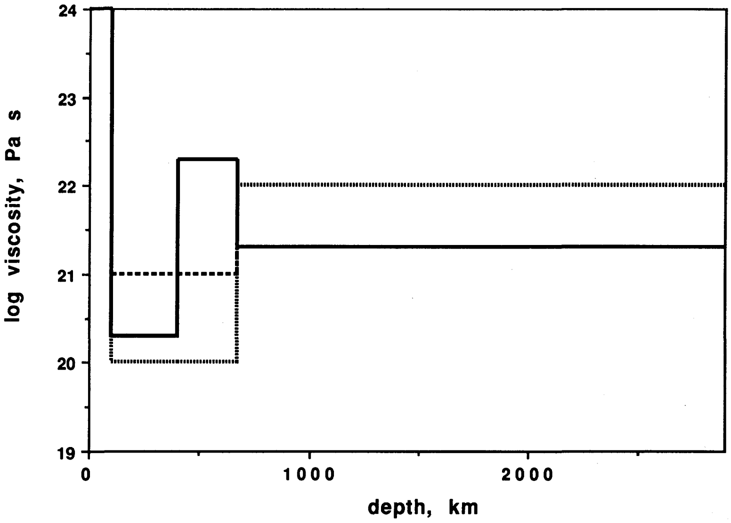

FIG. 9. Depth variation of viscosity of the mantle. The three curves are the viscosity-depth profiles consistent with various time-dependent deformation (such as post-glacial rebound and geoid anomalies), and show the range of uncertainties involved in these studies. Average viscosity of the mantle is determined to be $\sim 10^{21}$ Pa s by the analysis of the post-glacial rebound. The existence of a low-viscosity layer at $\sim$100–200 km and of relatively high-viscosity layer(s) in the deep mantle are suggested by laboratory studies and from the analysis of geoid anomalies. However, the viscosities in the deep mantle (below 400 km) are poorly constrained.

not well known. One of the major issues is the depth extent of subduction and the style of mantle convection. One hypothesis is that the subducting slabs penetrate into the lower mantle and the convection occurs in a single cell as a whole mantle. The other alternative is that the subducting slabs do not penetrate deeper than ~700 km, implying that the upper mantle (including the transition zone) and the lower mantle convect separately.

One of the powerful ways to distinguish these hypotheses is to study the fine structure of the mantle using seismological techniques. This is called seismic tomography, in which fine details of three-dimensional structures of the Earth can be revealed. In seismic tomography, deviation from a simplified layered Earth model such as PREM is mapped. There are two different types of deviations: lateral heterogeneity and anisotropy.

The lateral variations of temperature and chemistry are the most likely causes of lateral heterogeneities. When the major source of lateral heterogeneity is the heterogeneity in temperature, low velocity reflects high temperature and high velocity reflects low temperature.

The correlation of lateral heterogeneity with tectonic setting is clear in the shallow portions [Plate I(a)]. Ocean ridges and young oceanic lithosphere show up as low-velocity anomalies, and old continents such as North America and Africa show up as high-velocity anomalies. The origin of velocity anomalies in the deep portions is not clear, but an important example is the depth extent of subducting slabs [Plate I(b)]. A cold slab is expected to show up as a high-velocity anomaly. The recent studies on slab penetration suggest that slabs do penetrate deep into the lower mantle in some areas (e.g., Kamchatka-Kuril) but they are deflected at the ~670-km boundary and do not penetrate into the lower mantle in other areas (e.g., under the Izu Bonin island arc in western Pacific).

Another fine structure that is related to Earth's dynamics is anisotropy. Most minerals have anisotropic elastic properties, and therefore if they are aligned nonrandomly in a rock, the rock will show anisotropy. Such anisotropy was first observed in the oceanic upper mantle in 1960s and was interpreted in terms of the preferential alignment of olivine as a result of mantle flow related to plate tectonics. Such studies have been extended during the past few years to probe the anisotropy in the deeper portions of the Earth and on a global scale. In most cases, the direction of the fast seismic-wave velocity in the upper mantle is parallel to the flow direction. Therefore an anisotropy map such as Plate I(c) is considered to show the pattern of mantle convection.

Computer modeling of mantle convection plays an important role in the study of mantle dynamics. The equation of motion of a viscous fluid (Navier–Stokes equation) for a given set of material parameters (such as viscosity, density, and thermal expansion) may be solved with appropriate boundary conditions. The results of such studies can be used to predict possible convection patterns for a given set of material parameters and boundary conditions. Alternatively, such calculations may be used to put constraints on some material parameters such as depth variation of viscosities, by comparing the predicted results for various parameter sets with geophysical observations. These studies indicate that the material properties such as viscosity vary significantly with depth and that these variations in physical properties with depth have critical effects on the convection pattern.

4.3.3 Geochemical Observations on Mantle Heterogeneities. The best documented large-scale chemical heterogeneity of the Earth's mantle is the differences in trace-element abundance pattern between the source of the mid-ocean ridge basalt (MORB) and ocean island basalt (OIB). MORBs' trace-element abundance pattern shows that they originate in a region where incompatible elements are depleted. This indicates that MORBs are formed by the partial melting of rocks that have already undergone significant differentiation. In contrast, OIBs originate from a region which is enriched (or undepleted) in incompatible elements. Geochemical observations also indicate that these two regions have been separate for the time scale of a billion years. However, geochemical observations do not tell where these source regions are located. One possibility is that the depleted region corresponds to the upper mantle, and the undepleted region to the lower mantle. An alternative hypothesis is that these two regions are mixed like raisin bread, and that the mantle is homogeneous on the large scale.

PLATE 1. Some results of seismic tomography. (a) Global maps of lateral heterogeneity of seismic wave velocities (distribution of anomalies in shear wave velocities at various depths in the upper mantle and transition zone; from Dziewonski and Woodward, 1991). Note that the scale for the velocity anomalies varies with depth. (b) Anomalies of compressional wave velocities in the vicinities of subduction zones (Izu-Bonin and Kurile). Top, locations of earthquakes; middle and bottom, velocity anomalies based on two different standard models together with the foci of earthquakes (shown by white dots) (van der Hilst *et al.*, 1991). High velocity anomalies (i.e., a subducting slab) appear to be deflected horizontally at ~670 km in the Izu-Bonin arc but they seem to be continuous down to ~1000 km in the Kurile arc. (c) Anisotropy of Rayleigh-wave (with period 167 sec) velocities in the asthenosphere. The directions of the bars indicate the directions of the fast Rayleigh waves, which is parallel to the orientation of convective motion (Montagner and Tanimoto, 1990).

The whole-mantle convection is consistent with the latter idea, whereas the layered-mantle convection is consistent with the former idea.

While the chemical heterogeneity is evident in incompatible elements, the abundance pattern of compatible elements (Mg, Si, Ca, Al, Ti, and heavy rare-earth elements) of mantle xenoliths, sources of MORBs and OIBs, show little heterogeneity. This indicates that major fractionation involving melting in the transition zone or in the lower mantle did not occur, or else vigorous convective mixing occurred after or during the differentiation.

5. SUMMARY

The Earth is a chemically differentiated and dynamically evolving planet. The most significant differentiation processes are the formation of the crust and the core. The crust is composed of silica-rich rocks, the core is composed mainly of iron-rich alloys, and the mantle is composed of (Mg,Fe)O–SiO_2 rich rocks. There are some fine details in the structure of each layer, an important example of which is the discontinuities in the mantle at 400- to 670-km depth range. High-pressure experiments show that most silicate minerals undergo a series of phase transformations at this depth range. Thus a significant part of these discontinuities is due to phase transformations. A remaining question is whether all of these discontinuities are attributed to the phase transformations or some of them are due to changes in chemical composition. Geophysical and geochemical studies are under way to solve this problem.

The Earth is stratified also in terms of rheological properties: strong near-surface layer (lithosphere), solid but relatively weak underlying mantle, liquid outer core, and solid inner core. Convection occurs both in the mantle and in the outer core (and presumably in the inner core). Convection in the mantle is responsible for plate tectonics, and convection in the outer core is responsible for the generation of the geomagnetic field. The nature of convection in the mantle is determined by the balance of the driving force and the resistance force for convection, both of which are determined by the physical properties of rocks such as density and rheological properties. These physical properties change significantly with depth as a result of phase transformations and the increase in pressure and temperature, leading to complicated convective motion in the Earth. A realistic picture of convective motion in the mantle is beginning to be inferred through the development of geophysical (seismic tomography) and geochemical observations combined with materials science studies of the properties of minerals under high pressures and temperatures.

GLOSSARY

Adams-Williamson Equation: The equation that describes the compression of a homogeneous body in a gravity field.

Archean: The period earlier than 2.5 billion years in the Earth's history. The earliest period from 4.6 to 4.0 billion years ago is sometimes called Hedean. If we adopt this classification, the Archean is defined as the period from 4.0 to 2.5 billion years.

Asthenosphere: A soft layer below the lithosphere (50- to 200-km depth).

Basalt: A fine-grained, mafic igneous rock composed largely of plagioclase feldspar and pyroxenes.

Brittle Deformation: Deformation due to fracture. Brittle deformation occurs at low temperatures and/or low pressures.

Carbonaceous Chondrite: One type of meteorite, which is mainly composed of silicates. It contains various minerals that are chemically in disequilibrium. This type of meteorite is believed to be the most primitive material in the solar system.

Ductile Deformation: Deformation due to plastic flow. Ductile deformation of rocks occurs mostly at high temperatures (and high pressures).

Geoid: The equipotential surface of the Earth's gravity field.

Incompatible Elements: The elements which tend to be partitioned into magmas relative to coexisting minerals upon partial melting. These elements are not accommodated in lattice sites of the minerals because of mismatching of the ionic radii with the lattice site.

Inhomogeneity Parameter: A parameter that indicates the deviation from adiabatic compression of a homogeneous body.

Komatiite: An igneous rock with ultramafic composition. The eruption of such ultramafic lavas is mainly observed in the Archean period (more than 2.5 billion years ago).

Lithosphere: Near-surface strong layer of the Earth (about 50–100 km thick). The (old) oceanic lithosphere is strong and moves without much deformation. The continental lithosphere is weak and is deformed when a significant force is applied.

Magma Ocean: A hypothetical thick layer of magmas that may have occurred on the Moon or on the Earth in their early history.

MORB: Mid-Oceanic Ridge Basalt. The basalt generated at the mid-ocean ridges. The oceanic crust is mainly composed of this basalt.

OIB: Ocean Island Basalt, which forms volcanoes in ocean islands (e.g., Hawaii). Its major-element composition is similar to MORB, but its trace-element composition is characterized by the enrichment of incompatible elements.

Peridotite: A ultramafic rock composed mainly of olivine and pyroxenes.

Plate Tectonics: A unified theory of the Earth's tectonics in which the relative motion of the near-surface layer (lithospheric plates) is responsible for major tectonic activities.

Pyrolite: A hypothetical primitive mantle rock proposed by A. E. Ringwood. Its composition corresponds to a mixture of basalt and peridotite. The mixing ratio is rather arbitrary but a typical one is one part basalt and three parts peridotite.

Q: The measure of energy dissipation. Q^{-1} represents the fraction of energy dissipated per unit cycle of deformation.

Seismic Tomography: Seismological technique to reveal three-dimensional fine structures of the Earth.

Wadati–Benioff Zone: A planar zone beneath ocean trenches where seismic activity is high. The Wadati–Benioff zone represents a subducting oceanic lithosphere.

Xenolith: A fragment of rock that is carried up to the surface by volcanoes. Xenoliths provide useful information as to the temperature and chemical composition of the Earth's deep interior.

INTRODUCTION

Electricity is a unique energy intermediary. In most countries it is produced by conversion of chemical energy to thermal energy and then to mechanical energy to drive electric generators. The thermal energy is extracted mainly from a variety of carbon-based fuels that occur naturally. In several countries the thermal energy is derived mainly from uranium (France, Belgium, Spain, Sweden, Taiwan). Solar energy is used via four methods: hydroelectric, photovoltaic, and solar thermal generation, and heat pumps. Wind power

and wave power are used to capture the mechanical energy of wind or waves to drive electric generators.

The conversion of various forms of energy to electricity involves a wide variety of physical and chemical processes. Thermal cycles produce heat energy at high temperatures by the combustion of fossil fuels, by the fission of uranium and plutonium atoms, by the fusion of light elements, or by use of mirror concentrators for solar thermal energy. Still another variety of solar energy conversion accumulates solar heating in density-stratified brine pools. Heat energy can also be extracted from the earth as geothermal energy or from the ocean by using the temperature difference between warm surface layers and cooler deep water (ocean thermal).

Heat energy is converted to mechanical energy by the expansion of a working fluid, primarily through use of the Carnot cycle. The Brayton, Rankine, and Heber cycles have been used in special applications, depending on the working fluid and the temperature differences available.

Photovoltaic electricity involves the direct conversion of solar radiation to elevated electron energies and then to electric current. While there was some decline in commercial developments and prospects during 1985–1990, there are now important new developments that are reviving interest and prospects. These developments include multilayered solid-state structures that use a larger portion of the incident solar radiation spectrum, high-temperature concentrator systems with initial conversion efficiencies more than twice as high as conventional solar cells, and low-cost mass production of thin-film devices. As the performance and lifetime testing of such systems proceeds, there is a good prospect that solar energy will begin to fulfill some of the hopes that it has generated for many decades.

Magnetohydrodynamic generation involves the direct conversion of the mechanical energy of a conductive gas, plasma, or liquid moving through a magnetic field to a potential difference and electric current. When fusion devices become practical, a combination of magnetohydrodynamic (MHD) ducts for direct conversion of the plasma energy to electricity almost certainly will be used, plus thermodynamic "bottoming" cycles to make use of the by-product heat.

Mechanical energy is captured from the motion of wind or waves to drive electric generators. The chemical energy of hydrocarbon fuels is also converted directly into electric current in electrolytic cells (fuel cells). Electrolytic cells also mediate as a storage and transport medium in a wide variety of chemical batteries under active development for electric-powered vehicles.

Three types of electricity production dominate in industrialized countries: thermodynamic cycles with combustion of fossil fuels, thermodynamic cycles with fission heat sources, and hydroelectric dams. However, nearly all of the other approaches mentioned earlier have found some economic niches in which they can be economically useful. Strong economic and environmental incentives drive active developments in all of the technologies involved in electricity production, distribution, and use. Despite the seeming scientific and technological maturity of this field, there remain many important scientific problems in the basic physical and chemical processes, as well as in the applied technologies themselves.

The classical domain of power engineering has been the development and large-scale application of conversion and distribution technologies. Increasingly, these applications depend on collateral developments in the science and technology of the conservation of energy by end users; the refinement of designs, materials, and processes to minimize adverse environmental effects; and the improvement of the efficiency of utilization of electricity in residential, commercial, and industrial applications. As a uniquely convenient and controllable form of energy, electricity can be made available almost anywhere and in any amount through distribution cables. Most control actions can be completed in a few milliseconds, and much faster when necessary. Environmental impacts are largely associated with the generation processes, less so with distribution, and least of all at the end-user locations.

The convenience and control attributes often have led to new types of production techniques, and to an enormous array of consumer products, communication products, and a wide variety of convenience products that are taken-for-granted amenities in industrialized and developing countries. The almost universal use of refrigeration in food trans-

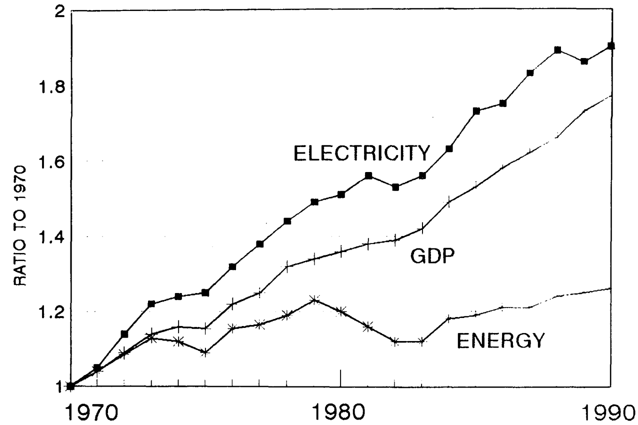

FIG. 1. Relative growth of energy and electricity use vs gross domestic product, for OECD countries, 1970–1990.

port and preservation has the effect of extending the supply of usable food for a given amount of farmland by roughly one-third, relative to the supply-to-land ratio without refrigeration. On the other hand, there is serious basis for concern that the productivity of agriculture is increasingly fossil-fuel intensive for both fertilizers and production. The concern is that this trend, together with expected escalation in oil and gas prices, will make food much more costly after the turn of the century, and will end the era of the United States as a net exporter of food (Gever *et al.*, 1989).

The application of comfort air conditioning has changed the economic geography of the United States by making living and working in warm, humid, or subtropical climates more feasible and attractive. The great demographic shifts from north to south in the United States are largely attributable to this factor.

The conversion and transport processes for electricity produced from heat energy or potential energy are costly relative to direct use of fuel for space heating or process heat. Yet the unique attributes of convenience, controllability, and cleanliness for the end user often make electricity preferable and also economically competitive for many applications that also could be accomplished by direct use of combustion fuels. The pervasiveness of uses

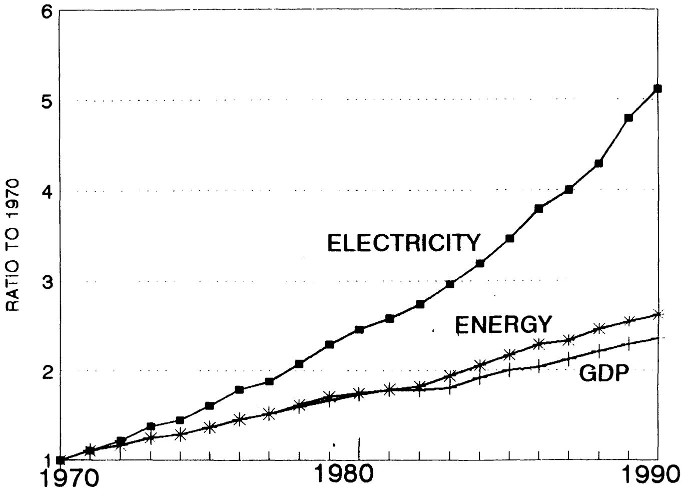

FIG. 2. Relative growth of energy and electricity use vs gross domestic product, for developing countries, 1970–1990.

of electricity in residential, commercial, communications, and industrial sectors is reflected in the close proportionality of electricity output to gross national product (GNP) for many decades, for most countries, and also on a world aggregate basis (see Figs. 1 and 2). In contrast, total energy consumption has generally declined relative to GNP, especially in industrialized countries.

In the United States, the production of electricity accounts for 37% of all energy consumed. The percentage is trending upwards towards an estimated limiting value of about 45% for the United States early in the next century, and estimated limiting values over 60% in Europe. Figure 3 shows the present annual rates of consumption of electricity in the United States by three main sectors of the economy: homes and apartments, commercial buildings, and industrial operations. The forecasts for the years 2000 and 2010 are the median-value forecasts, taking into account aggressive conservation measures, improved efficiencies for many end uses, and population growth. The remaining fuel consumption is divided between space and process heating and transportation. Europe differs from the United States in the shorter distances involved in highway transport, the high degree of electrification of rail, urban, and interurban transport, and the larger fraction of supply from nuclear energy. In the United States, 1.6×10^6 km (nearly 10^6 miles) of transmission lines link every region of the country, distributing some 2.5×10^{12} kW h of electricity each year.

As the scope and complexity of the electric power industry have grown, so has the field of power engineering. Traditionally, power engineering has consisted mainly of the classical hardware-oriented disciplines of electrical, mechanical, and civil engineering, resting on classical scientific foundations in physics, chemistry, and materials science. The need to adapt to changing requirements and growth in the variety of uses and in the demand for electricity has widened the field to include a much wider range of applied and basic science disciplines. These are as diverse as environmental and atmospheric sciences, network analyses, safety and risk assessment, artificial intelligence and neural networks, biological science, applied physics and engineering, and data, information, and simulation sciences for operations and for education and training. In the last decade there has been an increasing rate of development in analysis-based management control disciplines and in the institutional structures to track, coordinate, and regulate the huge array of disparate activities. These are required to assure both economic operations and compliance with environmental and social goals.

Electric power is unique in that, unlike other energy forms, bulk storage has been impractical except indirectly (for example, pumped storage of potential energy of water in elevated reservoirs; see STORAGE OF EN-

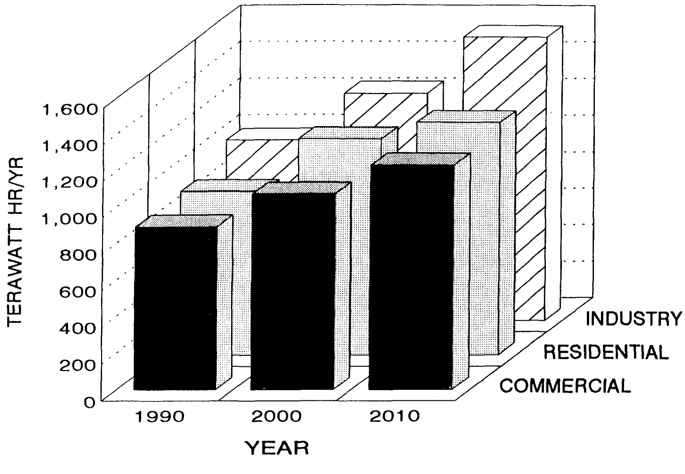

FIG. 3. Annual consumption of electricity by sector, U.S., 1990–2010.

ERGY). Unlike other commodities, it is consumed virtually at the instant of production. As world societies become increasingly electrified and computerized, reliability of supply is becoming recognized as an important factor in the productivity of an economy rather than just a convenience. Economic analyses of the consequences of occasional widespread blackout events have indicated economic losses to the regions involved ranging upwards of several hundred million dollars per event. One of the key socio-economic issues of future development of electricity supply infrastructure is the need to address the valuation of what economists call "consumer's surplus," that is, the unrecognized economic value of high reliability of supply.

Electricity production and distribution have traditionally been highly regulated in virtually all aspects, in respect to technology, location, price, allowable return on investment, and environmental and conservation practices. This approach was rationalized at a time when the production and distribution of electricity was viewed as a highly arcane technology. In return for being a designated regional monopoly, producers have a legal "obligation to serve" that has yielded a highly reliable system of supply. The nominal target of 1 hour in 10 000 unavailability of supply is usually attained.

In the last decade, the formation of independent and relatively unregulated producers has been encouraged by legislation. This has produced lively growth rates for the capacity of independent producers. This remains a small percentage of total supply and consumption, but is important in providing some degree of competition for lowest marginal costs of added capacity. Together with effective conservation measures this has significantly reduced the demand-driven pressure for building new capital-intensive base-load generating capacity. A large proportion of the independent producer capacity is fueled with natural gas that permits low capital costs. Prior to the development of highly efficient gas turbines, independent production had been at the expense of relatively high fuel costs and increased rates of depletion of a premium fossil fuel. Other independent producers, including those working on many solar- and wind-power projects, have also been encouraged by limited periods of substantial subsidies. Wind power is unfirm (that is, not reliable), and so the economics depend on how it is integrated into an overall power system that provides the needed reliability. Experience on the effective durability and lifetime of some designs is accumulating to support favorable economics in special locations with steady winds.

The rise of more competitive situations for electricity supply has changed the basis of electricity supply decisions. Where reliability of supply was once the primary factor for justifying the maintenance of a margin of base-load capacity, many other complex considerations are now involved. These include the compound goals of providing energy supply at the lowest cost while meeting a wide range of environmental and financial regulations set by federal, state, regional, and local government agencies. The trend to frequent disallowance of some capital investments from utility rate bases has often made the return on investment in new capacity risky and unattractive. Along with the surplus of capacity that developed in most regions of the United States in the 1980s and the effects of investments in energy-conserving technologies, little new generating capacity is being planned. As the average age of fossil-fuel plants rises above 30 years, replacements for obsolescence, as well as to meet modest rates of further growth, are expected to increase rapidly in the years after 1995.

1. ROLE OF ELECTRIC POWER IN THE ENERGY ECONOMY

As power lines reached through cities and across the countryside, electricity transformed the way we live and work. In the home, electric devices took over many back-breaking household tasks and created a level of comfort, convenience, and degree of emancipation for housekeepers undreamed of three or four decades earlier. In industry, electricity has helped to produce an unprecedented revolution in productivity. With the widespread transition to industrial electrification in the 1920s, natural productivity increased an average 5.2% a year, in sharp contrast to increases of less than 1% annually that marked the previous two decades. During the same period, the intensity of total energy use declined sharply in manufacturing. (Intensity here refers to the ratio of total energy input to manufacturing output.) This ratio fell by an average value of 4.3% per year during the 1920s.

Declines in energy intensity have continued with increased use of electricity by industrial societies. The greater efficiency and controllability of electrified production, even accounting for the thermodynamic and conversion losses inherent in converting primary fuels to electricity, allowed manufacturers to do more with less energy. In 1900, only 5% of industry used electric motors; today, more than 90% depends on them. Over that time, the raw energy input per unit of GNP has been roughly cut in half.

More recently, the widespread use of microprocessors has produced another revolution in manufacturing, allowing far more precise and flexible control of many kinds of industrial and commercial operations. The advent of inexpensive microprocessors has also created rapid growth and diversification in the communications, information management, and entertainment industries.

2. STRUCTURE OF THE ELECTRICITY INDUSTRY

Further development of efficiency in production and use are central to the growth and competitiveness of modern industrial economies. The pace of application of new developments contends with the environment of an extremely large U.S. base of existing capacity, namely 700 GW (7×10^{11} W). For several decades, the construction of electricity-generating and -distribution capacity represented 20%–30% of the total annual investments in national industrial infrastructure. Understanding the likely technological options, the possible rates of change, and probable impacts of new developments depends on some knowledge of the structure of the industry and its infrastructure.

Some countries have national electricity agencies. These have commonly been organized as semiautonomous industries—for example, in France, the former Soviet Union, South Korea, and many developing countries. A more common pattern is an electrical supply industry with several or many independent units, generally only partially government owned—for example, Belgium, Canada, Finland, Germany, Great Britain, Italy, Japan, Spain, Sweden, Taiwan, and the United States. Except for its size, the complexity of the U.S. industry is not atypical of the complexity evident worldwide.

Many diverse organizations form the structure of the electricity industry in the United States. This includes more than 3000 separate electric utilities, including private, municipal, and federal. Large networks of suppliers provide the equipment, parts, and a wide variety of support services and fuels to these companies. The engineering and specialized equipment and technical support services are now international in scope with companies partly or wholly owned by French, Canadian, German, and British parent organizations active in the United States, and U.S. companies active in many other countries. Electric utilities are generally categorized according to form of ownership, as listed in Table 1. Each state has some type of regulatory agency that controls the price, or rates, that utilities are permitted to charge their customers for electricity. In all cases they have jurisdiction over investor-owned utilities; in some states they also control rates charged by state- or municipal-owned systems and by cooperatives. Members of these commissions are sometimes elected, but are commonly political appointees.

The development of new technology to support the electric power industry is conducted by suppliers and individual utilities, and to a large extent is supported by the Electric Power Research Institute (EPRI) in the United States, and similar organizations in other leading countries, such as CRIEPI (Central Research Institute for the Electric Power Industry) in Japan. Founded by a consortium

Table 1. Ownership of U.S. utilities (Macdonald, 1991).

Form of ownership	Number	1989 market share (kW h basis)
Investor (shareholder) owned	208	81.1
Municipal and regional government owned	1899	7.8
Consumer owned (cooperative)	934	5.0
Federal government owned	37	6.1

of both private and public utilities in 1973, EPRI conducts research and development on a collaborative basis for electric utilities and electricity consumers. The U.S. national laboratories also conduct some relevant basic and some applied work. Except for fusion energy, their major focus is on regulatory and environmental science and technologies. The utility industry is represented by several trade associations, including the American Public Power Association for municipally owned utilities, the Edison Electric Institute for stockholder-owned companies, and the National Rural Electric Cooperative Association for cooperatives.

2.1 New Trends in the Electric Power Industry

The 1990s are a period of many rapid changes for the U.S. electric utility industry. These trends often dictate new or intensified incentives (or sometimes disincentives) for specific technological and scientific developments. Fossil-fuel costs have fluctuated dramatically during the last two decades, and long-term trends are slowly but inevitably upward as the world population increases. Increasing costs are driven by increasing demands from growth of populations, the increasing demands from the industrialization of developing countries, and the effects of increasing recognition of environmental and regulatory constraints in many countries. Many constraints now affect costs or tend to limit the recovery and production of coal, oil, natural gas, and uranium, or the construction of hydroelectric dams. Average capital costs of new or refurbished generating capacity have risen because of environmental and regulatory requirements and because of the regulatory and litigation delays now common in most large-scale industrial activities. The administrative delays commonly experienced in the construction of nuclear plants and now also for many fossil-fuel units have been a major factor driving increased capital costs. (The description of the dominant influence of such "transaction costs" led to a Nobel prize in economics in 1991.) The U.S. economy still has the benefit of a large fleet of coal (55% of output) and nuclear generating plants (21% of output) that produce electricity at low marginal costs. Many of these were built at relatively low capital costs before or early in the period of the dramatic escalation of "transaction costs" that started in the mid-1970s.

Along with society generally, the electrical industry has experienced a rapid increase in the number and complexity of environmental regulations, virtually all of which increase operating costs and involve new capital investment. For example, a single piece of legislation that sets the timing of reductions in the allowable emissions of sulfur compounds has estimated cost impacts of 50 to 200 billion dollars. These are obviously desirable enhancements for the environment, but also involve obvious major costs to the economy. In some cases, producers are squeezed financially and thus limited in the ability to implement the best available technologies.

At the same time, the general trend in the United States toward selective areas of deregulation, along with legislation aimed at fostering alternative and more efficient energy systems, has led to a number of new approaches to meeting growth in electricity demand. For example, an increasing number of industrial companies and some institutions such as hospitals and universities generate their own electricity. This is commonly called "co-generation" and combines electricity production with raising steam for process use. The electricity is used in the institution and any excess is sold to the local utility. This pattern is especially attractive to producers that have a steady year-round use for the steam production—for example, for steam injection commonly used to enhance production from depleted oil fields.

The number of independent power producers (IPPs) has also grown. Some utilities now routinely use competitive bidding from IPPs to get new blocks of power output. Others have even established nonregulated affiliates as IPPs, which compete to supply power in the service territories of other utilities—a strategy that remains controversial among utilities and regulators. The rise of IPPs and increasing competition from inside and outside the industry have given rise to other issues related to the use of distribution networks.

High-voltage transmission systems allow electric energy to be moved ("wheeled") for hundreds of miles. This is used routinely to compensate for shortfalls in available capacity in one region by temporary borrowing from another region. The borrowing is preferably temporary because there are significant losses of energy as the distance of transmission is increased. The ability to exchange power with nearby regions reduces by as much as 15% the total amount of generating capacity required to maintain a desired level of reliability of supply. These exchanges are covered by both short-term and long-term sale-purchase agreements between utilities. At present, most transmission lines are owned and controlled by the utilities that built them, many of which have formed power pools to dispatch power in a coordinated way from generating stations in the pool. Allowable contributions to the pool involve an agreed-upon economic rank order. The overall economics of the pool is optimized by sets of prioritization algorithms that take account of the generating units with the lowest marginal costs of production, tempered by the increasing costs and electrical losses as average transmission distances increase. The unifying principles shared by utilities in a power pool are the "obligation to serve" and the need to demonstrate lowest achievable costs.

Legislation has been proposed to treat transmission lines as common carriers. This has aroused concerns that if use by IPPs becomes large, system reliability may suffer, since IPPs are generally exempt from the obligation to serve and would experience appreciably higher costs if this obligation were to be imposed.

Most utilities now actively promote and subsidize measures to reduce electricity consumption—for example, by improved thermal insulation, more efficient lighting systems, better automatic controls to eliminate unneeded uses, and voluntary demand-side controls that reduce peak loads. As has been more common in other industries, mergers are now being more often considered where these can provide improved economies of scale, avoidance of some kinds of duplication, and better matches of assets and needs.

3. SUPPLYING ELECTRICITY

The classical electric generator consists of a shaft on which an array of coils is mounted, rotating within a magnetic field. The mechanical energy that provides the motive force to spin the shaft is extracted from a working fluid, typically steam or air, at high temperature and pressure, by allowing it to expand through a series of turbine stages.

In hydroelectric generating systems, the potential energy of water stored behind dams is converted to mechanical energy in hydraulic turbines. Most electricity worldwide is produced in thermal power stations using steam as the working fluid. Fuel is burned in boilers to produce heat, which is used to convert water at high pressure into steam at high pressure. The expansion of high-pressure steam through modern multistage turbines extracts mechanical energy at near-theoretical efficiency. The steam condenses in a water-cooled condenser to be recycled as feedwater for the boiler.

This cycle, known as the Rankine cycle, is most often fueled by coal, oil, or gas. Almost any fuel—wood, peat, or refuse, for example—can be used in an appropriately designed boiler. Efficiency depends primarily on the temperature range in which the steam is expanded and condensed. It can be improved if heat is recovered from exhaust streams and that energy is ultimately recovered in the steam turbine. The overall thermal efficiency of this cycle of converting the chemical energy in fuel to electricity has increased from average values near 20% as late as 1950 to over 33% currently, and leading units reach well over 40%.

Gas turbines (see TURBINES, GAS), on the other hand, use the energy contained in hot pressurized combustion gases that result from burning pressurized liquid or gaseous fuels with air at high pressure. Expansion of the gas through the gas turbine section provides the energy to turn the turbine and compressor shaft. The excess energy over the amount required by the compressor is available to turn a generator shaft to produce electricity. This cycle, known as a Brayton cycle, has an efficiency of 25% to 35%, depending on the temperature of the combustion gas entering the expansion section. By utilizing a heat-recovery steam generator in a steam turbine cycle, additional energy can be recovered from the exhaust gas from the gas turbine, which normally exits at 426.7 °C (800 °F) to 565.5 °C (1050 °F). The hot exit gas is used to heat water and produce steam in a boiler. This feeds a second cycle ("a bottoming cycle" since it recovers some of the lower-temperature energy). Such combined-cycle systems can achieve efficiencies of up to 50%. While there is added complexity and capital cost for a combined cycle, the added efficiency can offset the added cost of liquid fuels relative to coal or nuclear fuel.

Gas turbines with simple Brayton cycles have been used for several decades for "peaking units." These are low–capital-cost and high–fuel-cost units. They are economic if operated only at times of peak loads, since they serve to reduce the amount of base-load capacity that is generally much higher in capital costs. As high-temperature materials have been improved in the last decade, the practical size of gas turbine units has increased from the 10- to 15-MW range to 150–200 MW and larger. The efficiencies of simple cycle unit have also increased. Gas turbines combined with steam cycles are now increasingly widely used to generate electricity.

An important new development is to avoid the costs of premium liquid fuels by adapting gas turbines to use coal as fuel. This is done in conjunction with coal gasification plants, which produce clean gas from coal. The gas produced is lower in energy content per unit volume than natural hydrocarbon fuels ("low-BTU gas"), requiring special design considerations for turbines and boilers. However, the fluid-bed gasification process permits the use of low grades of sulfur-containing coals, while at the same time providing a major environmental advantage by eliminating the emission of sulfur compounds from the plant. Sophisticated systems known as integrated coal gasification combined-cycle power plants have been developed that produce electricity from coal at thermal efficiencies of 35% to 45%.

Electrochemical cycles can also be utilized to make electricity directly from fuel gases (see ELECTROCHEMISTRY). Methane or hydrogen from natural hydrocarbons, or from coal gasification or coal, is the reactant supplied to the anode of a fuel cell. Air or oxygen is supplied to the cathode. Electrons freed at the anode travel through an external circuit, generating direct-current electricity, and then combine with the oxidant at the cathode. Unlike steam and gas turbine cycles, the fuel-cell system does not require any mechanical moving parts to produce electricity, and there are virtually no environmental emissions to be controlled. Initial applications include urban substations where the absence of noise, vibration, or environmental effects can justify the higher costs. Such electrochemical cycles can achieve thermal efficiencies of 50% to 60% including the conversion of dc to ac, and there is potential for further improvements.

The following sections describe five typical configurations for modern electricity-generating stations.

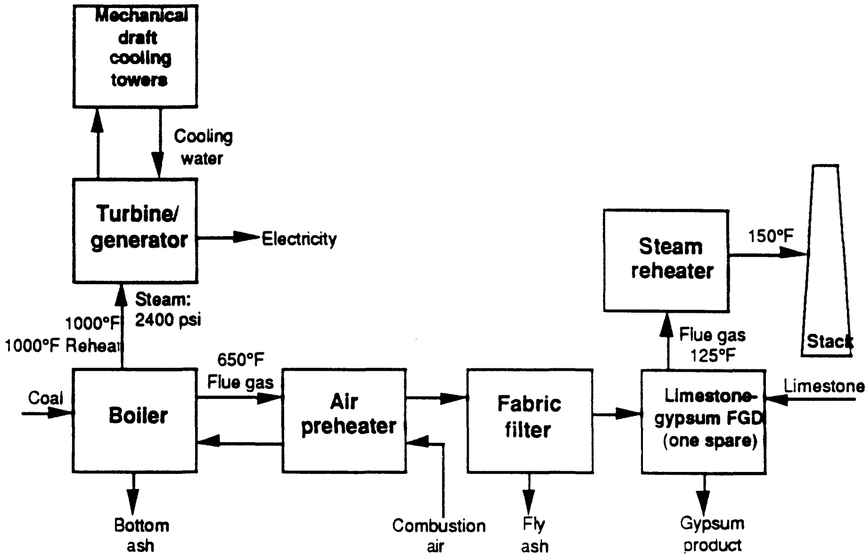

FIG. 4. Conventional pulverized-coal power plant with wet limestone flue-gas desulfurization (FGD). Primary steam outlet conditions are 1000 °F, 2400 psi; reheat to 1000 °F (538 °C).

3.1 The Pulverized-Coal–Fired Plant

Figure 4 depicts the typical pulverized-coal plant (see COAL). It can be fueled by high-sulfur bituminous coal with steam conditions of 16.5 MPa (2400 psig) and 538 °C (1000 °F) and reheat to 538 °C (1000 °F). In this cycle, steam leaving from the high-pressure section of the steam turbine is reheated in the boiler before entering the intermediate-pressure section of the turbine. A limestone scrubber removes 90% to 95% of the sulfur. This process is referred to as flue-gas desulfurization (FGD). Combustion modifications that reduce peak local temperatures are used to limit the formation of nitrogen oxides. The heat rate for such a plant is between 2343 and 2520 kcal per kW h (9300 to 10 000 Btu/kW h). The next generation of pulverized-coal plants is scheduled to use supercritical double-reheat steam cycles at 31.0 MPa and 593.3 °C (4500 psig and 1100 °F) and advanced stack-gas cleanup processes. Such systems will reach heat rates of approximately 2268 kcal per kW h (9000 Btu/kW h) or 37.9% thermal efficiency.

3.2 The Atmospheric Fluidized-Bed Combustion Plant

Atmospheric fluidized-bed combustion (AFBC) (see COAL), shown in Fig. 5, generates power using a steam cycle with the same steam conditions as the pulverized-coal plant. Their heat rates, 2369–2470 kcal/kW h (9400 to 9800 Btu/kW h), are similar. The combustion system is a bed of coal (either bubbling or circulating) fluidized by the incoming stream of air that supports combustion. The beds operate at fairly uniform temperatures between 1500 and 1700 °F (815–927 °C). Steam is generated and superheated in conventional water-wall and convection-pass tube banks, although in-bed evaporation tubes are used in some configurations. Economizing and air preheating are conventional. Limestone sorbing is added to the bed of coal to capture 90% to 95% of the potential SO_2 emissions. Because FBC units require almost twice as much sorbent as that required for the scrubbers for pulverized-coal plants, the amount of solid waste is correspondingly larger. NO_x emissions, however, are substantially lower because of the fluidized bed's relatively low and uniform combustion temperature, compared with peak temperatures over 1038 °C (1900 °F) for combustion in conventional boilers and superheaters.

3.3 The Pressurized Fluidized-Bed Combustion Plant

Pressurized fluidized-bed combustion (PFBC) (see COAL), shown in Fig. 6, is similar in many respects to AFBC, except that the boiler operates at an elevated pressure of 0.62–1.72 MPa (90–250 psig). The hot pressurized gas exiting from the boiler is expanded in

a gas turbine. This turbine provides all the pressurized fluidizing air for the boiler and also generates up to 20% of the gross plant power output. Since PFBC extracts part of its energy at the higher temperatures acceptable in modern gas turbines, as well as the lower temperatures practical for steam cycles, heat rates in the range of 2192–2520 kcal/kW h (8700–10 000 Btu/kW h) are calculated from the known separate efficiencies of the two cycles involved. For the scrubbers for pulverized-coal plants, the amount of solid waste is correspondingly larger. In this case, also, the emissions of NO_x are substantially lower.

consisting mostly of hydrogen and carbon monoxide (see COAL). The gas first passes to a gas turbine, producing part of the output of the plant. If gas leaving the gasifier is at a high temperature, as is the case in some gasification processes, the remaining available heat is recovered by heat transfer in a boiler to generate steam. The steam is used in a steam turbine to produce the remainder of the plant output. This part of the cycle is called a "bottoming" cycle since it recovers the lower-temperature portion of the heat energy available in the synthesis gas. This part of the cycle operates at nominal values of 16.5 MPa and 537.8 °C (2400 psig and 1000 °F) and with reheat to 537.8 °C (1000 °F). Particulates are completely removed from the gas in a water wash, and the gas is further cooled to allow removal of sulfur and nitrogen. Conventional chemical- or refining-industry technology is used to remove virtually all sulfur-containing compounds and to recover elemental sulfur. Ammonia formed in the gasifier from some of the nitrogen present in coal (which could contribute to NO_x emissions) is also removed. The gas is then reheated and saturated with water vapor utilizing low-level heat that was recovered as the gas was cooled. The water vapor further limits NO_x emissions in the subsequent combustion step. Finally, the gas is burned in the combustion turbine of a conventional combined cycle. The combustion turbine produces approximately 60% of the plant's power output.

If a modern gas-turbine 1260 °C (2300 °F) firing temperature is used, IGCC plant thermal efficiencies are from 37.5% to 39.7%, depending on local ambient temperatures of air and of the heat sinks available. Advances in gasification, gas-turbine technology, and plant configuration—including tight integration of the oxygen plant with the gas-turbine compressor and fuel system, 1371 °C (2500 °F) firing temperature turbines, and hot or warm gas cleanup—are expected to lead to IGCC thermal efficiencies up to 42.6%.

3.5 The Integrated Gasification Molten-Carbonate Fuel Cell

In Fig. 8, high-pressure clean, preheated, moist synthesis gas ("syngas"), much as it might come from an IGCC plant's saturator, is first reduced to atmospheric pressure through an expansion turbine that produces about 10% of the plant's gross power output. The fuel gas is then fed to the fuel cell anode. The electrolyte is a molten mixture of alkali-metal carbonates that provide a convenient range of temperatures and low vapor pressures. About 35% of the heating value of the gas is converted directly into electricity, by the electrochemical processes, producing 55% of the total power output. Because fuel-cell power output is in the form of direct current, inverters are used to produce alternating current. The remaining unconverted fuel in the exhaust gas from the anode is catalytically

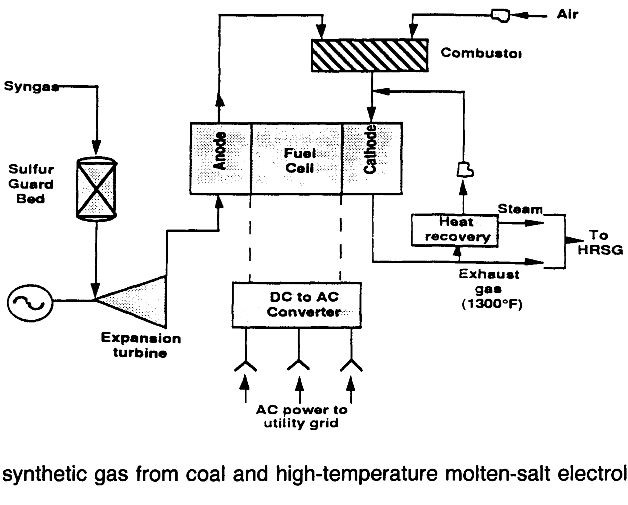

FIG. 8. Fuel cell using synthetic gas from coal and high-temperature molten-salt electrolyte.

burned, mixed with the incoming combustion air, and returned to the fuel cell's cathode. The anode exhaust plus the cathode recycle provides carbon dioxide to the cathode. The cathode exhaust gas goes to a heat recovery steam generator (HRSG), where heat is recovered for a conventional steam bottoming cycle, providing 35% of the total power output. The fuel cell operates at about 1200 °F and the catalytic combustor only slightly higher. At these low temperatures, essentially no nitrogen oxides are produced. Sulfur compounds must be completely removed from the fuel gas since they poison the electrodes of the fuel cell. The emissions of SO_x and NO_x are negligible.

4. NUCLEAR POWER

Fission reactions, which involve the breakup of the nucleus of high-mass atoms, yield energy per atom reacting more than a millionfold greater than that for chemical reactions involving the burning of fuel. The oxidation of an atom of carbon releases only 4 eV, for instance; the fissioning of an atom of uranium yields about 200×10^6 eV (i.e., 200 MeV). U.S. deposits of uranium, and the availability of unused uranium enrichment facilities from the Manhattan Project, led the federal government to provide incentives and virtual directives to electric utilities and to major suppliers to develop and adopt nuclear power for baseload generation of electricity. First-generation nuclear units, a few of them still operating, were built in three to four years from time of commitment to time of practical output. Capital costs were less than 50% higher than equivalent coal units, and overall economics were favorable for many projects because of the lower costs of nuclear fuel. However, many of the units completed after the mid-1970s experienced extensive regulatory delays, up to 17 years in one case, and the period costs (the cost of servicing the bonds that finance the construction) served to double or triple the total capital costs. Regulatory requirements have continued to escalate and are still subject to rapid change. This situation, together with the excess capacity that was available in most regions prior to 1991, makes investment in added nuclear units in the United States unlikely until and unless these circumstances change substantially. Meanwhile, France, Belgium, and Sweden get over half of their electricity from nuclear units, and Japan continues to build essentially identical types of plants economically in three to four years. Since 1991 approximately 21% percent of the U.S. generation has been supplied by over 100 nuclear power units. A similar percentage exists in Great Britain.

The only fissionable material found in nature is uranium-235. Nuclear fuel is typically enriched to about 5% in uranium-235. Part of the "fertile material" uranium-238 is converted into fissile plutonium-239 by the absorption of neutron and two subsequent β decays. The fission of the *in situ*-produced plutonium adds about one-third to the energy output available per unit of fuel. In several countries, notably France, Japan, and to some extent Belgium and Germany, the plutonium in spent fuel is recovered by chemical processes, and it is recycled by adding it to new fuel, reducing the amount of uranium-235 required. The dominant fuel cycle is the uranium-plutonium cycle in light-water reactors that are the predominant source of nuclear electric power in the world today. India, with abundant reserves of thorium, carries on development of a thorium-232 and uranium-233 fuel cycle.

Other reactor types have been developed and have reached practical commercial use. These include heavy-water natural-uranium reactors in Canada, graphite-moderated light-water–cooled reactors in the former Soviet Union, and gas-cooled, graphite-moderated reactors in Great Britain and for a time in France. None of these has had significant market penetration outside the country of origin, and capital costs are generally lower for light-water reactors in stable regulatory environments. Prototypes of other reactor types have been developed and built, notably sodium-cooled reactors without moderators to slow down the fast neutrons resulting from fission, that operate in a fast-neutron spectrum. These have been built in small numbers in France, Russia, Japan, India, and the United States. The attraction for development of the fast-neutron spectrum reactors is that highly extended reactivity lifetimes are feasible (ten or more years between refuelings), or else they can be configured to make excess fuel, as so-called "breeder" reactors. The early perceptions of limited supplies of natural uranium have been superseded by a picture of a glut of uranium supply and very large known reserves in the United States, Australia, Canada, and Russia.

The possible incentive for the breeder reactor as a producer of extra fuel is now generally viewed as arriving only in the third or fourth decade of the 21st century, since light-water reactors can be fueled with available uranium for the next 30 to 40 years. However, the breeder-reactor development continues to have the attraction of providing security of fuel supply for countries such as Japan, France, and India, which have only minor reserves of uranium. The use of fast-neutron "burner" reactors for energy production and for disposal of decommissioned nuclear weapons materials is also under discussion.

The two basic types of present commercial nuclear power reactors differ mainly in whether the coolant water is allowed to boil. These are the boiling-water reactors and pressurized-water reactors, illustrated in Figs. 9 and 10. Shielding is provided to limit external radiation levels, and pools of water are used for fuel storage and for transferring fuel in and out of the reactor core. (See NUCLEAR ENERGY, FISSION.)

Containment buildings surround the reactor system and most auxiliary systems except for the turbine-generator and the feedwater systems. The structures are designed and tested to hold safely the total thermal and pressure energy available if a complete rapid depressurization of the coolant system should occur by rupture of the primary piping. The containment also serves to provide a secure enclosure to minimize potential escape of radioactive material to the surroundings. The effectiveness of containment was evident in the accident at Three Mile Island, where the core had a complete meltdown and release of roughly 20 MCi of radioactivity to the containment, but only minor release of rare gases to the atmosphere. In contrast, the reactor at Chernobyl, without a full containment structure, released massive amounts of radioactivity, seriously damaging the environment for more than a 20-km radius, and with detectable radioactivity deposition over much of the world.

4.1 The Boiling-Water Reactor

The boiling-water reactor (BWR) design depicted in Fig. 9 can produce about 3580-MW thermal and 1220-MW net electrical power. Each fuel assembly typically contains 63 fuel rods, and there are 732 fuel assemblies. The neutron reactivity is controlled and shut down by means of control blades arranged in cruciform cross section. The blades move up from the bottom of the reactor in the gaps between four fuel assemblies. The water coolant is circulated up through the fuel assemblies by 20 jet pumps at about 7 MPa (70 atm), and net boiling occurs within the core. Fine control of the nuclear reaction is provided by varying the speed of the pumps. Because of the strong negative void coefficient of the reactor power, the power level (for a given setting of the control blades) stabilizes at constant volume fraction of steam in the core. The negative void coefficient arises because the reactor lattice is designed to be slightly undermoderated. That means that removing water (producing steam void) lowers the reactivity (the neutron multiplication rate) of the reactor. Conversely, adding water tends to increase reactivity, which tends to produce more heat and thus more steam void. This situation permits convenient control of reactor power by varying pump speed and incoming water flow. When pump flow is increased, the reactivity increases until a new higher power level is reached. If pump flow decreases, the power level decreases until the same volume fraction of steam is reached. The steam is separated from the steam–water froth by centrifugal and vane separators and then is fed to the turbine through four steam lines. About one-third of the energy released by fission is converted into electrical energy by the turbine generator, and the remaining low-grade heat is rejected in the condenser, for a thermal efficiency of about 33%. This part of the cycle is the same in both fossil-fuel and nuclear power plants requiring the dissipation of low-grade heat to the environment. Some limited use of the energy rejected by the condenser is possible but is not as yet economic. Because the steam produced is at lower temperatures and pressures, nuclear plant cycles are several percent lower in thermal efficiency than those in the most modern fossil-fuel plants, and require slightly greater

radioactivity from the atmosphere of the containment buildings and from the turbine air ejector stream.

4.2 The Pressurized-Water Reactor

Unlike the BWR, in which steam from the reactor is fed directly to the turbine, the pressurized-water reactor (PWR) shown in Fig. 10 uses a second closed system. The water coolant in the primary system is pumped through the reactor vessel, transporting the heat to a steam generator, and is recirculated in a closed primary system. A separate secondary water system is used on the shell side of the steam generator to produce steam, which is fed to the turbine, condensed, and recycled back to the steam generator. A pressurizer is used in the primary system to maintain about 15 MPa (150 atm) pressure to suppress boiling in the primary coolant. Two circulating primary loops are shown here, but up to five loops have been used. Different fuel assembly configurations are used by different manufacturers. One type of assembly, for instance, contains 264 fuel rods, with 193 fuel assemblies used for the 3411-MW (thermal), four-loop plant. In this arrangement, the control rods are grouped in clusters of 24 rods, with 61 clusters. In PWRs, the control rods enter from the top of the core. Reactor operations are carried out by using both the control rods and a system to increase or decrease the boric acid content of the primary coolant. The latter is used to compensate for long-term changes in the reactivity of the core, while the former allows fine tuning of the power level and rapid shutdown of the nuclear reaction when needed.

4.3 The Future of Nuclear Power

With over 25 years of favorable operating experience worldwide, as well as extensive development and testing programs, light-water reactors such as those described above are likely to remain the dominant nuclear power technology for the next several decades. Well-tested and mature designs are offered and sold by suppliers in France, Germany, Japan, and the United States, and the capability for supplying most of the systems exists in many more countries—for example, England, Spain, Belgium, Sweden, and Russia. Currently, the U.S. Department of Energy and the utility industry are conducting an advanced light-water reactor program to develop the designs, safety standards, and regulatory requirements for a possible next generation of nuclear power plants. Substantially simpler plant design will help increase lifetime reliability, reduce capital costs, shorten construction times, lower operating and maintenance costs, and increase safety margins by a proposed factor of 10, as measured by the disciplines of probabilistic risk analysis (PRA).

Next-generation designs have already been committed to construction in France (1450-MW rating), and a joint U.S.–Japan design of an advanced BWR design (1350-MW rating) is under construction in Japan.

Breeder-reactor development continues at a modest pace in France, Japan, and India, and on a small scale in the United States and Great Britain. At one time the world uranium reserves, even used in breeder reactors, were considered to be merely about equal in energy content to the world reserves of oil and gas. Subsequently, world uranium reserves of over 10×10^6 tons are reasonably assured at moderate prices (for breeder-reactor use). This represents an energy resource larger than the total reserves of all fossil fuels including coal, lignite, tar sands, etc. However, there is no pressing economic need to deploy a fleet of breeder reactors for at least 30 years, since present low-conversion reactors do not seriously deplete low-cost uranium reserves until then. The present approach in countries carrying on breeder-reactor development may be described as maintaining the breeder reactor as a contingency against unexpected rises in the market price of uranium, and as a contingency for when fossil fuels plus alternative sources such as renewable resources and fusion are not able to fully satisfy world needs after the first quarter of the 21st century.

5. TRANSMISSION AND DISTRIBUTION

The power delivery system of U.S. utilities comprises the largest interconnection of electrical transmission, distribution, and control equipment in the world—a vast network made up of transformers, circuit breakers, fuses, overhead and underground lines, computers, relays, and data recorders. Electric power is delivered on demand, reliably and safely, through the voluntary cooperation of over 3000 utilities, which own and operate thousands of power plants, over 4.8×10^6 km of overhead transmission and delivery lines, over 300 000 km of underground cable, tens of thousands of substations, and a myriad of associated hardware, computers, and software components.

Fundamental changes in both the delivery and use of power are now under way. There is growing demand for more and better-quality power, with fewer outages, even momentary ones. This demand is expected to increase as consumers employ an increasingly wide range of new technologies. Utilities, too, are changing. Engineers are employing an unparalleled range of new technologies to meet changing demand—including the application of a variety of basic innovations: versatile, high-power semiconductors; higher-speed computer processors and systems capable of real-time control of complex systems; high-energy surge arrestors; stronger and more durable materials; advanced automation techniques; and simplified but more effective communications systems.

5.1 Flexible ac Transmission Systems

With few new power plants or lines being built, utilities have to route more power over longer distances on available lines. Because these lines were never designed for such heavy loadings, the on-line control of power flow, voltage, and stability becomes more of a challenge. Operators must rely largely for control on mechanical devices that do not respond quickly to changing conditions.

A comprehensive control system governed by high-power thyristors and advanced microprocessors—a flexible ac transmission system, or FACTS—is being developed to enable utilities to direct power with unprecedented precision. Unlike mechanical devices, thyristor-based controllers can easily manipulate power flow and voltage while maintaining stability. Thyristors are essentially high-speed switches arranged in a variety of configurations to switch and adjust electrical components on high-voltage, high-current power lines. Single solid-state thyristors are capable of handling power-class voltages up to 8500 V and currents up to 3500 A. They can be connected in series and parallel combinations to achieve very high power levels.

These controllers—which include phase-angle regulators, modular series capacitors, static VAR (volt-amperes reactive) compensators, damping devices, dynamic load brakes, circuit breakers, load tap changers, surge suppressors, and fault-current limiters—manipulate power flow by adjusting voltage, optimizing power angle (the phase difference between voltages at opposite ends of a line), changing impedance, or some combination of the three. To compensate for electrical phenomena that inhibit power flow in ac networks, they can direct power flow by manipulating resistance, capacitance, and inductance. They can also minimize potentially damaging power oscillations by damping unwanted frequencies. Because thyristor-based devices guided by microprocessors respond so speedily to changing system conditions, they will enable operators to use transmission lines consistently to more nearly their full thermal-electrical capacity while maintaining required stability margins.

5.2 Energy Efficiency in Transmission and Delivery

In some utility transmission and delivery systems that involve long distances, energy losses can amount to as much as 10% of the energy produced. Even a 1% energy-loss reduction could save as much as $1.5 billion a year nationwide. Currently, approximately 1 million new distribution transformers are installed annually on U.S. utility systems. The use of amorphous steel alloys that can reduce the core loss of distribution transformers by approximately 60% to 70% could dramatically decrease transformer load losses. Replacement by amorphous core units could result in an energy savings of nearly 6×10^8 kW h per year.

Meanwhile, other developments promise to improve energy efficiency further in transmission and delivery. A low-loss winding developed for larger power transformers, for instance, can significantly lower not only losses, but size and weight as well—reducing energy operating losses up to 30%.

6. POWER APPLICATIONS OF SUPERCONDUCTIVITY

The discovery of high-temperature superconductivity (HTSC) (*q.v.*) in ceramic materials in 1986 has led to an international research program to understand the physics, chemistry, and physical processing methods to evaluate their characteristics and possible methods of manufacture. The materials carry electric currents with no resistance losses at liquid-nitrogen temperatures (77 K). Considerable progress has been made, including the production of tapes, wires, and films that have useful engineering characteristics. Both continuing basic research and the development of practical applications of high-temperature superconductors remain one of the most important scientific challenges of power engineering.

Because superconductors can transmit direct current without resistive loss and alternating current with extremely low loss, superconducting devices could generate, transmit, and store electricity far more efficiently than conventional devices. Moreover, because superconductors can carry large currents per unit cross-sectional area, the iron in conventional electromagnets can be removed and the devices operated at higher field strengths, yielding more compact motor and generator designs and higher efficiencies. The key attributes—and the limiting properties so far—have been the current-carrying capacity of HTSC materials and the limited ability to withstand magnetic fields without collapse to the nonsuperconducting state. The limitations of brittle ceramic materials have been largely overcome by the use of metal-ceramic composites in the form of wires or ribbons.

Table 2. Cost and performance comparison for a 300-MW generator (millions of 1989 dollars).

Parameter	Conventional generator	Using LTSCs	Using HTSCs
Efficiency (%)	98.6	99.6	99.7
Capital cost	880	1240	740
Annualized capitalized losses	1400	430	280
Annual capital costs	165	230	140
Total annual costs	1565	660	420

Several superconducting devices—including generators, motors, transmission lines, magnetic storage transformers, fault-current limiters, and power electronics—have been proposed, and some working models have been built for use in the electric utility sector. Because HTSCs are still in the early stages of development, their ultimate cost and performance is highly sensitive to the degree to which the key attributes mentioned above can be improved. The incentive remains strong for improved materials since such superconductors may yield a variety of more efficient, more compact, lighter, and less expensive power applications devices.

6.1 Generators and Motors

Utility generators range from less than 100 to 1350 MW and already have a mechanical-to-electric energy conversion efficiency of between 97% and 99%. Even so, small efficiency improvements could yield significant cost savings. The two largest losses in ac generators, in the rotor and the armature, represent approximately 30% each. During operation, the rotor's dc field coil rotates with an essentially constant field, surrounded by an ac armature. A recent study of cost and performance for 300-MW generators suggests that HTSCs could improve the efficiency of conventional generators by 1% and reduce total annual capital costs to less than one-third, as Table 2 illustrates.

Table 3. Comparison of costs and efficiency for 10 000-MVA ac transmission lines (millions of 1989 dollars).

Parameter	Aerial/ Underground	HPOF	Underground LTSC	HTSC
Efficiency (%)	98.3	96.4	97.3	99.3
Capital cost	852	2546	1821	1759
Capitalized losses	419	986	713	190
Total costs	1271	3532	2534	1949

Although generators employing low-temperature superconductors (LTSCs) are estimated to have a capital cost 40% higher than the conventional generators, the HTSC, because of its reduced insulation and refrigeration requirements, may actually have a lower annual capital cost. As Table 2 illustrates, even a small gain in efficiency can yield a substantial reduction in capitalized losses. The lower effective capital cost and higher efficiency of the HTSC could eventually lower the cost-effective size of generators and motors from 300 MVA to perhaps several MVA, greatly enhancing the HTSC's market potential.

6.2 Transmission Lines

Superconducting power transmission lines may be able to transmit electricity more efficiently, at lower voltages, and at lower cost than conventional, underground, high-pressure, oil-filled pipe transmission lines (HPOF). Both ac and dc versions have been proposed. In each case, a set of coaxial cables would be contained in an insulated enclosure surrounded by a vacuum chamber. A 115-m superconducting ac transmission line rated at 100 MVA at liquid-helium temperatures was designed, constructed, and tested at Brookhaven National Laboratory during the 1970s.

As Table 3 demonstrates, the aerial and underground system has by far the lowest total cost (including capitalized losses), but the HTSC system is the most efficient. Because the HPOF system is the most expensive and least efficient, it is used only when aerial systems cannot be used, such as in heavily congested urban areas or waterway environments. Some laboratories believe that further gains in reducing current-related losses in niobium-tin tapes could reduce the cost of the LTSC system, offsetting much of the efficiency and cost advantage of HTSCs.

6.3 Superconducting Magnetic Storage

Superconducting magnetic energy storage (SMES) efficiently stores energy in a magnetic field associated with a circulating current. An inverter or convertor is used to transform ac power to direct current, which is then used to charge a large solenoid magnet. Upon discharge, power is withdrawn from the magnet and converted to ac power. SMES has a round-trip (charge to discharge cycle) efficiency between 90% and 93%—the highest of all proposed utility-side storage devices—and its ability to switch from charge to discharge mode in less than a second provides valuable system-stabilization characteristics. Large-scale SMES devices (500–10 000 MW h) would provide the most economical form of storage.

An 8.3-kW h (30-MJ), 10-MW SMES was designed, constructed, and installed for operation in the Tacoma substation in the Bonneville Power Administration utility system, where it was operated for about one year, during 1983 and 1984, at frequencies from 0.1 to 1 Hz, for more than 1×10^6 cycles. In 1982, the Japanese began a three-year design study for a 5-GW h device. In 1986, work was begun on a 5-GJ (1.4-MW h) SMES test facility, which is expected to be operational by 1992. Japanese interest has concentrated on small-scale SMES devices for load leveling of commercial building loads, although there is a long-range plan to start building a 500-MW h utility-scale SMES in 2004.

HTSCs could also be used to replace conventional leads in an LTSC SMES that has current densities of hundreds of A/cm^2 and operates in regions of low magnetic field and temperatures below 77 K, where HTSCs perform best. An HTSC current lead, designed and fabricated by Argonne National Laboratory, is being tested at Westinghouse. Such current leads could also be useful for other LTSC devices, including generators, motors, transformers, and transmission lines.

6.4 Transformers

Because conventional large-scale transformers are already 99.7% efficient and their current is always ac, which results in losses in the superconductor, the use of superconductors in transformers poses a challenge. As Table 4 indicates, LTSC and HTSC transformers have 38% and 60% lower total costs, respectively, than conventional transformers. The table enumerates the costs of operating a conventional, LTSC, and HTSC transformer for a 30-year period. Because losses are so low in conventional transformers, HTSCs must have very low ac losses. For this design, materials that can sustain a minimum current density of 10^5 A/cm^2 in a field of 0.2 T are required.

Table 4. Cost and performance comparison for 1000-MV A transformers (millions of 1989 dollars).

Parameter	Conventional transformer	LTSC	HTSC
Efficiency (%)	99.7	99.85	99.9
Capital cost	8	16	14
Capitalized losses	92	46	26
Total annual costs	100	62	40

6.5 Other Applications of Superconductors

Superconductivity may be applicable to power electronics, power switching, current limiters, sensors, and computers. For example, HTSC could be used to create a transistor that changes states from on to off, for use in motor controllers. A superconducting switch could have switching speeds as fast as 1 ns, no losses in the on state, and losses in the off state proportional to the product of the normal-state resistivity and the critical current density, ρJ_C. Careful design of the interface between the power leads and the superconducting switch would be crucial to minimize heat leaks and the associated refrigeration power.

7. END-USE TECHNOLOGIES

Electricity is used in a wide range of applications across the residential, commercial, industrial, and transportation sectors, as Table 5 illustrates. Electric motors represent the largest users of electricity across all sectors, accounting for over 50% of electricity use. Lighting accounts for about 20%. About 20% of total electricity goes to cooling and refrigeration, while about 15% goes to space and water heating. (The total exceeds 100% because of the double counting of electric motors contained in refrigeration, cooling, and heating equipment.)

7.1 Electric Motors

Electric motors have become essential to a wide array of end-use applications. The efficiency of today's electric motors ranges from 65% in the smaller fractional horsepower sizes to over 95% in motors with over 125 hp.

Table 5. Electricity usage.

	1987 (GW h)	Percent of sector use	Percent of total use
	Residential		
Refrigerator + freezer	206 391	24.3	8.2
Space heating	159 824	18.8	6.3
Lighting	127 350	15.0	5.1
Water heating	103 499	12.2	4.1
Space cooling	83 381	9.8	3.3
Cooling	30 390	3.6	1.2
Other	138 165	16.3	5.4
Total residential	849 000	100.0	33.6
	Commercial		
Lighting	238 488	31.5	9.4
Space cooling	154 299	20.4	6.1
Information systems	100 000	13.2	4.0
Space heating	77 245	10.2	3.1
Ventilation	76 959	10.2	3.1
Refrigeration	60 883	8.0	2.4
Water heating	24 068	3.2	1.0
Cooking	16 172	2.1	0.6
Other	7 886	1.2	0.2
Total commercial	756 000	100.0	29.9
	Industrial		
Motor drives	570 934	67.5	22.7
Electrolytics	98 193	11.6	4.0
Lighting	84 527	10.0	3.6
Process heating	83 008	9.8	3.2
Other	···	0.8	
Total industrial	845 000	100.0	33.5
	Other		
	76 000	···	3.0
Total consumption	2 526 000	···	100.0

Motors in the 5- to 100-hp range are typically 80% to 90% efficient. Since the 2% of motors over 5 hp use over 45% of all electricity consumed in the United States, small increases in their efficiency yield significant energy savings.

Motor efficiency can be improved either by reducing the losses within the motor itself or by electronically varying the motor speed to match the demand (rather than using a variety of backpressuring devices, such as valves or vanes, which overload the motor and waste energy). With a wide variety of advanced, highly efficient motors becoming available—including magnet, homopolar, and reluctance motors—efficiency improvements of 2% to 4% (absolute) are achievable over the next decade. Moreover, adjustable-speed drives can reduce the annual electricity consumption in a typical motor drive application by 20%. Taken together, more efficient motors coupled with adjustable-speed drives could save 10% of U.S. electricity consumption. Application of such improvements has been limited to date because of the added first cost of the motors and control systems, and the huge existing fleet of installed motors. However, many new applications, such as highly efficient heat pumps, air conditioners, and refrigeration systems, are becoming commercially viable.

7.2 Lighting

Energy-saving compact fluorescent lights are slowly but steadily replacing traditional incandescent lamps. A wide variety of lighting sensors and controls are also available that can automatically dim or turn off lights as appropriate. It is estimated that energy-efficient lighting technology available today could save over 10% of all the electricity now used in the United States.

7.3 Cooling and Refrigeration

The energy efficiency of cooling and refrigeration equipment continues to increase, as Fig. 11 demonstrates, creating the potential for energy savings of as much as 10%. However, because they deplete stratospheric ozone, the chlorofluorocarbons (CFCs) and hydrochlorofluorocarbons (HCFCs) used exten-

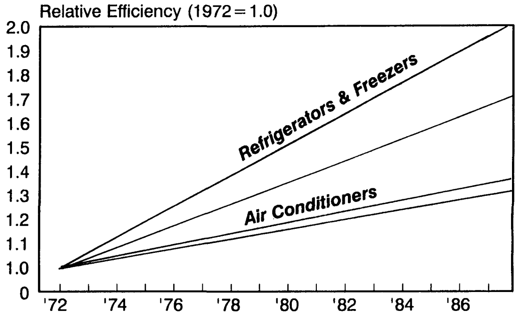

FIG. 11. Trends in energy utilization efficiency of major appliances.

sively as refrigerants in cooling and refrigeration equipment are scheduled to be phased out of production. CFCs will be eliminated by the year 2000; HCFCs will be phased out between 2020 and 2040. The shift to alternative refrigerants may limit future efficiency gains. Figure 12 shows the effects of the near-term phaseout of CFCs on both equipment and cost. Note that the increased cost of equipment may be of even greater concern than uncertainties in efficiency.

7.4 Space and Water Heating

Over the past decade, highly efficient heat pumps have been developed for a wide range of residential, commercial, and industrial applications. Heat pumps remove heat from the environment in order to heat space or water. The efficiency of a heat pump is defined by its coefficient of performance, which is the ratio of the total energy produced as heat divided by the electric energy input. By drawing on heat from ambient air, water, or ground source, heat pumps typically produce 2 to 3 times more heat than the electricity they consume. In that sense, they represent an impressive family of solar-energy devices. Heat pumps used in space and water heating have the potential to save significant amounts of energy—between 40% and 50% for water heating, for instance, and as much as 30% for space heating.

7.5 Other End-Use Technologies

A wide variety of information technologies—from office equipment to computers, printers, and storage and display devices—now account for about 4% of total electricity use. While the number of such devices in use is certain to grow, the improved energy efficiency from increasingly sophisticated computer control is expected to result in a larger reduction in total electricity consumed than is used by computers and their peripherals.

The role of electric-powered transportation is also likely to increase, both for vehicles and for mass transit. This is in response to growing concerns over the environmental and geopolitical impacts of the growing consumption of oil, gasoline, and natural gas. A typical electric vehicle might consume 10 to 30 kW h each day. Large transit systems could increase electricity use by as much as 50 000 GW h annually.

8. ENVIRONMENTAL ISSUES

Like every human activity, the generation and transmission of electricity have an impact on the environment (see AIR POLLUTION: COMPONENTS, CAUSES, and CURES). The primary environmental concerns related to electric-power generation and transmission focus on acid rain, air quality and human health, CO_2 and global climate, electric and magnetic fields, nonradioactive waste disposal, and nuclear waste disposal.

8.1 Acid Rain

Acid rain, a dilute solution of sulfuric acid and nitric acids with a *p*H generally below 5.0, is common in many industrial regions, most notably in western Europe and eastern North America. All rain is naturally acidic because

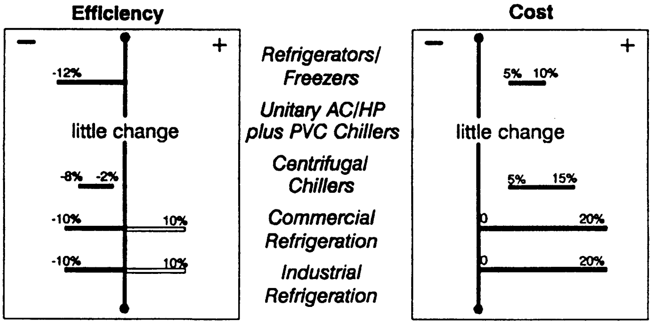

FIG. 12. Distribution of impacts of the phaseout of chlorofluorocarbons (CFCs) on equipment cost and energy efficiency.

of the equilibration with atmospheric carbon dioxide. When anthropogenic emissions of sulfur and nitrogen oxides are oxidized to sulfuric and nitric acids, respectively, they increase rain acidity considerably. Such rains can have a harmful effect on the environment through lake acidification, forest damage, reduced crop yields, material damage, visibility degradation, and impact on human health.

Over the past 15 years, massive research efforts in the United States and Europe have increased our understanding of the acid rain phenomenon. The most visible and serious damage has been lake acidification and resultant damage to fisheries. Fortunately, impact is generally limited to areas where soils have low neutralizing capacity, such as glaciated areas of parts of eastern Canada, the northeastern United States, and northern Europe. Even here, the percentage of known acidified lakes is small. In northern New York state, the most heavily affected area in the United States, for instance, well under 10% of lakes (by surface area) are acidified. Still, there is concern that continued emissions of sulfur and nitrogen oxides at their present levels could cause more widespread and permanent damage to the ecosystem.

Forest decline is another concern. Although impact in North America has been limited, forest declines in some regions of western Germany have been considerable. Acidic deposition appears to be just one factor causing forest decline. However, overall forest mass has increased in Europe.

Sulfate particles derived from sulfur dioxide emissions contribute to reduced visibility, although the relation between visibility impairment and emissions is significantly nonlinear; hence, large emissions reductions are probably needed to effect any meaningful improvement in visibility. Impact on crop productivity and yield appears to be negligible. Because of atmospheric and other factors, it is difficult to assess the role acidic deposition plays in material damage. Indirect health concerns from acidic deposition are minimal.

8.2 Air Quality and Human Health

As the severe episodes in London of the 1950s demonstrated, air pollution can cause increases in morbidity and mortality. In terms of electric-power generation, concern centers on the health effects of atmospheric concentrations of sulfur dioxide, nitrogen oxides, ozone, and acid aerosols. Because of many confounding factors, however, epidemiologic studies have not been able to relate trends in morbidity and mortality or any specific dysfunction to any of these constituents at low levels.

8.3 CO_2 and Global Climate

The use of coal-powered electricity generation has contributed to increasing atmospheric concentrations of CO_2, which some experts believe could lead to dramatic global climate changes. Electricity generation currently accounts for about 30% of CO_2 emissions in the United States. World wide, power production accounts for less than 10% of the CO_2 entering the atmosphere.

Carbon dioxide emissions could be reduced in a number of ways, including scrubbing CO_2 from flue gas, switching from coal to natural gas, increasing the use of nuclear energy, adopting renewable generating technologies, and improving end-use efficiency. Unfortunately, conventional and advanced generating technologies do not seem to offer much hope for reducing or even stabilizing CO_2 emissions well into the next century. The general use of scrubbing can double the cost of electricity, for instance, and it creates large amounts of liquid or solid wastes that must be disposed of at as yet undefined disposal sites. Solar technologies, while promising, probably will not have any meaningful impact for decades. Energy efficiency, on the other hand, remains an attractive means to reduce atmospheric emissions. In the United States, a 10% improvement in energy efficiency would stabilize utility emissions at the 1990 level.

8.4 Electric and Magnetic Fields

Extensive animal studies have minimized earlier concerns about the health impact of exposure to electric fields. But recent studies have raised new concerns about the effects of magnetic field exposure. While several epidemiologic studies showed marginal statistical links between residential electricity distribution lines and cancer, especially childhood leukemia, others have found no correlation.

The electric utility industry has developed more sensitive measurement technologies and is currently funding an extensive epidemiologic study of childhood leukemia and magnetic field exposure in the Los Angeles area. Early results show a weak but not statistically significant association of leukemia with the highest measured fields. However, childhood leukemia is also weakly associated with home use of pesticides and parental occupation during the time of the mother's pregnancy, making interpretation difficult. Epidemiologic studies found an association of cancer with the electric wiring configurations outside the home, but the wiring configuration is only poorly correlated with magnetic field.

As these findings suggest, the impact of electric or magnetic fields at typical domestic levels on human health is far from clear. The electric utility industry continues to pursue research to assess the possibility of health effects of electric and magnetic fields and their potential risks, and possible remedies in designs.

8.5 Nonradioactive Waste Disposal

U.S. utilities produce over 80 million tons of solid waste, mostly ash from coal burning. Although ash is not classified as a hazardous material, it contains constituents that could pose a threat to human health through either the food chain or drinking water. Groundwater sampling at some sites has shown concentrations of sulfate, boron, and iron that exceed proposed water quality standards. Although there have been no cases of drinking-water contamination from these constituents, the utility industry is developing techniques to minimize leaching from disposal sites and to predict the fate of contaminants in ground water.

8.6 Nuclear Waste Disposal

Providing for safe disposal of nuclear waste materials is essential if nuclear energy is to maintain or increase its role in electricity generation. Low-level waste disposal is not a serious concern. Typically, wastes are placed in drums or in lined plastic containers and buried in shallow pits. Over the past few years, because of changes in management practices, the amount of low-level waste produced in the United States has decreased by nearly 50%, despite an increase in nuclear power generation. High-level wastes—including spent fuel with its uranium, transuranics, and other fission products—pose a more serious concern. These wastes are stored on site as a temporary measure until a decision is made about long-term, permanent storage. One proposed approach is deep subsurface storage in salt strata or domes, tuffs, or basalt beds. (See NUCLEAR WASTE DISPOSAL.)

9. STORAGE TECHNOLOGIES

Managing electricity supply is an increasingly difficult challenge for the utility planner and engineer. Pressures to reduce costs are forcing utilities to improve the productivity of both generation and electrical supply systems. Growing use of complex electronic equipment has placed greater emphasis on power quality. To help match electricity supply and demand on a daily basis—and to assure power stability on a millisecond basis—many utilities are investigating energy storage systems (see STORAGE OF ENERGY).

Storage technologies now available convert ac electricity into a suitable form for storage: the potential energy of elevated water or compressed air, the chemical energy of reactive molecules such as hydrogen, the kinetic energy of a flywheel, or the energy stored in a magnetic field. Stored energy can be recovered (with some inevitable losses) and converted again to electricity that can be fed to distribution systems.

Storage systems are comprised of two major subsystems: the power conversion required to change ac electricity into another form of energy and the reservoir to store that energy. Selecting a storage technology is primarily determined by the required response time of the power conversion system and the capacity requirements for the duration of power recovery (and therefore cost) of the power conversion and reservoir systems. In most applications, the power converter and reservoir are separately sized to meet the demands of a given application. Thus a storage device might be sized to provide 1000 MW for 5 s for transmission stability or 100 MW for 10 h for leveling the daily demand for power on the utility's generating equipment.

As Table 6 shows, storage systems being deployed for utility application include lead-acid batteries, pumped hydroelectric storage, compressed air, and superconducting mag-

Table 6. Key storage systems.

Technology	Batteries	Pumped storage	Compressed air	Superconducting magnet
Power converter	ac–dc converter and electrochemical reactor	motor-pump–turbine generator	motor-compressor and expander-generator	ac–dc converter
Reservoir	Reactive chemicals	Elevated reservoir	Underground cavern	Superconducting coil
Storage equation	$\eta F\epsilon m/\mathrm{MW}$ η=electron change F=Faraday's constant ϵ=potential m=mass of chemicals MW=molecular weight	pVh p=density of water V=volume h=head or height of reservoir	PV P=pressure V=volume	$\frac{1}{2}Li^2$ L=inductance i=current
Response (time to full power)	0.02 s	10 min	10 min	0.02 s
1991 U.S. capacity (MW)	10	18 000	100	400 planned for 1996
Capital cost (1991 $)				
Power ($/kW)	150	1000	500	150
Reservoir ($/kW h)	200	10–50	1–5	300
Efficiency (input/ kW h of output)	1.4 kW h	1.4 kW h	0.8 kW h 4100 Btu gas	1.1 kW h

nets. Flywheels have been considered extensively, but the energy storage density and the cost are limited by the strength of materials.

9.1 Lead-Acid Battery

One of the oldest and best known devices to store energy, the lead-acid battery, uses the reduction of lead dioxide to lead sulfate at the positive electrode and the simultaneous oxidation of lead to lead sulfate at the negative electrode. The electrolyte, sulfuric acid, is consumed, and energy is discharged. Energy is stored by reversing the reaction; that is, charging the battery. Under suitable operating conditions, a well-designed and -manufactured lead-acid battery can achieve 2000 cycles and last 10 years. Individual cells with capacities ranging up to a few kW h can be combined in lead-acid battery systems. The cells are arranged in series strings to achieve the desired dc voltage for conversion or for a given application. The number of strings depends upon the energy requirements. Several lead-acid battery systems have been installed for utility energy management, most notably Southern California Edison's 10-MW,40-MW h system in Chino, CA, which has been operating successfully since 1988.

9.2 Pumped Hydroelectric Storage

Pumped hydroelectric storage (or pumped storage, as it is often called) has been used in electric utility systems for over 50 years and now provides 18 000 MW of U.S. capacity. Electricity is used to drive a motor-pump combination that pumps water to an elevated reservoir. When energy is required, water is allowed to flow back to a lower reservoir through the same equipment, which then serves as a turbine-generator. In areas where topographic or ecological considerations rule out conventional pumped hydroelectric plants, the upper reservoir may be at or near the surface, and the lower reservoir can be located about a mile below the earth's surface in a hard-rock cavern.

9.3 Compressed-Air Energy Storage

Compressed-air energy storage (CAES) stores energy by compressing air into an underground cavern or reservoir (excavated rock—for instance, solution-mined salt—or aquifer). Favorable geological sites exist in about 75% of the United States. For the maximum recovery of energy, the energy of compression is augmented by heating the air with oil and gas combustion and expanding the hot gas through a gas turbine to drive a generator. CAES technology has recently been commercialized for electric utility combustion. The commercial units incorporate modified combustion turbines in which the compressor and expander are physically separated by clutches and a motor-generator. The first U.S. plant was built for Alabama Electric Cooperative in 1991 and produces 110 MW for 26 h. A 290-MW CAES plant using two underground salt caverns is currently operating in Huntorf, Germany.

9.4 Superconducting Magnetic Energy Storage

The magnetic energy storage system uses an ac–dc–ac converter system, like batteries, and a large coil of a superconductor such as niobium-titanium alloy. To maintain the superconductive state, the conductor is bathed in liquid helium at about 1.8 K. Superconducting magnetic energy storage (SMES) is particularly attractive for applications where high power is required for very short periods. Best known, of course, is the superconducting magnet at the Fermi National Accelerator Laboratory near Chicago, which is used to focus particles in the accelerator. A small 10-MW 3-s experimental system was recently built to inhibit subsynchronous resonance in a high-voltage ac line from the state of Washington to California. Small SMES systems are now becoming commercially available for improving utility-customer power quality and assuring transmission stability.

9.5 The Future of Energy Storage

Storage systems offer many advantages to electric utilities. Underutilized plants can be used to charge storage systems, thus increasing the capacity factor of base-load plants. Distributed, fast-responding storage systems can level the transmission load and help ensure stability, improving throughput of transmission facilities as well as overall power quality. Because the cleanest plants can be used to charge storage systems, these technologies provide a novel way to manage emissions of generating plants. Storage technologies can reduce the impact of fuel price changes, leverage purchases of wholesale energy, minimize cycling costs of generating plants, and provide economical emergency capacity. Moreover, the ability to store energy will facilitate the use of intermittent renewable energy systems like solar and wind power systems.

Even so, utilities have been relatively slow to deploy storage technologies, in part because the economic advantages have been difficult to evaluate. Conventional utility economic analyses, for instance, while sophisticated and complex, treat storage as electrical generation, not as energy management. Moreover, these analyses usually arrive at single numbers that represent the present value of adding energy storage facilities without taking into account corporate strategies and risks of change (load growth—for instance, load shape—, regulations, and fuel costs), as well as novel applications and opportunities. As the advantages of energy storage become more widely recognized, however—and economic planning tools become more refined—it is expected that energy storage will become an essential part of electric utility systems. With the appropriate support of regulatory agencies, utilities in the future will have practical economic options of maintaining 10% to 20% of their capacity in stored energy. This can become a significant plus for the national economy by adding a highly reliable element of power supply systems that also enables system management options to maximize the productivity of generating and distribution systems.

10. SUMMARY

In the course of 100 years, the field of power engineering has changed dramatically. To the classical disciplines of electrical, mechanical, and civil engineering has been added a wide range of other research fields, from nuclear engineering and data and information analysis to the environmental and atmospheric sciences. New ways to generate electricity have been developed. A vast distribution network that increasingly uses power electronics has been created. The uses of electricity have grown from what first appeared to be a few novelty items to an immense variety of residential, commercial, communications, and industrial end uses. Electricity and its manifold applications have done more, perhaps, than any other single technological factor in recent history to change the shape of human activities.

The future is likely to bring other changes. Environmental concerns, which have already had a profound effect on the electric utility industry, are expected to intensify, and applications of electricity will commonly be part of the remedial and control measures. Advances in superconductors and other materials research and development will offer new and better ways to generate and deliver electric power. The demand for greater energy efficiency will drive the trend toward increased electrification of industrial processes. New end uses—from electric vehicles to increasingly computerized sensors and control devices—will shape the way we use electricity.

A highly reliable and efficient system of generating and delivering electric power wherever and whenever it is needed will continue to be a driving force for both national and international economic stability and growth.

ACKNOWLEDGMENTS

GLOSSARY

Bottoming Cycles: Recovery and use of the rejected low-temperature thermal energy from high-temperature cycles to add to the net energy conversion efficiency.

Breeder Reactor: A reactor cooled by liquid metal such as sodium or lead. It sustains a chain reaction almost entirely with fast neutrons (> 0.5 MeV). With appropriate blanket arrangements, up to 1.5 new fissile atoms are produced for each atom fissioned, for a conversion ratio of 1.5.

Burner Reactor: A reactor similar in physics to a breeder reactor but designed for no net production of fissile material. The high conversion ratios are used internally to provide very long effective reactivity and fuel lifetimes, resulting in low fuel costs.

Combined Cycles: The combination of a primary high-temperature energy conversion cycle with a low-temperature cycle. The latter captures the rejected heat from the high-temperature cycle and commonly uses a different working fluid to attain higher overall conversion efficiency of heat energy to electricity.

End User: In the literal sense, a person or agency using electricity; alternatively, the device or appliance or system that uses electricity.

Fluid Bed: A bed of finely divided solid material held in suspension at lower density by the upward flow of a stream of gas. Fluid beds are used to carry out solid-to-gas heat transfer, chemical reactions, and mass transfer. Examples of applications of fluid beds include gas scrubbers, coal gasifiers, and combustion furnaces.

Megawatt: 10^6 watts; used for either thermal or electrical energy; abbreviated MW. For example, MWt refers to thermal megawatts; MWe refers to electrical megawatts.

Network Analysis: The mathematical description of current flows, especially of transients and abnormal oscillations in high-voltage power distribution networks.

NO_x: The mixture of nitrogen oxides that are produced as a by-product of combustion at high temperatures.

Negative Void Coefficient: Term describing a system that is designed so that an increase in void (or steam) content from a given steady-state condition reduces the reactivity or the multiplication constant of the chain reaction.

Neutron Reactivity: The multiplication constant of a chain reaction, which is 1.000 000 at steady state.

Ocean Thermal Cycle: A low-temperature, low-efficiency Carnot cycle that uses the difference between surface-water and deep-water temperatures.

Power Pool: A regional group of public and private utility generating companies that are linked by a transmission network. The network is operated subject to defined algorithms for the dispatch of power from different producers as a function of the system loads and spatial distributions and producer costs.

Primary System: The cooling circuit that passes through the core of a nuclear reactor.

Quality of Power: A group of attributes of electricity supply, including the annual rates and durations of power outages, the frequency of momentary interruptions, the stability of voltages and electrical frequencies, the degree of purity of wave form and absence of transients, the damping of harmonic and subharmonic oscillations, and phase-stability characteristics of multiphase circuits.

Rate Base: The amount of investment considered in setting the rates charged by a regulated utility. The rate base is governed by rules on what costs are allowed to be counted in the rate base and by the rates of depreciation of the allowed investments.

Reheat: Addition of heat to ("reheating") the working fluid while it is at an intermediate pressure; produces an improvement in the efficiency of the overall cycle.

Renewables: Energy sources that do not deplete their supply—for example, tidal or wind power, various forms of solar-derived energy including biomass for direct combustion or fuel alcohol or methane production, photovoltaic energy, hydroelectricity, and most of the output of heat pumps.

Risk Assessment (Also Called Safety Assessment): The discipline of developing systematic fault trees and event trees to describe known or postulated failure and recovery sequences in complex engineered systems. This process commonly also involves the quantification of the relative and absolute risk levels of the various sequences for purposes of setting priorities for prevention and mitigation measures, and for estimating their relative effectiveness. The quantification process is called probabilistic risk analysis (PRA).

SO_x: Oxides of sulfur, predominantly SO_2.

Space Heating: Comfort heating of habitations, as distinguished from process heating.

Superheat: The condition of a working fluid (commonly steam) that is heated to a temperature higher than the saturation temperature at the given pressure.

Thermal Efficiency: The conversion ratio to characterize any given energy cycle. In the electricity producing industry this is typically expressed as the ratio of energy in units of heat input divided by the output measured in electrical units (e.g., Btu per kilowatt hour). In both engineering and scientific terms it is often expressed as a percentage, the quotient of energy units output from a process divided by the energy input required (×100), both expressed in the same units.

Water Wall: A closely packed planar array of tubes that constitute the walls surrounding the combustion chamber of a boiler and that provide heat transfer from the flame region to water and steam by radiation and convection.

INTRODUCTION

The electrical properties of biological materials are most unusual: Their dielectric constants often reach extremely high values, in excess of 10^6 relative to free space, as the frequency decreases below 1 kHz. Furthermore, they change in distinct steps as functions of frequency. We summarize these and other characteristics with the intent to identify relevant conduction mechanisms. We do this by explaining observed properties in terms of "dispersions" caused by "relaxation mechanisms" as revealed by "dielectric spectroscopy."

1. SOME HISTORY

Interest in the response of biological materials to electricity developed early. These efforts may be considered the first of a biophysical nature and mark the beginnings of electrophysiology. This field originated some 200 years ago with the pioneering work of Galvani and Volta. In 1848 du Bois Reymond

digital Encyclopedia of Applied Physics

published his important two-volume text *Untersuchungen ueber die Tierische Elektrizitaet.* Others of the Berlin group include Mueller and Helmholtz. Helmholtz combined expertise in physiology and anatomy and physics. During the 1870s important work was done by Herman (1871). He determined, for the first time, the resistance anisotropy ratio of muscle and nervous tissues at dc and studied excitability. His results were found to be consistent with the assumption that cells are surrounded by an envelope. The envelope, termed membrane, was thought to contain a "polarization" element. It also became clear that excitability threshold currents are lower if applied in the direction of the fibers instead of across them. Limited instrumentation was applied with great ingenuity at the time.

The early electrophysiology work included study of the electrical conductance of blood and tissues and study of excitability and contractility. First determinations of the electrical properties of blood were carried out shortly after the introduction of the Wheatstone bridge and the precision conductivity determinations of electrolytes by Kohlrausch. Hoeber (1910, 1912) compared the conductivities of erythrocytes at low and high frequencies and deduced, from the difference, the existence of a cell membrane. This was the first work to do so from purely electrical data.

Interest in the electrical properties of cells and tissues increased rapidly during the period separating the two world wars. H. Fricke, K. S. Cole, H. J. Curtis, and H. Daenzer were the first to apply potential theory based on Maxwell's early work (Maxwell, 1873) to cell suspensions. Advanced instrumentation was applied to collect data spanning an ever increasing frequency range extending from some kHz to about 100 kHz. This work resulted in an explanation of the dispersive behavior in the rf range (termed β dispersion by Schwan, 1957). A detailed survey of the earlier work was given by Rajewsky (1938) and later in part I of Cole's text (Cole, 1968). After World War II the frequency range was extended to include data well below the kHz range, and upwards into the microwave frequency range. Additional and partially unexpected dispersion phenomena were discovered (α, δ, and γ; Schwan, 1957). Extension into the nonlinear range led to important contributions to membrane biophysics and identification of the mechanism responsible for excitability (Cole, 1968).

2. ELEMENTS OF DIELECTRIC SPECTROSCOPY

The linear electrical properties of matter are defined as follows:

Conductivity σ=conductance G of a unit volume of sample.

Permittivity (or dielectric constant) $\epsilon=\epsilon_r\epsilon_v$ =capacitance C of a unit volume.

ϵ_r is relative permittivity ($=\epsilon/\epsilon_v$) where ϵ_v is the permittivity of free space (8.85×10^{-12} F/m).

Conductivity and permittivity can be combined into complex forms: $Y=\sigma+j\omega\epsilon$ =admittivity (or specific admittance); $\epsilon^*=\epsilon'-j\epsilon''=\epsilon-j\sigma/\omega$=complex dielectric constant. ($\omega=2\pi f$ with f frequency and $j=\sqrt{-1}$. Often ϵ is used in place of ϵ' to represent the real part of complex permittivity.)

Admittivity Y and complex permittivity are related by $Y=j\omega\epsilon^*$. ϵ and σ are usually scalar quantities. Very rarely, however, they must be treated as tensors.

ϵ and σ often change with frequency. In the simplest case such frequency dependence can be expressed by the equations

$$\epsilon^*=\epsilon_\infty+\frac{\epsilon_0-\epsilon_\infty}{1+j\omega\tau}-\frac{j\sigma_0}{\omega}, \tag{1}$$

$$\sigma^*=\sigma_0+\frac{\sigma_0-\sigma_\infty}{1+j\omega\tau}+j\omega\epsilon_\infty. \tag{2}$$

The subscripts 0 and ∞ indicate limit values at low and high frequencies, and the third terms, $j\omega\epsilon_\infty$ and $-j\sigma_0/\omega$, have been added to include low- and high-frequency limits of σ and ϵ, caused by other mechanisms. The "relaxation" mechanism responsible for this dispersive behavior is characterized by the time constant τ and the dielectric increment $\epsilon_0-\epsilon_\infty$.

The frequency dependency stated in Eq. (1) corresponds to an exponential time response of dielectric displacement **D** to a sudden change in field strength and that in Eq. (2) to a change in current density J. Equations (1) and (2) are interrelated through

$$\epsilon_0-\epsilon_\infty=(\sigma-\sigma_0)\tau. \tag{3}$$

Equations (1) and (2) can be separated into

$$\epsilon=\epsilon_\infty+\frac{\epsilon_0-\epsilon_\infty}{1+(\omega\tau)^2},\quad \sigma=\sigma_0+\frac{\sigma_\infty-\sigma_0}{1+(\omega\tau)^2}. \tag{4}$$

If the time response is not exponential, the behavior may be characterized by a sum or integral of exponential responses. A more generalized equation has been formulated for multiple relaxation times as

$$\epsilon^*=\epsilon_\infty+(\epsilon_0-\epsilon_\infty)\int_0^\infty\frac{G(\tau)d\tau}{1+(\omega\tau)^2}, \tag{5}$$

where $G(\tau)$ is a distribution function. A popular distribution of such responses is the logarithmic symmetrical Cole–Cole distribution of time constants. It yields simple extensions of Eqs. (1) and (2):

$$\epsilon^*=\epsilon_\infty+\frac{\epsilon_0-\epsilon_\infty}{1+(j\omega\tau)^\alpha}-\frac{j\sigma_0}{\omega}, \tag{6}$$

$$Y=\sigma_0+\frac{\sigma_\infty-\sigma_0}{1+(j\omega\tau)^\alpha}+j\omega\epsilon_\infty. \tag{7}$$

Equation (6) yields circles in the dielectric plane (plot of ϵ'' vs ϵ') if $\sigma_0=0$, and Eq. (7), likewise, produces circles in the admittance plane ($\omega\epsilon'$ vs σ) if $\sigma_\infty=0$. The circle centers are below the real axis for $\alpha<1$. Plots in dielectric and admittance planes are useful in order to determine limit values at low and high frequencies. Figure 1 summarizes the above discussed frequency dependences. For details see Cole and Cole (1941), Boettcher (1952), and Froehlich (1949).

3. RELAXATION MECHANISM

The relaxation mechanism responsible for dispersive behavior may be caused by either permanent or field-induced dipoles.

3.1 Maxwell–Wagner Effects

A strong contribution to dielectric relaxation in biological cell suspensions and tissues is caused by the charging of interfaces separating different cellular compartments. Since $D=\epsilon E$ and $J=\sigma E$ (D is dielectric displacement, J current density, and E electrical field strength), D/J is equal to ϵ/σ. In a system free of electrical charges, D is continuous across any given interface. Hence the current density component normal to the interface will vary unless the ratio ϵ/σ is the same on both sides of the interface. Thus charges accumulate at the interface with time until J becomes continuous. The speed of adjustment depends on geometry and electrical properties. Simple models were first treated by Wagner (1914, 1924), who extended relevant dc calculations by Maxwell (1873) to alternating fields. These include an arrangement of two slabs of material in series and suspensions of spherical particles. The admittivity Y of a suspension of spherical particles is given by

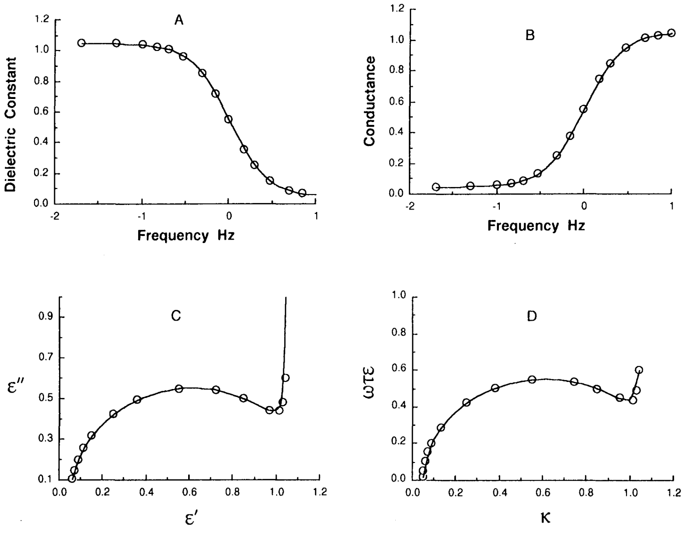

FIG. 1. Dispersion behavior of the permittivity ϵ and conductivity σ as function of frequency (curves A and B) and in the complex dielectric and admittance planes (curves C and D).

$$\frac{Y-Y_a}{Y+2Y_a}=p\,\frac{Y_p-Y_a}{Y_p+2Y_a}\,. \tag{8}$$

Here Y_a and Y_p indicate the admittivity of external medium and particle, and p is the particle volume fraction. This equation can be transformed into Eq. (4) with the parameters (Pauly and Schwan, 1959)

$$\tau=\frac{(1-p)\epsilon_i+(2+p)\epsilon_a}{(1-p)\sigma_i+(2+p)\sigma_a}\,, \tag{9}$$

$$\epsilon_0-\epsilon_\infty=\frac{9p(1-p)(\epsilon_a\sigma_i-\epsilon_i\sigma_a)^2}{[(1-p)\epsilon_i+(2+p)\epsilon_a][(1-p)\sigma_i+(2+p)\sigma_a]^2}\,, \tag{10}$$

where ϵ_i and σ_i are the permittivity and conductivity of the cell interior. The dielectric increment $\epsilon_0-\epsilon_\infty$ is usually of the order of a few dielectric units relative to free space, i.e., of small magnitude.

We consider next a spherical model for a biological cell, assuming a homogeneous interior, the cytoplasm, surrounded by a membrane. In this case Maxwell's "equivalent homogeneous" particle admittivity equation

$$\frac{Y_p-Y_m}{Y_p+2Y_m}=\frac{R^3}{(R+d)^3}\,\frac{Y_i-Y_m}{Y_i+2Y_m} \tag{11}$$

can be used to reduce the shell-surrounded particle to a homogenous one (Y_p is the equivalent particle admittivity, R core radius, and d membrane thickness; i and m indicate cell interior and membrane). Extension of Maxwell's dc equations to the complex case is justified since all boundary conditions such as continuity of potentials and current density normal to the interfaces remain valid.

Combination of Eqs. (8) and (11) gives the electrical properties of a suspension of spherical biological cells. The result is given by the sum of two relaxation equations of the type stated in Eqs. (4). For $d \ll R$ and parameters typical of biological cells, the two time constants differ by a factor of nearly 100. Then the following excellent approximations for the parameters result for the low-frequency dispersion (Pauly and Schwan, 1959):

$$\tau=RC_m\,\frac{(2+p)\rho_i+(1-p)\rho_a}{2+p+RG_m[(2+p)\rho_i+(1-p)\rho_a]}\,, \tag{12}$$

$$\epsilon_0-\epsilon_\infty=\frac{9p}{(2+p)^2}\,\frac{RC_m}{[1+RG_m\{\rho_i+\rho_a(1-p)/(2+p)\}]^2}\,. \tag{13}$$

$C_m=\epsilon_m/d$ and $G_m=\sigma_m/d$ are membrane capacitance and conductance per unit area, $\rho_i=1/\sigma_i$ and $\rho_a=1/\sigma_a$ are the resistivities of internal and external fluids, and p is volume concentration. The parameters for the high-frequency dispersion are identical with Eqs. (9) and (10).

Maxwell's derivations of Eqs. (8) and (11) assume that charges only accumulate at surfaces, i.e., that there are no space charges. Thus Laplace's potential equation can be assumed to be valid in all phases. This is not quite correct for charged particles suspended in aqueous media, and Poisson's equation ought to be solved. However, the error has been demonstrated to be small for cellular dimensions which are large compared to the Debye screening length (Garcia *et al.*, 1985).

In Table 1 are listed values for the case of typical cell suspensions. The data demonstrate the following:

1. The magnitude of low-frequency dispersion is very large, resulting in ϵ values above 10^3. Thus, the Maxwell–Wagner mechanism predicts a large magnitude dispersion at frequencies between 0.1 and 10 MHz.
2. The high-frequency dispersion is independent of C_m and G_m. It is, therefore, simply that of a suspension of core particles without a membrane and its magnitude is small.

Maxwell–Wagner dispersion effects occur if the composition of matter is heterogeneous. The accumulation of charges of opposite sign

Table 1. Maxwell–Wagner β dispersion parameters are given for two cell sizes. The following typical cell properties are used: $C_m = 1$ μF/cm^2, $\rho_i = 120$ Ω cm, $\rho_a = 60$ Ω cm, and $p = 0.3$. The effect of the membrane conductance has been neglected since it is usually small. The data are theoretically predicted [Eqs. (3) and (9)–(13)]. The low-frequency β_1 dielectric increment (relative to free space) is many orders of magnitude stronger than the high-frequency β_2 dispersion. The conductivity increments (in mS/cm) differ by a factor of nearly 100.

β dispersion	R(μm)	f_c(MHz)	$\epsilon_0 - \epsilon_\infty$	$\kappa_\infty - \kappa_0$
1	10	1.15	5760	3.68
	1	11.5	576	3.68
2	10	370	0.20	0.04
	1	370	0.20	0.04

on both sides of the interfaces create induced dipole moments. Thus the dispersion effects reflect frequency-dependent induced dipoles.

3.2 Counterion Relaxation

Another induced dipole relaxation is caused by the movement of counterions. Frequently particles carry fixed charges and are surrounded by an atmosphere of counterions of opposite charge. The application of an electrical field results in a displacement of this atmosphere creating an induced dipole moment. Colloidal suspensions display very large $\epsilon_0 - \epsilon_\infty$ increments and low characteristic frequencies, as reported by us (Schwan, 1957; Schwan *et al.*, 1962). Figure 2 presents some typical data. The time constant τ of this strong effect was found to be proportional to $1/R^2$.

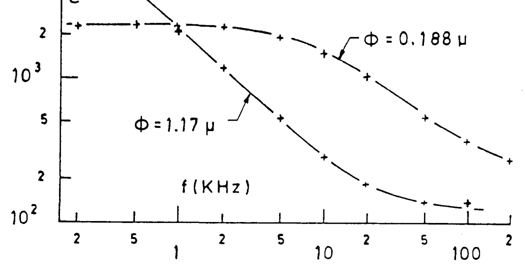

FIG. 2. Dielectric dispersion of polystyrene particles suspended in aqueous media. Numbers for each curve indicate the radius of particles in μm. [From Schwan (1957); reprinted by permission of Academic Press.]

Schwarz (1962) developed a first model for counterion relaxation. His equations for time constant τ and dielectric increment are

$$\tau = R^2/2ukT, \tag{14}$$

$$\epsilon_0 - \epsilon_\infty = \frac{9p}{(2+p)^2} \frac{e_0^2 R \delta_0}{\epsilon_v kT}, \tag{15}$$

where e_0 and u are charge and mobility of counterion; R, particle radius; p, particle volume concentration; T, absolute temperature; δ_0, counterion charge density; and k, Boltzmann's constant. Schwarz's theory was generalized to apply to prolate ellipsoids and further modified for long rodlike molecules (Takashima, 1989):

$$\epsilon^* = \frac{e_0^2 \delta_0 a^2}{b \epsilon_v kT} \frac{9p}{(1+p)^2} \frac{1}{1+j\omega\tau}. \tag{16}$$

Here, a and b are major and minor axes of very long rods.

Refinements of the Schwarz theory have been formulated recently (Fixman, 1983; Chew, 1984; Grosse and Foster, 1987). Since biological cells carry many fixed charges, counterion movement does contribute to their dispersive behavior at low frequencies.

3.3 Membrane Relaxation

The electrical properties of biological membranes are characterized by membrane capacitance per unit area C_m and membrane conductance G_m. Typical membrane capacitance values are about 1 μF/cm^2 and appear to be fairly frequency independent above some kHz. This value corresponds to a lipoprotein film of about 40 Å with a dielectric constant of about 4.

Membrane conductance values range from 0.001 to 1 S/cm^2. They are caused by membrane pores, "channels," responsible for ion exchange. Membrane conductance values at low frequency change with the applied field strength and frequency. The model equations by Hodgkins and Huxley (1952) describe experimental data. The linearization of these equations for small applied fields results in dispersion equations which fit experimental data (Fishman, 1985). Time constants are of the order of ms or less. Thus dispersive behavior is observed below 100 Hz. The mechanisms which cause the frequency dependence of C_m and G_m have not been clarified so far.

Since the membrane conductance changes with frequency, the membrane capacitance must also change as predicted by Eq. (3). Furthermore, since dielectric increments of cell suspensions are proportional to the membrane capacitance [Eq. (13)], membrane properties must cause changes in the low-frequency properties of cell suspensions. This membrane effect is superimposed on the counterion effect discussed above.

3.4 Permanent Dipole Effects (Debye Theory)

Many molecules possess electrical dipoles caused by an asymmetric distribution of positive and negative charges. These polar molecules tend to orient with an applied field, while thermal motion opposes preferential orientation. The development of the theory of polar molecules by Debye (1929) had a far-reaching impact. On the basis of the concept of orientational polarization, Debye derived an equation for the static electric polarization of molecules so dilute that intermolecular interaction can be neglected:

$$\frac{\epsilon_0-1}{\epsilon_0+2}V=\frac{4\pi N_A}{3}\left(\alpha+\frac{\mu^2}{3kT}\right). \tag{17}$$

Here ϵ_0 is the static (low-frequency) dielectric constant, V the molar specific volume, N_A Avogadro's number, and μ the dipole moment. The term α represents electronic and atomic distortions. It determines the high-frequency limit ϵ_∞ since these processes are very fast. For dilute molecules, the dielectric constant ϵ is not much larger than 1 and under these conditions Eq. (17) yields satisfactory results. It soon became apparent that this theory has limited applicability for polar substances having large dielectric constants. The shortcoming was found to stem from an insufficient analysis of internal fields. Subsequently, Onsager (1936) introduced the concept of a "direction field" and successfully eliminated the inconsistency of Debye's equation. Onsager's equation is

$$\frac{(\epsilon-n^2)(2\epsilon+n^2)}{\epsilon(n^2+2)^2}=\frac{4\pi N_A\mu_0^2}{9VkT}, \tag{18}$$

where n is the refractive index and μ_0 the dipole moment. Onsager's equation correctly predicts the dielectric constant of many polar substances. However, Onsager's equation was not able to account for the electric polarization of polar liquids such as water with large dielectric constant. The distribution of polar molecules in liquids is more ordered than in gases. Consequently, the mean dipole moment of liquids is not necessarily zero in the absence of an electrical field. Thus two reference axes are needed to define the orientation of individual molecules in liquids. One axis is parallel to the net dipole moment of the liquid with zero field, and the other to the vector of the applied field. Kirkwood (1939) derived

$$\frac{(\epsilon-1)(2\epsilon+1)}{9\epsilon}V=\frac{4\pi N_A}{3}\left\{\alpha+\frac{g\mu^2}{3kT}\right\}, \tag{19}$$

where g is the "correlation parameter" defined by

$$g=1+z\langle\cos\theta\rangle; \tag{20}$$

z is the number of nearest neighbors, and θ is the angle between adjacent molecular axes. For example, in liquid water with tetrahedral structure, $z=4$ and $\theta=45°\text{–}50°$. Satisfactory agreement with experimental results, however, demands not only the nearest neighbors but also additional layers of molecules to be included. Further refinements assume bending (Pople, 1951) or breaking of hydrogen bonds (Haggis *et al.*, 1952) between adjacent water molecules.

Dielectric relaxation of polar molecules is caused by the phase lag between the applied sinusoidal field and the dipole orientation. Dipolar molecules are unable to follow closely changes in the direction of the applied ac field. This causes phase shift and energy dissipation, resulting in a decrease in dielectric constant. If the relaxation is characterized by only one relaxation time, the dispersion of the dielectric constant is given by Eq. (1) (Debye, 1929), with τ now a cubic function of molecular radii. Distributions of relaxation times are often caused by molecular inhomogeneity and nonspherical shape. They are fairly common with synthetic polymers and biopolymers such as DNA. The origin of the distribution of relaxation times has been discussed by various authors.

The time constant of dielectric relaxation is, as mentioned before, proportional to the cube of the radii of molecules. For example, the dielectric dispersion is observed at 15–20 GHz for water, and 400–500 MHz for simple amino acids. The dispersion curves of some spherical proteins fit nicely the Debye theory of single relaxation time. However, the dispersion curves of other proteins deviate from it, indicating the presence of more than one relaxation time. For ellipsoidal molecules, there are separate orientations along major and minor axes. Then, Eq. (5) must be rewritten using two dispersion terms (Oncley, 1943):

$$\epsilon-\epsilon_\infty=\frac{\Delta\epsilon_1}{1+(\omega\tau_1)^2}+\frac{\Delta\epsilon_2}{1+(\omega\tau_2)^2}, \qquad (21)$$

where $\Delta\epsilon_1$ and $\Delta\epsilon_2$ are the dielectric increments due to the orientation along the major and minor axes. τ_1 and τ_2 are relaxation times associated with these orientations. The rotation of ellipsoidal molecules can be analyzed using Perrin's theory of rotary diffusion (see Oncley, 1943). This theory relates the rotary diffusion constants of ellipsoidal particles to their axes a and b. The relaxation time is calculated as the reciprocal of the rotary diffusion constant. Therefore, for a certain value for a/b, the ratio τ_1/τ_2 can be calculated. The ratio of $\Delta\epsilon_1$ and $\Delta\epsilon_2$ is determined by dipole angle, i.e., the angle between dipole vector and molecular axes. Therefore, Eq. (21) can be solved from assumed axial ratio and dipole angle θ. By best fit, we can obtain satisfactory agreement between calculation and experiment, and determine the shape of the protein molecule. This approach is useful for proteins with large axial ratios, i.e., 5–10. However, the theory is of limited use for proteins with an axial ratio of less than 2–3.

4. EXPERIMENTAL DATA

Figure 3 displays the dielectric behavior typical for many tissues and cell suspensions. Three relaxation regions of large magnitude are apparent at low, medium, and very high frequencies, identified as α, β, and γ (Schwan, 1983). Figure 4 details the same principal behavior for a protein solution. In this case there is no α effect and the magnitude of the β effect is less pronounced. There is evidence for a weak and broad additional relaxation effect labeled δ. Clearly, magnitude and time constants of observed dispersions vary considerably. A summary of these dispersions is provided in Table 2. We now consider the various components of cell suspensions and tissues and their individual dielectric properties.

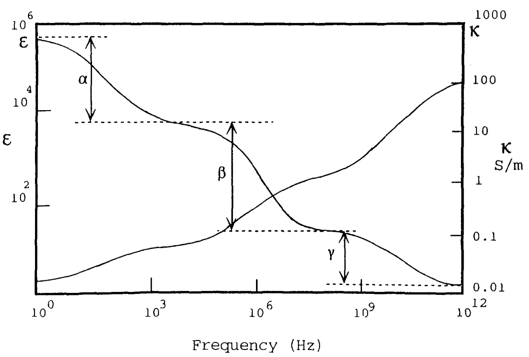

FIG. 3. Stepwise dispersions of biological materials. α dispersion is due to ionic processes, β dispersion is due to charging up of the membrane or orientation of permanent dipoles. γ dispersion is due to the orientational relaxation of water.

4.1 Electrolytes

Water is in many ways unique: It has high heat capacity, a high boiling point, and a large dielectric constant. The dipole moment of water is 1.84 D bisecting the angle between two OH bonds. Formation of intermolecular hydrogen bonds makes water a highly ordered liquid. Calculations of its dipole moment using Kirkwood's equation (1939) did not yield good results. Better agreement was obtained by Pople (1951) by allowing the bending of hydrogen bonds. Even better agreement was obtained by Haggis *et al.* (1952) by assuming the breaking and reforming of hydrogen bonds and including several layers of molecules. It was also found experimentally that the energy barrier of dipole rotation of water is about 3–4 kcal/mol (Hasted *et al.*, 1953). This observation indicates that the orientation of a water molecule requires a breakage of only one hydrogen bond.

The dielectric relaxation is characterized by only one time constant corresponding to a characteristic frequency $f_0=1/2\pi\tau$ near 20 GHz at room temperature. The dielectric constant decreases from about 78 to 4 as the frequency increases. The low-frequency term σ_0 is about 10^{-5} S/m. The dielectric response of electrolytes is quite similar, except for a small decrease of ϵ_0 and a larger conductivity σ_0. The low-frequency conductance is caused

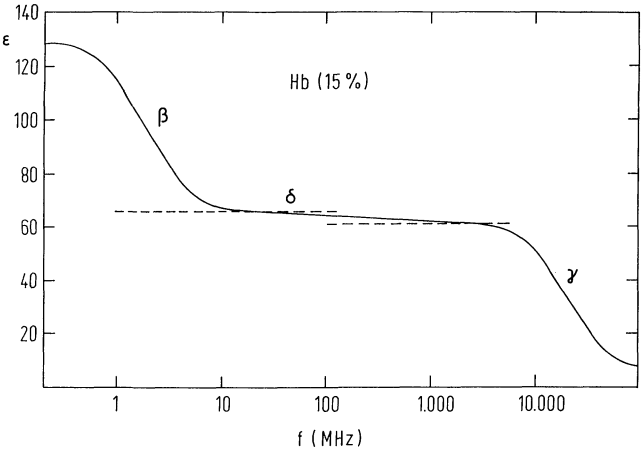

FIG. 4. Schematic presentation of the dielectric dispersion of hemoglobin solution. δ dispersion is due to the water bound to the surface of protein molecules. Abscissa, logarithmic scale of relative frequencies (f/f_r, where f_r is the center frequency). [From Schwan (1983); reprinted by permission of Springer-Verlag.]

by the mobile ions and is approximately proportional to the ion concentration.

The behavior of water in biological cells has been debated vigorously (Whipple, 1965; Hazelwood, 1984). In spite of the gel-like nature of cytoplasm, the dielectric behavior of intracellular water is amazingly similar to that of bulk water except for water tightly bound to macromolecules and membranes. Protein-bound water appears to display an entirely different behavior (Schwan, 1957 and 1965; Grant, 1965). The relaxation frequency is much lower than that of normal water. In addition, the behavior indicates a broad spectrum of relaxation times, corresponding to frequencies ranging from some hundred MHz to a few GHz. Permittivity limit values ϵ_0 and ϵ_∞ are comparable to those of water and ice.

4.2 Biological Macromolecules

4.2.1 Polypeptides, Amino Acids. Polypeptides, proteins, and nucleic acids are the most investigated biopolymers. Early dielectric constant measurements were performed with amino acids and simple peptides. It was found that amino acids possess large dipole moments. This dipole moment is due to the charge pair of COO^- and NH_3^+ groups, separated by about 3.33 Å in α amino acids and

Table 2. Relaxation mechanisms which determine the dielectric response of electrolytes, biological macromolecules, and cells. Strong ELF, rf, and MW responses are labeled α, β, and γ. γ stands for the water dispersion, β is the external cell membrane charging response, β_1 and β_2 the weaker protein response and that from intracellular organelle membranes. α_t and α_1 are contributions from membrane systems connecting with the outer cell membrane and counterion displacement near fixed surface charges of the membrane glycocalix, and α_m is caused by membrane channels. The weaker δ response at UHF is caused by protein-bound water and submacromolecular partial rotation. The table demonstrates participation of an increasing number of relaxation mechanisms as we proceed from simple water to the complex cell.

Water and electrolytes	γ
Biological macromolecules	
Amino acids	$\delta+\gamma$
Proteins	$\beta_1+\delta+\gamma$
Nucleic acids	$\alpha_1+\beta_1+\delta+\gamma$
Biological membranes	α_m
Vesicles	$\beta+\gamma$
Organelles (no surface charge)	$\beta_2+\delta+\gamma$
(with surface charge)	$\alpha_1+\beta_2+\delta+\gamma$
Cells with proteins	$\beta+\beta_2+\delta+\gamma$
+organelles	$\beta+\beta_1+\beta_2+\delta+\gamma$
+surface charge	$\alpha_1+\beta+\beta_1+\beta_2+\delta+\gamma$
+membranes+channels	$\alpha_m+\alpha_1+\beta+\beta_1+\beta_2+\delta+\gamma$
+tub. system, etc.	$\alpha_t+\alpha_m+\alpha_1+\beta+\beta_1+\beta_2+\delta+\gamma$

4.16 Å in β amino acids (Wyman, 1936). The formation of peptides increases the distance between positive and negative charges, hence causing a larger dipole moment. There are two known conformations for highly polymerized polypeptides and/or polyamino acids. These are the random coil and alpha helix structures (Pauling *et al.*, 1951). The former is an amorphous structure without an internal regularity, and the peptide chain configuration is random and flexible. The net dipole moment of random-coil polypeptides is usually very small. The latter is in a crystalline state characterized by a highly ordered secondary structure having polar groups aligned in one direction along the helical axis. The sum of the dipole moments of these polar groups turns out to be very large and proportional to the degree of polymerization (Wada, 1962). In addition, there is another structure called β-pleated sheet. However, no information is available as to the dipole moment of this configuration.

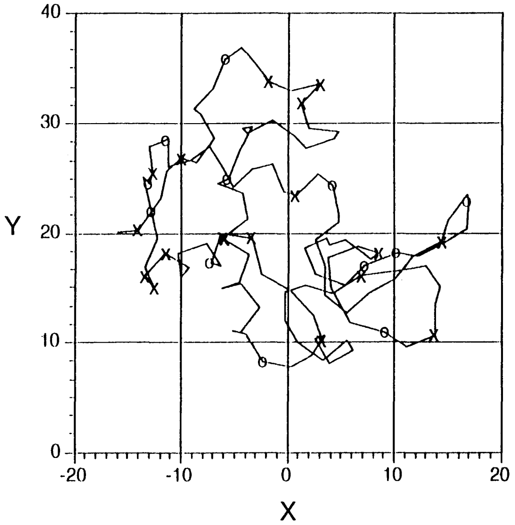

FIG. 5. Two-dimensional presentation of a protein molecule, lysozyme, in the *X*-*Y* plane. Crosses represent positive charges and open circles represent negative charges.

4.2.2 Proteins. There are two types of protein molecules: fibrous proteins such as collagen and muscle proteins, and globular proteins such as hemoglobin, albumin, and insulin. Although the internal structure of these proteins is very complex, the coordinates of their amino acids are accurately known for many proteins from x-ray crystallography. The folding of the peptide chains in proteins often appears to be structureless, except for helical regions, because of their extreme complexity. The conformation of protein molecules is now known to be the result of an intricate interplay among hydrophobic and electrostatic forces. Protein molecules carry positive and negative charges on the surface, and their locations are well known (see Fig. 5). The dipole moment of proteins is largely determined by the distribution of these charges. The distribution of surface charges has been found to be rather uniform in many proteins and the net moment is smaller than expected for their large size. Calculations of the net dipole moment based on the knowledge of the distribution of surface charges have been conducted for many proteins as shown in Table 3 (Schlecht, 1969; South *et al.*, 1972; and Barlow *et al.*, 1983). The calculations consist of two parts, the dipole moment due to fixed surface charges (column 1), and the vector sum of bond dipole moments of individual amino acids (core moment, column 2). The core moment is considerably smaller in magnitude than that due to surface charges, and its vector is often opposite to that of the fixed charges. Column 4 shows the results of the measurements of the dipole moments of these proteins. In general, agreements are reasonably good for small proteins (see myoglobin and cytochrome *C*, e.g.), and poor for large and complex proteins which often have subunits.

4.2.3 Dielectric Properties of DNA. DNA is a very large fibrous polymer which stores all genetic codes using the unique sequences of its base molecules. It has been postulated that the origin of the dipole moment of polyelectrolytes stems from the fluctuation of mobile counterions caused by an electrical field. Some exemplary results of dielectric-constant measurements with DNA solutions are presented below. Because of the double helical structure, DNA molecules are fairly rigid even in solution. Moreover, polynucleotide chains are negatively charged because of the presence of phosphate groups. Because of their large sizes, the dielectric dispersion occurs at very low frequencies, namely around 5–8 Hz. Figure 6 shows the frequency profile of the dielectric constant of a dilute solution (0.05%) of a highly polymerized DNA (molecular

Table 3. Calculated and measured dipole moments of globular proteins (in Debye units). [From Takashima and Asami (to be published).]

		Calculated dipole moment				
Name	M.W.	Charge	Core	$\langle\theta\rangle^a$	Total	Measured
Myoglobin	17 000	247	57	148	200	172
Cytochrome C	13 000	255	72	142	203	227
Lysozyme	14 600	130	61	90	141	122
Trypsin^b	23 000	356			356	345
Ribonuclease	13 700	330	19	85	270	281
Carboxypeptidase	34 000	435	152	2	575	760
Alcohol dehydrogenase	79 000	710	174	122	633	531

weight about 3×10^6) (Hayakawa *et al.*, 1975). We first point out that the static dielectric constant of DNA solution reaches a high value of 4×10^4 at a concentration of only 0.05%. This corresponds to a dipole moment of 1.5×10^6 D. This large dipole moment was found to be proportional to the degree of polymerization (Takashima, 1966), indicating that the dipole moment of DNA exists along the major axis of the double helix, in contrast to the early concept that DNA has a transverse moment (Allgen, 1949). Structural considerations, i.e., the antiparallel double helical configuration, preclude the possibility of the DNA molecule having a large permanent dipole moment. This is because of cancellation of possible dipole moments in each strand.

Left for consideration is counterion polarization. For DNA molecules, the magnitude of major axis a is of the order of 5–6 μm, the minor axis b is of the order of 20–30 Å, and charge density δ_0 about 10^{13} cm^2. Thus, Eq. (16) predicts an exceedingly large dielectric increment as observed.

The theory above uses a model in which charged molecules are surrounded by a continuous distribution of counterions. This model does not consider the specific interaction between ions and charged sites. Binding of counterions to charged sites on the polyion's surface has a profound effect on the dielectric behavior of polyelectrolytes. For example, binding of counterions causes a drastic reduction of the dielectric constant of polyelectrolytes. In order to account for this effect, the model must have a feature which can explain the observed effects of ion binding. A model which may be termed "a discrete potential well model" has been used for some time for linear charged polymer molecules. Figure 7 is a schematic presentation of this model (Mandel, 1961). It consists of an array of potential wells which are separated from one another by an energy barrier h. If ions are found in these potential wells, they are considered bound to charged sites, i.e., neutralization of the charge, otherwise they are considered unbound. The dipole moment of linear poly-

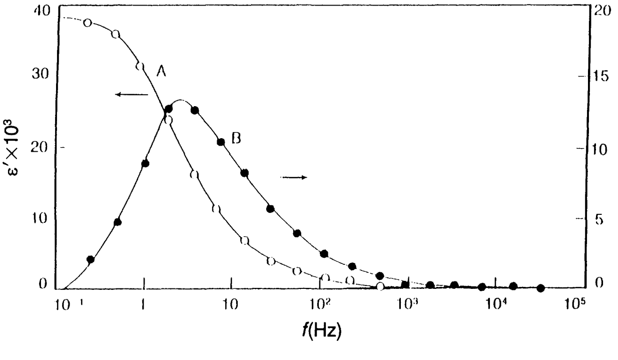

FIG. 6. Dielectric dispersion of the DNA solution measured with a four-terminal technique. A is the dielectric constant, and B is the dielectric loss: dissipation of energy.

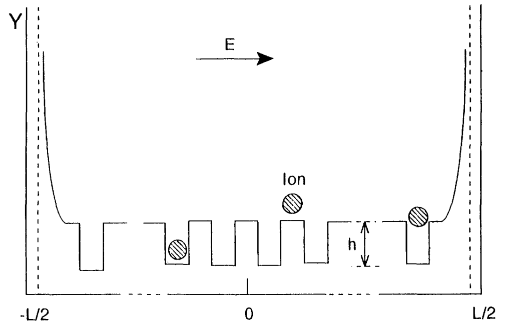

FIG. 7. Schematic presentation of a one-dimensional discrete potential well model. *h* is the height of potential barriers, and shaded circles show counterions. *L* is the length of linear polymers.

ions is calculated by computing the distribution of unbound as well as bound counterions along the fiber in the presence of an electrical field. This discrete potential well model has been used by several investigators (Mandel, 1961; McTague and Gibbs, 1966; Oosawa, 1970; Warashina *et al.*, 1973; and Minakata *et al.*, 1972). According to these investigations, the binding of counterions causes an increase in dielectric constant when charged sites are only partially occupied. However, further ion binding causes a marked decline of the dielectric constant (Minakata *et al.*, 1972). This prediction is in agreement with the results with synthetic polyelectrolyte molecules. Counterion binding to charged DNA-phosphate groups causes a marked decrease in dielectric constant. However, the initial rise in $\Delta\epsilon$ which is predicted by aforesaid theories has not been observed (Takashima, 1966).

Macromolecular solutions display a variety of responses as indicated in Table 2 and Fig. 3. They all share the γ response due to the presence of water. In addition they display a weak δ response which is probably mostly caused by bound water. The amount of bound water is about 0.3 g of water per g protein for globular proteins. Macromolecular solutions frequently display a γ dispersion which is shifted to slightly lower frequencies and involves a broadening from one to a small distribution of relaxation times. The mechanism of this effect remains unclear. It can result from the interaction of the high-frequency tail of the δ spectrum with the γ dispersion. We support this by two arguments: (a) The effect apparently increases with macromolecular concentration. (b) It appears to be unlikely that all free water shifts its properties in common as proteins are added to the pure water. Relaxation contributions depend on the distance of the water from the macromolecule, with "distant" water less affected. The δ dispersion of macromolecular solutions is about one dielectric unit per g protein per 100 cm^3, i.e., of fairly small magnitude. Its cause is mostly due to bound water as discussed above. But partial rotation of macromolecular subunits probably also contributes.

The high-frequency limits ϵ_0 of the δ dispersion are not precisely known since the dispersion extends into the γ range. However, limit values ϵ_∞ of the δ dispersion are about as expected from the mixture equation if the bound water surrounding protein is of low permittivity compared with that of the nonbound water.

At radio frequencies, about 0.1 to 10 MHz, protein solutions display another relaxation (β). Its mechanism is most probably caused by the permanent dipole moment of the macromolecules as discussed earlier. An alternative model was proposed by Kirkwood and Shumaker (1952). They pointed out the importance of the role of mobile protons as the origin of the large dipole moment of protein molecules. Protons can migrate from one amide group to another when an electrical field is applied. The fluctuation of the proton distribution can produce mean square fluctuation of the dipole moment even if the mean permanent dipole moment of the protein is zero, namely,

$$\langle\mu^2\rangle=\langle\mu\rangle^2+\Delta\mu^2. \tag{22}$$

Here $\Delta\mu^2$ is the moment produced by the fluctuating protons and is given by

$$\Delta\mu^2=e^2f^2b^2\sum_\alpha\frac{n_\alpha}{2+K_\alpha/[\mathrm{H}^+]+[\mathrm{H}^+]/K_\alpha}, \tag{23}$$

where e, b, and n_α are elementary charge, radius of equivalent sphere, and number of αth charge. f is a shape factor and K_α is the dissociation constant of the αth group. This equation indicates that $\Delta\mu^2$ increases when the *p*H of the protein solution approaches the *pK* value of the αth group on the surface. Numerical calculations by the authors demonstrate that the dipole moment of proteins can be accounted for by the proton fluctuation mechanism. However, theoretical and experimental analyses (Scheider, 1965; Takashima, 1965) demonstrated that the proton fluctuation moment is small for proteins with a molecular weight below 10^5. Kirkwood *et al.* were, nevertheless, the first to point out the importance of the fluctuating proton distribution to generate a mean square dipole moment. This mechanism is now considered unimportant for small proteins because of their small values. However, the concept of nonvanishing mean square dipole moments due to the fluctuation of mobile surface ions played an important role in the development of counterion polarization theories for polyelectrolytes, as discussed earlier. Amino acids display a dielectric dispersion around a few hundred MHz. Because of this, the dispersion should be termed a δ dispersion. Their δ behavior is of polar origin, rather than the relaxation of bound water. Neither amino acids nor proteins appear to show any α effect, i.e., their permittivities are frequency independent in the low-frequency range.

4.3 Biological Membranes

Biological membranes consist of lipids and proteins. Attempts to reconstitute biological membranes using purified lipids and proteins have not met, so far, with much success, except for a few special cases. It is, however, possible to form pure artificial bilayer membranes. Electrical membrane properties can be measured using metal electrodes placed on both sides of an aperture on which the membrane is formed. The membrane capacitance of lipid bilayers is of the order of 0.4–0.6 μF/cm^2 and no frequency dependence has been observed (Hanai *et al.*, 1964). The conductances of lipid bilayer membranes are extremely small. Only when lipid bilayers are doped with certain peptide molecules, called ionophores, do membrane conductances increase manyfold and the membranes become permeable to ionic species.

The membrane admittance of nerve cells has been investigated using internal–external electrode arrangements. Nerve cells are long cylinders, and those of some sea animals have a large diameter of 300–700 μm. This permits insertion of a wire electrode (Pt wire with a diameter of 50–70 μm) axially inside the cell, and a larger electrode in the medium. The interpretation of the results is, however, difficult because of membrane instability, systematic errors due to poor contact between the membrane and electrodes (Takashima *et al.*, 1974), and parasitic capacitance due to fringe effects at the tip of internal electrodes (Schwan, 1981).

Biological membranes also contain some protein molecules which are not essential to the transmembrane ion flow but cannot be eliminated. In addition, time-dependent nonlinear ionic currents produce reactive components which mask the real admittance of the membrane: Sodium currents produce a capacitive reactance and potassium currents an inductive one. They are the cause of the membrane-induced α dispersion effects discussed above. Nerve membrane capacitances and conductances, free of these additional α effects, can be obtained if all ionic currents are blocked using pharmacological agents. With these precautions, the membrane capacitance of nerve cells was found to be slightly frequency dependent, decreasing from 1 to 0.8 μF/cm^2 in the frequency range between 100 Hz and 1 kHz, and independent of membrane potential. Only in the presence of ionic currents do nerve membrane capacitance and conductance become dependent on the membrane potential. The phenomenological admittance due to nonlinear ionic currents has been investigated by Fishman *et al.* (1977), using linear approximations as indicated in Sec. 3.3.

4.4 Cells

Cells are surrounded by membranes, which separate the cytoplasm from the medium surrounding the cell, i.e., interior phase. There exists an immense variety of biological cells. Prokaryotes are primitive cells which emerged much earlier than the highly differentiated eukaryotes. The cytoplasm of the more highly developed eukaryotes contains many smaller celllike structures including the cell nucleus, mitochondria, lysosomes, Golgi apparatus, ribosomes, and endoplasmic reticulum, each with a specialized function. The nucleus contains nucleic acids including DNA, carrying the genetic code. The cell nucleus and other "subcellular organelles" such as mitochondria are surrounded by membranes. Some membrane systems interconnect. The cytoplasm contains many proteins. Part of them are arranged in the cytoskeleton, a web of string-like structures which appear to provide some structural rigidity to the cell. It is linked to a similar membrane structure which connects part of the membrane proteins, while others have been shown to move under the influence of electrical fields. The glycocalyx, a loose brushlike structure fixed to the outer surface of the membrane, consists of glycoproteins and sugars. It is highly permeable and rich in fixed charges. Its thickness is about 100 Å, i.e., comparable to or larger than the Debye screening length for the medium outside the cell.

The electrical properties of cell suspensions have been studied by many investigators, particularly Fricke, Cole, Schwan, Carstensen, and Hanai and their colleagues, as reviewed by Cole (1968) and Foster and Schwan (1989). This work led to an understanding of the important role of cell membranes in the rf range. The principal mechanism responsible for the β dispersion is the accumulation of charges at membranes from extracellular and intracellular fluids (Maxwell–Wagner effect). In addition, cell suspensions display the above discussed relaxations, since they contain water and macromolecules. Furthermore, they often display strong dispersions at low frequencies (α dispersions). We summarize these cases in Table 2.

First, we consider suspensions of cells or vesicles without macromolecules in the fluids inside and outside the cell. Then Eqs. (12) and (13) are applicable. Assuming physiological conditions, these equations predict time constants corresponding to relaxation frequencies between 0.1 and 10 MHz for micron sized cells. Dielectric increments for volume fractions near 30% range in the thousands. Therefore suspensions display strong Maxwell–Wagner β effects in the rf range. Their magnitudes are considerably greater than that of the β effect of proteins. In addition, the cell suspensions display a γ effect since they contain water. The magnitude of the γ effect corresponds to the volume taken up by water.

Cells containing proteins (about 30% in the cytoplasm and 5%–10% in the medium outside the cells) display the β and γ effects listed above. In addition, the proteins add their own β effect and cause the δ effect due to their bound water. Relaxation frequencies of the β dispersion of proteins are somewhat higher than those responsible for that of cells, but of much smaller magnitude. This results in a slight lifting of the high-frequency tail of the β dispersion. Cells with surface charges and/or dispersive membranes display α relaxation effects caused by the counterion atmosphere and frequency-dependent membrane properties.

Many cells possess membrane systems which extend from the cell membrane or the nuclear membrane into the cytoplasm. These structures can act like transmission-line sections, causing frequency-dependent contributions to the membrane properties. Characteristic frequencies are near 100 Hz for the tubular system of muscle. Thus, apparent membrane properties change at low frequencies, causing an additional α dispersion effect (Schwan, 1954; Fatt, 1964).

Organelles such as mitochondria and cell nuclei have dielectric responses identical to those of cells since they are surrounded by membranes separating electrolytes. Because of their small sizes, their dispersions occur at higher frequencies and their magnitudes are smaller. Organelles inside cells contribute therefore to the tail of the β dispersion of cell suspensions, as may be predicted by Eqs. (12) and (13) (Irimajiri *et al.*, 1979; Stoy *et al.*, 1982). The contributions of subcellular organelles diminish as the frequency decreases below the characteristic frequency of the cell suspensions. This is due to the shielding effect imposed by the cell membranes at lower frequencies. A detailed theory of a "multistratified shell" model has been applied to the case of organelles or nuclei inside the cell (Irimajiri *et al.*, 1979).

5. TISSUE IMPEDANCE

5.1 Frequency Dependence

Biological tissues are complex combinations of concentrated cells with interconnections. They therefore display many of the characteristic features typical of concentrated cell suspensions. The mechanism responsible for the electrical properties of such suspensions are largely responsible for those of tissues. Tissues display the same three main dispersion regions α, β, γ, as discussed above for cell suspensions. However, magnitudes and relaxation frequencies may be different.

Tissues can be divided into various categories:

1. Soft tissues with high water content. Most body tissues belong to this group. High cell concentrations, electrolytes inside and outside the cells, and protein concentrations at about 20% are typical. The model of a highly concentrated cell suspension is particularly appropriate to this class of tissues.
2. Soft tissues with low water content. Fatty tissues belong to this group. These tissues also have cellular structure. Fat concentrations in the fluid compartments are high.
3. Hard tissues, which contain many minerals in solid form. However, even they display dielectric properties somewhat similar to those of other tissues.

Brain, in particular white matter, also contains fat. Its electrical properties place it somewhere between the soft tissues with high and low water content. The same is true for white bone marrow, while red bone marrow exhibits properties close to those of highly concentrated blood suspensions, as might be expected from its composition.

The electrical properties of tissues have been extensively investigated. A compilation of resistivity data for many tissues at low frequencies has been given by Geddes and Baker (1967). Data in tabular form and covering the total frequency range have been published by Schwan (1963). For a detailed compilation of these data and those obtained in recent years, as well as their interpretation, see Foster and Schwan (1986).

The conductivity is the dominant part of tissues' admittivity at low frequencies. For alternating current, the corresponding frequency range is below about 1 to 10 khz. Conductivity data are difficult to interpret because of the complexity of tissue structure. However, a simple analysis based on the mixture theory is fairly accurate. Assuming a typical fraction of the extracellular fluid near 10% and conductivity of 2 S/m, and effectively nonconducting cells, a dc conductivity of 0.14 S/m is predicted by the Maxwell mixture theory. This is typical for soft, high-water-content tissues at low frequencies.

The contribution of the α dispersion to the conductivity is small. As the frequency approaches the β dispersion, the conductivity beings to increase noticeably. At frequencies above the β dispersion region, the cell membranes are short circuited. Then the mixture theory can be applied with reasonable success, assuming the excluded volume to consist of poorly conducting proteins plus its water of hydration. In this range, the conductivity of most tissues is not strongly dependent on frequency. The conductivity increases again above 100 MHz. Contributions resulting from the Debye relaxation processes of water become significant compared to the ionic frequency-independent electrolyte contribution. Several other relaxation processes indicated in Table 2 affect the electrical data. These effects have been reviewed in greater detail by Foster and Schwan (1986).

The permittivity data are displayed for muscle tissue in Fig. 3. Outstanding are the extremely high values at low frequencies. Large permittivity values are generated by ionic diffusion processes, ion channels, and subcellular structures such as the tubular systems as discussed before (Schwan, 1981a). Application of the Schwarz theory (1962) to muscle cells, with a diameter near 100 μm, gives low-frequency permittivity values comparable to those observed experimentally, i.e., above 10^6 relative to free space. But the frequency range of the α dispersion of muscle does not fit theoretical prediction. An alternative theory was suggested by Falk and Fatt (1964). They proposed that the α dispersion is caused by the sarcotubular system which extends from the membrane into the cytoplasm. At low frequencies, the current penetrates deep into this system, thereby not only charging the cell membranes but also the membranes of the tubular system. At higher frequencies the tubular system's capacitance is no longer charged. This happens when the frequency becomes higher than the inverse of the time constant given by the system's capacitance and the access resistance. The Falk–Fatt theory is generally accepted. However, other tissues, such as liver and subcutaneous fat, display similar behavior at low frequency without a tubular system. Clearly, different mechanisms exist and remain to be sorted out (Schwan, 1981a).

Application of the theory of the β dispersion explains the radiofrequency data. Finally, the γ dispersion for soft tissues of high water content is consistent with the assumption that tissue water has properties comparable, if not identical, to those of normal water.

5.2 Special Topics

We discuss next several other relevant topics which have been investigated extensively.

5.2.1 Anisotropy. The anisotropy of muscular-tissue impedance, first observed at low frequencies by Hermann (1871), then at higher frequencies by Sapegno (1930) and by Epstein and Foster (1983), results from the structure of muscle, which consists of bundles of cells which are long compared to their diameter. "Longitudinal" resistance values are observed to be much lower than "transversal" ones at low frequencies. This is anticipated from relevant mixture theory. However, at high frequencies this structural anisotropy disappears, since membranes are then shortcircuited. Indeed, Epstein and Foster demonstrate that the ratio of electrical properties in and perpendicular to the cell direction diminishes as the frequency increases. Many other soft tissues, such as liver, kidney, and heart muscle, are structurally isotropic and, hence, their electrical properties are also.

5.2.2 Live and Excised Tissues. Most tissue properties were obtained using excised samples. Are they representative of "live" tissue samples? Studies were undertaken comparing *in situ* data with excised samples. Redistribution of blood volume appears to be a significant factor contributing to changes with excision. Air strongly affects lung data, rendering excised data almost worthless (Schwan and Kay, 1956). Changes in membrane properties occur slowly after death. Thus the β dispersion disappears after one or two days, as the cell membranes disintegrate after metabolic activity stops. Differences between excised and *in situ* tissue samples are most pronounced at low frequencies. Disintegration of membranes does not affect high-frequency data, since such data, obtained at frequencies above the β range, are not affected by membranes as outlined above.

5.2.3 Influence of Tissue Morphology. The complexity of tissues contributes to a broadening of relaxational response curves. This effect has been investigated for the β dispersion range by Stoy *et al.* (1982) investigating liver tissues. Hepatocytes, the abundant liver cells, cell organelles such as nuclei, mitochondria, endoplasmic reticulum, and the tissue proteins were considered, and their relative contributions to the electrical properties evaluated. The cellular contribution is the largest. The proteins and, to a lesser extent, the cell organelles explain the experimentally observed broadening of the high-frequency tail of the β dispersion.

5.2.4 Temperature Coefficients. The dominant charge carriers in tissues are electrolyte ions. The conductances of tissue electrolytes have a frequency-independent positive temperature coefficient of about 2% per °C and about −0.5% for the permittivity. In spite of this simple behavior, the temperature dependence of the electrical properties of tissues is complex. The reason for the complications is the temperature dependence of the various time constants responsible for the relaxation effects as indicated in Table 2. Positive and negative temperature coefficients exist in different frequency ranges. This behavior is fairly well understood. For a detailed analysis see Foster and Schwan (1986).

5.2.5 Diagnostic Applications. Unusual electrical properties have been frequently suggested as indicators of diagnostic value. We list here only a few:

Extracellular electrolyte volume is responsible for low-frequency conductance properties, while high-frequency data relate to total electrolyte, since membranes are shortcircuited. A comparison of both low- and high-frequency data might permit the determination of both extracellular and intracellular water (Settle *et al.*, 1980; Thomasset *et al.*, 1984). However, the technique is complicated because of other factors such as cell shape and uncertainty of appropriate mixture theory.

Tissue impedance plethysmography has been studied by many authors, beginning with Nyboer (1970). Some of the techniques measure minute tissue impedance changes which are synchronous with blood flow. The technique has not gained widespread recognition. Other applications are concerned with the changes in the impedance of the chest with breathing and heart activity (Geddes and Baker, 1975).

5.2.6 Nonlinear Properties. So far, all properties considered above pertain to low field-strength levels. However, as the field level exceeds a certain value, properties are affected. Threshold levels for such changes are in part due to the phenomenon of dielectric saturation, the nonlinear properties of membrane ion channels, the field-dependent contractile properties of muscle cells, and, at even higher *E* values, outright membrane destruction.

Muscle nonlinearity manifests itself in a change of low-frequency conductance near 1 V/cm in the medium surrounding the cells. Corresponding field strength values in the membranes surrounding muscle cells would be approximately 10 kV/cm. The low-frequency permittivity of protein solutions approaches dielectric saturation at about 10 kV/cm in the medium. The conductance of membrane channels changes at membrane voltages near 10 mV, corresponding to field strength values in the membrane of the order of 10 kV/cm. Corresponding field-strength values in the medium are about 1 V/cm. Apparently, threshold field-strength levels in the medium vary by four orders of magnitude, while corresponding values in the cell membrane are surprisingly similar. This illustrates that in all cases the onset of nonlinearity appears to be governed by dielectric saturation in the membrane constituents, presumably membrane proteins.

5.2.7 Brain Tissue Studies. Extensive efforts were undertaken to study the electrical properties of brain tissues during the 1960s and early 1970s. Agreement between electron microscopic determinations of extracellular space and that derived from impedance data was reported to be satisfactory by van Harreveld (1970). But Adey *et al.* report that impedance changes do not parallel changes in extracellular space (Adey *et al.*, 1969). The frequency dependence was investigated (Ranck, Jr., 1963). Noteworthy is the pronounced increase in cerebral cortex impedance during spreading depression (Leave and Ferreira, 1953; Marshall, 1959; Ochs, 1962). Activity in this field decreased after 1973. Important questions about the relative role of extracellular space, cellular conductances, their changes under abnormal conditions, and the effects of fluid and ion exchanges between inside and outside of the various cellular compartments remained unanswered.

6. FIELD EFFECTS

A variety of moderate to strong field effects on biological tissues are known.

6.1 Cell Manipulation Techniques

Cells can be manipulated by alternating electrical fields for a variety of purposes.

Pearl chain formation is the term often used to describe the alignment of biological cells or particles which has been observed in fields (Schwan and Sher, 1969). The effect is used in order to assure close cellular contact, a prerequisite to cell fusion.

Cell fusion is accomplished by application of a brief field pulse to two adjacent cells, strong enough to destroy membrane structure at the point of contact and yielding the formation of a larger cell. It is a new technique of potential value in biotechnology (Arnold and Zimmermann, 1984).

Cell rotation occurs in rotating fields and can be used to study the electrical properties of single cells over a broad frequency range (Arnold and Zimmermann, 1982).

Electroporation is achieved when a single cell is exposed to a brief strong field pulse. It opens briefly a part of the membrane, permitting the entry of extracellular material into the cell. The technique is useful in order to incorporate macromolecules such as nucleic acids into the cell, and is of biotechnological interest (Neumann, 1972; 1982).

Cell deformation occurs when cells are exposed to alternating electrical fields. The effect has been used to study the mechanical properties of cell membranes (Bryant and Wolf, 1987; Engelhardt and Sackmann, 1988; Chang *et al.*, 1985; Ashe *et al.*, 1989).

Cells and particles move in inhomogeneous electrical fields. This effect can also be used to determine the electrical properties of single cells (Burt *et al.*, 1990; Kaler and Jones, 1990).

Other reported effects include cell destruction, the ejection of small vesicles, and protoplasmic streaming.

The physical basis of these phenomena is well understood. They occur when related electrical potential energy changes are larger than kT. The needed threshold field strength is given approximately by the condition

$$\epsilon E_{\mathrm{th}}^2 R^3 = kT, \tag{24}$$

where ϵ is the permittivity of the medium, E_{th} is the threshold field strength, R is the cell or particle radius, k is the Boltzmann constant, and T is absolute temperature. For cellular size, theory predicts threshold field strength levels of the order of 1–100 V/cm in the medium surrounding the cell, in agreement with experimental data available so far (Schwan, 1985a, 1985b).

6.2 Nerve Conduction

The electrical properties of nerve cells change significantly when membrane potential changes of 10 mV or more are applied. These changes have been studied extensively and are summarized by a set of nonlinear equations formulated by Hodgkin and Huxley (1952). The changes were later recognized to take place at specific sites responsible for the control of ion exchange between media inside and outside of nerve cells. These ion channels selectively control the flux for individual ions such as sodium, potassium, and calcium. The detailed mechanism responsible for these changes in the conformation of ion channels has not been clarified. Field-strength level changes of the order of 10 kV/cm correspond to 10 mV across the membrane, which is only 10 nm thick. For such high local field-strength levels, the Langevin criterion and Eq. (17) are satisfied for molecules such as membrane channel proteins, and changes in conformation can be expected.

The propagation of an electrical signal of 10 mV or more along the nerve fiber can be analyzed using the same transmission-line equations which describe the propagation of an electrical signal along a cable. However, the nerve membrane parameters to be used are nonlinear and the theory becomes accordingly complex.

6.3 Muscle Contraction and Shock

Muscle contraction can be triggered by electrical pulses and low-frequency fields. Here again thresholds exist and are comparable to those which elicit nerve impulses. The mechanism of muscle contraction is less well understood than that causing nerve stimulation. It is generally believed that induced membrane potentials are transmitted to the cell interior, where muscular macromolecules then undergo conformational changes. Muscle contraction, as well as nerve stimulation are induced only at frequencies below approximately 10 kHz.

Shock is induced by external fields applied to the human body. This hazard has been extensively studied. Threshold levels have been established for sensation (a fingertip contact with a small electrode), muscular contraction (determination of let-go current), and fibrillation (dangerous heart muscle contractions). In all cases, corresponding current density levels in the tissues are about 1 mA/cm^2, field strength levels near 1 V/cm, and induced membrane potentials near 10 mV. Another type of shock occurs when a charged object is contacted—e.g., a doorknob after walking on a carpet, thereby charging the walker by friction. Fairly large discharges can occur when large objects such as trucks located in a high field, such as exist under high voltage transmission lines, are contacted. These discharges may be brief on short contact or continue if contact is maintained. Abundant data are available. See, e.g., Dalziel (1956) and Geddes (1971).

7. TECHNIQUES

Techniques for the determination of the dielectric properties of macromolecules, cells, and tissues fall into two classes:

1. Techniques for the study of single cells. They are limited to low frequencies, except for some novel techniques introduced recently.
2. Suspension techniques. Measurements integrate over many molecules, particles, or cells. They extend over a broad frequency range (dielectric spectroscopy), but require that one can extract particle or cell properties from measured bulk data using some mixture theory.

Table 4 summarizes the advantages and limitations of two experimental methods, i.e., dielectric spectroscopy and the cell rotation technique.

7.1 Suspension Techniques

The following types of instruments have been employed.

Table 4. Advantages (indicated by +) and limitations (−) of dielectric spectroscopy (S) and electrorotation (R). The rotation technique requires high field strength. This causes undue heating unless the medium's conductivity is reduced. The levitation and rotation technique share similar advantages and limitations.

7.1.1 Bridges and Transmission Lines. A variety of bridges, such as the Wheatstone bridge, are commercially available, but of limited accuracy and resolution. Special-purpose bridges of very high resolution have been reported. They are able to resolve impedance magnitudes to better than 1 part in 10^6. With such resolution, permittivities of cell suspensions can be determined down to less than 100 Hz if the cells are suspended in a physiological medium, and to lower values if the cells are suspended in a poorly conducting medium. The upper frequency limit of this technology extends to about 100 MHz.

Transmission-line techniques and waveguides have been developed to cover the frequency range from some hundred MHz to about 100 GHz. Such techniques include the evaluation of the signal which is reflected from the sample to be investigated, or the comparison of two branches of a network, one containing the sample, and the other a calibrated phase shifter–attenuator combination. Accuracies of these techniques are better than 1% for permittivities and 1%–2% for conductivities, for electrolytes and biological samples.

7.1.2 Modern Commercial Equipment. Commercially available impedance analyzers provide a fast and convenient means to scan rapidly over broad frequency ranges. Models cover the total range from MHz to GHz. Resolution of impedance magnitude ranges from 10^{-4} to 10^{-5}, i.e., it is high, but lower than provided by the special research equipment mentioned above. Time-domain technology provides even more rapid spectroscopy over broad frequency ranges. A pulse is applied and the response subjected to a time domain–frequency domain transformation using appropriate Fourier algorithms. Commercial equipment is now available. However, accuracy is somewhat more limited than that of frequency-domain techniques. For more detailed surveys of instrumentation and evaluation techniques, see Grant *et al.* (1978) and Macdonald (1987).

7.1.3 Advantages and Limitations of Suspension Techniques.

7.1.3.1 Electrode Polarization. Low-frequency limits to dielectric spectroscopy are imposed by electrode polarization (Schwan, 1963; 1968). The impedance of electrodes increases with decreasing frequency and, since in series with the suspension, adds increasingly to the measured impedance as the frequency is decreased. This is demonstrated by the following approximate equations (Schwan, 1963):

$$C=C_s+\frac{G^2}{1+\omega^2R^2C_p}, \tag{25}$$

$$R=R_s+R_p+R_s(R\omega C)^2. \tag{26}$$

R and C are measured resistance and capacitance, R_s and C_s are those of the sample, and R_p and C_p are the components of the polarization impedance $Z_p=R_p-j/\omega C_p$. The equations are valid approximations if $R\omega C<1$ and $R_p<R_s$.[1] Electrode artifacts contribute to measured capacitance values below about 3 kHz when cells are suspended in a physiological media ($\sigma\cong 10$ mS/cm).[2] Large sample size, proper electrode treatment, and methods to correct for the electrode effect can reduce this limit about tenfold. Electrode contributions to measured data decrease rapidly when the medium conductivity is reduced. They can be

---

[1] These conditions can be shown to apply if the polarization impedance components are smaller than those of the sample resistance (see Schwan, 1963). This is usually the case.

[2] Assuming a 10% error, Eq. (24) reduces to $f^2C_pd\epsilon=3\times10^{12}\sigma^2$. For example, for a Pt electrode covered well with Pt black, C_p is about 1 mF/cm^2 at 1 kHz. Thus, for $d=5$ cm, $\sigma=0.01$ S/cm, and $\epsilon=1000$ relative to free space, the frequency is $f=2.4$ kHz.

eliminated entirely by use of four-electrode technology (Schwan, 1963; Schwan and Ferris, 1968). This technology uses different current- and potential-sensing electrodes. Care is required to exclude the potential-sensing electrodes from currents and to avoid capacitive contributions which may mimic relaxation phenomena. No good commercial equipment is yet available for this purpose.

7.1.3.2 Resolution. Permittivity determinations are limited by the high dielectric loss-tangent values, $\tan \delta = \sigma/\omega\epsilon$, typical of cell suspensions at low frequencies (Schwan, 1963). Resolution is determined by the principle $d\sigma = \omega d\epsilon$. For physiological media and typical dielectric constants of cell suspensions (ϵ near 2000), dielectric constants can be resolved to 10% at 1 kHz with equipment providing a resolution of 10^{-5} in impedance magnitude. Such resolution is only obtainable with a few commercial products. Special laboratory devices providing resolutions as low as 10^{-6} and 10^{-7} have been reported (Schwan *et al.*, 1962; Schwan, 1963; Hayakawa *et al.*, 1975). Combination of four-electrode technology with very high-resolution equipment extends dielectric spectroscopy of biological solutions and suspensions to MHz frequencies (Fig. 6).

7.1.3.3 Drift. Biological conductivities have a temperature coefficient of about 2%/°C. Conductivity resolutions near 10^{-5} therefore require temperature stabilization to 10^{-3} °C. This drift problem can be reduced by alternating measurements at various frequencies with those at a fixed reference frequency and applying corrections using the data obtained at the reference frequency as time advances (Schwan, 1963; Hayakawa *et al.*, 1975).

7.1.3.4 Mixture Theories. Maxwell's mixture theory is not rigorous since necessary assumptions include the need for low particle concentrations in order to exclude the interference of other particles in the proximity. However, for low particle or cell concentrations, the Maxwell theory is appropriate and agrees well with other mixture theories. How serious are the errors introduced by the simple Maxwell equation? We first compare the prediction of Eq. (13), derived from Maxwell's equation (8) for the permittivity ϵ_0 of a concentrated cell suspension, with that of the simple model indicated in Fig. 8. This model assumes a densely packed number of cells of cubical shape and size $2R$. N such cells are arranged in a unit volume between the electrodes. Thin membrane surfaces perpendicular to the electrodes do not contribute to the total capacitance, and only the $2N$ membranes parallel to the electrodes need be considered. Therefore, $\epsilon_0 = C_m/2N = RC_m$, since $2NR = 1$. This is identical with Eq. (13) for $p = 1$, indicating that the Maxwell prediction is good for high particle volume concentrations. Experimental experience supports this conclusion (Kell, 1985). The validity of Maxwell's mixture equation has been also tested for the special case of nonconducting particles in a conducting medium, and was found to be excellent up to the highest possible concentrations (Cole *et al.*, 1969). Nevertheless, it is uncertain if Maxwell's mixture equation is the best choice under different circumstances. More sophisticated theories avoid the assumption made by Maxwell. In particular, Hanai's equation (1968) has been successfully applied to suspensions of particles and cells and appears to be an extension of Bruggemann's (1935) equation to complex admittances.

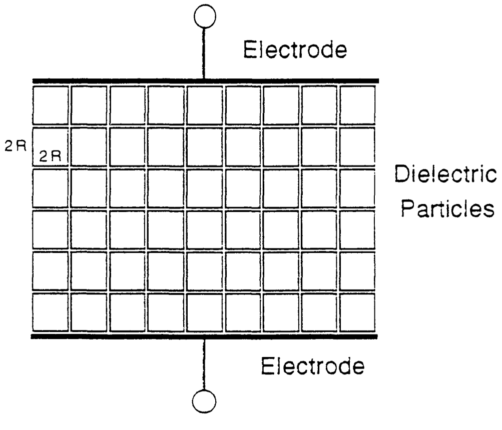

FIG. 8. A model of packed cubic dielectric particles. This model is used to prove the validity of Maxwell's mixture theory even at high volume fraction.

7.1.3.5 Membrane Conductance. Determinations of membrane conductances with the suspension technique are difficult. The reason is apparent from Eqs. (12) and (13): Typical G_m values vary between 1 and 1000 mS/cm^2, and therefore the second term in the denominator is small compared to 1 for typical cell size. Hence, the effect of the membrane conductance is usually weak and difficult to extract from measured data. This problem can only be circumvented if the second term in the denominator is made large by choice of large cells and medium resistivity. However, any increase in the resistivity of the medium may adversely affect cell properties.

7.2 Single-Cell Techniques

7.2.1 Microelectrode Technique. We discuss next the measurement of membrane capacitance and conductance of biological cells using methods which are more suitable to extract information about the membrane conductance. The membrane conductance is of greater interest than the membrane capacitance. The conductance is caused by channels and pores which regulate ion exchange and occupy only a small fraction of the membrane surface. Hence, it is functionally more important than the capacitance, which is mainly due to membrane bulk or the lipid layer.

7.2.1.1 Microelectrodes. There are two types of microelectrodes—those made of metal and of glass. Of particular importance is a glass microelectrode with a very fine tip of less than 1 μm. These electrodes are inserted into the cell interior, and transmembrane electrical properties such as the membrane potential are measured. Because of the very large tip impedance and various limitations thereof, i.e., limited frequency response and the propensity to be nonlinear, they are not suitable for the measurement of membrane admittances. In spite of these shortcomings, membrane capacitance and resistance can be measured using two such microelectrodes. With this technique, both electrodes are inserted into a cell. One of them is used for current injection, and the other for voltage recording. The membrane impedance can be obtained as a transfer function between voltage and current: $Z = V/I$. This technique was successfully used for the measurement of the transmembrane impedance of skeletal muscle between 1 Hz and 1 KHz by Falk *et al.* (1964).

7.2.1.2 Voltage Clamp Method. Originally, the voltage clamp technique was developed to investigate the current-voltage characteristics of squid axons (Cole, 1968). Using a negative-feedback control system and intracellular voltage sensing and current electrodes, the membrane potential of the nerve axon is clamped at a predetermined value, thus preventing the action potential from developing. Using this technique, a highly nonlinear current-voltage characteristic of nerve membranes was revealed (Hodgkin *et al.*, 1952). From the tangent of these current-voltage diagrams, we can calculate the conductance of nerve membranes. In addition, using the capacitive transients, the total capacitance of the membrane can be determined. A schematic diagram of the voltage clamp circuit is illustrated in Fig. 9. Finally, with the advent of the patch clamp technique (see BIOPHYSICS), it is possible to measure membrane properties of small spherical or ellipsoidal cells using a glass micropipet (Sakmann *et al.*, 1983). A glass micropipet is pressed against a small section of the cell wall with a gentle suction, in order to establish a tight seal with a very high resistance of more than 10^9 Ω. Application of a square pulse using the pipet, and subsequent current recording, permits determination of the membrane current-voltage characteristics. Of particular interest in this technique is its ability to investigate membrane "patches" and to measure single channel currents. Using a very small membrane patch, which is tightly sealed at the tip of the micropipet, spontaneous opening and closing of each channel can be recorded by monitoring small current pulses. Although channel opening and its duration are stochastic, the magnitude of single channel currents is usually of the order of 3–5 pA.

A variation of the patch clamp technique uses a glass micropipet tightly attached to the

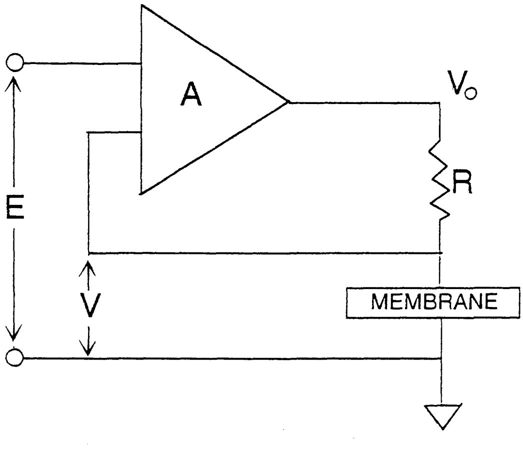

FIG. 9. A schematic diagram of the voltage clamp circuit. *E* is the command potential, and *V* is the membrane potential. *A* is the gain of differential amplifiers, and *R* is access impedance due to cytoplasm.

cell surface to measure the membrane admittance. Asami *et al.* (1990), using sinusoidal voltage inputs, successfully measured the membrane capacitance and conductance of small nearly spherical cells, such as myeloma and HeLa cells, between 1 and 1000 Hz. They found frequency-independent membrane properties $C_m \approx 0.8\ \mu\text{F/cm}^2$ and $G_m < 100\ \mu\text{S/cm}^2$.

The following single-cell technologies cover a much broader f spectrum extending from 100 Hz to more than 10 MHz. They share some disadvantages of dielectric spectroscopy, in particular the small effect of membrane conductance values on measured data, unless the second term in the denominator of Eq. (13) is made large by choice of large cells and medium resistivity.

7.2.2 Electrorotation. The rotation of particles and biological cells exposed to a rotating alternating field has been extensively investigated by Arnold and Zimmermann (Arnold, 1988; Arnold and Zimmermann, 1984, 1988; Zimmermann and Arnold, 1983) and by Glaser and Fuhr (1986). It peaks at the characteristics frequencies of the β dispersion, as may be predicted by application of the simple cell model characterized by Eqs. (9) to (13) (Schwan, 1985c). Fuhr *et al.* (1985, 1986) carried out more extensive calculations analogous to the Pauly–Schwan theory mentioned above. A rigorous discussion for arbitrary complex dielectric properties of particle and medium has been carried out by Sauer and Schloegl for cylinders and spheres (1985). The torque L which causes the particle to spin is given by $L = E\mu''$, with E field strength and μ'' the imaginary part of the induced dipole moment:

$$\mu = \mu' + j\mu'' = \epsilon_a R^3 E \frac{Y_p - Y_a}{Y_p + 2Y_a} = \epsilon_a R^3 E u, \qquad (27a)$$

where

$$u = \frac{Y_p - Y_a}{Y_p + 2Y_a}, \qquad (27b)$$

R is the particle radius, and the subscripts p and a indicate particle and outside medium. The Y's are admittivities and ϵ_a is the permittivity of the medium. If the suspending medium is an electrolyte, ϵ_a is frequency independent up to more than 1 GHz. Thus the frequency dependence of the rotation speed is directly proportional to the quantity u'', i.e., the imaginary part of u.

7.2.3 Levitation. If a particle is exposed to a divergent electrical field, it experiences a force given by

$$F = \epsilon_a u' \text{ grad } E^2, \qquad (28)$$

where u' is now the real part of the ratio u defined in Eq. (27b). u' can be either positive or negative. Thus, the force may be directed towards or away from the region of higher field intensity. This force may be used to balance gravitational forces, thus providing a null technique of potentially great accuracy. Stability criteria have been worked out, and the technique has been demonstrated to be useful for the investigation of particles and biological cells (Kaler and Jones, 1990). The relevant theory is very similar to the one for the rotational response. However, the frequency response of the gradient force is similar to the dispersion effect discussed for dielectric spectroscopy. For example, in the case of uniform particles, the force changes with frequency as expressed by the dispersion equations discussed above in Sec. 7.2. The magnitude of the dispersion is now

$$\Delta u' = \frac{3(\epsilon_a \sigma_i - \epsilon_i \sigma_a)}{(\sigma_i + 2\sigma_a)(\epsilon_i + 2\epsilon_a)} \qquad (29)$$

and, hence, can be either positive or negative. The time constant is identical to the one obtained for rotation and dielectric spectroscopy. In the case of shell-surrounded particles, two dispersions result with the same time constants as in the cases of rotation and spectroscopy.

Rotation and levitation techniques have much in common with dielectric spectroscopy. The same equations are used to obtain cellular data from the particle admittivity Y_p. In both cases u transformations must be used, as seen from the equations for torque L and force F. The difference is that u'' directly determines the rotational response, and u' that of levitation, while the transformation on the left-hand side of Eq. (8) needs to be made in addition, in order to relate suspension data to particle property. Thus the rotation and levitation techniques are one step more direct and not subject to the limitations of Maxwell's mixture equation (8). However, it is not possible to extract from either u' or u'' alone the dielectric properties ϵ and σ of the particle observed. Additional information must be provided. This can be done, e.g., by variation of the conductivity of the medium (Zimmermann and Arnold, 1983). The suspension technique provides both components of u from observed ϵ and κ data. It is also faster and easier to apply, and covers a much broader frequency range; and commercial instrumentation is available. The α dispersion observed with charged particles and data obtained from electrorotation do not agree (Arnold *et al.*, 1987). It appears that rotating and nonrotating fields interact with the counterion atmosphere in a different manner.

Table 4 attempts to summarize the advantages and limitations of various techniques.

7.2.4 Microspectroscopy. This technology appears to be just emerging as a byproduct of advances in the fabrication of very small electrode assemblies. Miniature electrode arrangements can be used to manipulate single cells and large macromolecules by electrical fields (Washizu and Kurosawa, 1990; Washizu *et al.*, 1990). This can be possibly done over a broad frequency range. Advantages combine those of suspension techniques with single-object assessment. Disadvantages include the complexity of operation necessitated by the small dimensions. Electrode polarization problems are much more pronounced with microelectrode arrangements unless four-electrode techniques are used or polarization impedances are reduced by use of high fields.

INTRODUCTION

An instrument is a device that is used in observing, measuring, or controlling a physical parameter or event. Almost every instrument (or instrument system) used today involves the detection of electrical signals at some point in the process. The parameter being measured produces an observable effect in a sensor or transducer that generates a corresponding electrical signal. The electrical signal is then amplified or "conditioned" and transmitted to an electronic instrument for measurement. This article will focus upon the various kinds of electronic instruments commonly used for signal measurement. The transducer and the signal conditioner are important parts of the measurement but are outside the scope of this discussion.

It is not necessary for the transducer to produce an electrical signal to make the desired measurement. A familiar example is the thermometer, which uses the expansion of mercury in a glass capillary as a measure of temperature. Although the mercury thermometer is an excellent instrument, its use has

digital Encyclopedia of Applied Physics

greatly decreased in recent years because of the availability of low-cost electronic thermometers. This is also true of most other kinds of nonelectrical transducers. The convenience and versatility offered by modern electronics, especially with microprocessors and digital technology, have resulted in a drastic increase in the use of electronic-based sensors and instruments.

The instruments and techniques for making accurate measurements of electrical quantities have been common laboratory tools for several decades. Advances in modern electronics, incorporating large-scale integrated circuitry and embedded microprocessors, have not drastically improved the ultimate capabilities of making precise electrical measurements, but they have created enormous changes in the cost, convenience, and availability of precision electrical measurement devices. Many of the time-consuming and carefully controlled adjustments, which used to be done by the operator, are now accomplished by internal microprocessors. More compact electronics and integrated circuits have resulted in much smaller instruments that can perform multiple functions, thus replacing several of the older devices. Digital recording and display devices have greatly extended the available options for storage and analysis of electrical signals.

Basic methods for measuring various electrical quantities and properties will be discussed, followed by a review of common laboratory instruments for display, storage, and analysis of electrical signals.

1. BASIC ELECTRICAL UNITS

The fundamental Système International d'Unites (SI) electrical unit is the ampere, which is defined as the current in two straight, parallel, infinitely thin and infinitely long conductors, separated by 1 m, which produces a force per unit length of 2×10^{-7} N/m. This force is related to the current by the expression

$$\frac{F}{L}=\mu_0\frac{I_1I_2}{2\pi D}, \tag{1}$$

where μ_0 is the magnetic permeability of free space, I_1 and I_2 are the currents in the conductors, and D is the separation. It can be seen that the SI definition is equivalent to setting the value of μ_0 equal to $4\pi\times10^{-7}$.

The SI volt and ohm are derived from the ampere. The volt is the potential drop that produces a power dissipation of 1 W at a current of 1 A. The ohm is the resistance that produces a potential drop of 1 V at a current of 1 A. These definitions are sufficient to establish the values of the electrical units, but it has not been possible to devise a real experimental apparatus to establish them with sufficient precision to serve as measurement standards. For this reason the volt and the ohm are represented independently by the Josephson effect and the quantum Hall effect (Taylor, 1987).

The Josephson effect allows the voltage drop V in a system of superconductors and oxide layers to be related to the frequency f of a microwave excitation source by a quantity that depends only upon fundamental physical constants. The relationship is shown by

$$V_h=\frac{h}{2e}f=\frac{f}{k_j}, \tag{2}$$

where h is Planck's constant, e is the electronic charge, and K_j is the Josephson constant (483 597.9 GHz/V).

The quantum Hall effect allows the Hall voltage observed in certain metal oxide semiconductor junctions at cryogenic temperatures (below 2 K) to be related to the current by a quantity that also depends only upon Planck's constant (h) and the electronic charge (e). The relationship is shown by

$$V=\left(\frac{h}{e^2}\right)\left(\frac{I}{n}\right)=R_h\left(\frac{I}{n}\right). \tag{3}$$

R_h is the von Klitzing constant (25 812.817 Ω) and n is a small integer.

2. MEASURING ELECTRICAL QUANTITIES

The advent of electronic-based measuring instruments has greatly enhanced our ability to measure without perturbing the medium being measured. The energy drawn from the system being measured by an electronic instrument is typically 1000-fold less than that required by electromechanical instruments. Such instruments were usually based on the d'Arsonval galvanometer (Sydenham, 1983) and required 50 μA (or more) full-scale operating current. The d'Arsonval galvanometer consists of a current-carrying coil suspended in a magnetic field by a torsion spring that opposes the torque produced by the current. The coil assembly is attached to a pointer that indicates the level of current on a scale. Electronic versions of such instruments can be designed to draw no more than a few nanoamperes (digital multimeters) and as little as 1 fA (electrometers).

2.1 General Principles

2.1.1 Electrical Voltage and Current Levels. Voltage and current signals can convey information by any combination of attributes such as amplitude, repetitive rate, time waveform, phase angle, and power spectrum. These signals can be classified as having either alternating-current (ac) or direct-current (dc) forms or a combination of both. These terms were originally associated with electrical wave forms produced by particular types of electrical power-generation equipment. In more recent times, these terms have taken on a broader connotation as their use persisted within rapidly expanding electronic technologies. Now, these terms are often used to classify electrical levels totally unrelated to power generation. In the world of electronic instruments, one usually thinks of a dc level as having an instantaneous value that can change significantly only at rates slow enough for direct observation by a human. Pure ac levels have instantaneous values that change at much faster rates, or with frequencies greater than several cycles per second (hertz), and with an average value equal to zero. An ac level is usually specified by a characteristic value obtained by squaring its time waveform point by point, taking the average of the resulting all-positive wave form, and taking the square root of the resulting value. This characteristic value is called the root mean square or rms value. If the wave form is sinusoidal, other representations such as amplitude or peak-to-peak are sometimes used; however, rms is generally preferred because of its application to power measurements as discussed in Sec. 2.6.

2.1.2 Instrument Components. Regardless of the particular electrical quantity to be measured, most modern electronic measurement instruments have several functional blocks in common. In the most modern designs, usually microprocessor-based digital instruments, the front-end or input circuit consists of some kind of excitation and/or linear preamplifier, the particular arrangement depending upon whether the source of the electrical parameter to be measured is active or passive. An active source is capable of imparting power to the measuring instrument. A passive source can only dissipate power and, therefore, requires electrical excitation from the instrument to produce a measurement. A linear preamplifier is usually required for converting the charge, current, voltage, impedance, or whatever is to be measured to a proportional, scaled internal signal level, usually voltage. To maximize the resolution of the measurement, the full dynamic range of the instrument should be used. This is accomplished by matching the maximum preamplifier output to the full input range of the next stage, typically an analog-to-digital conversion (ADC) circuit.

The ADC, in turn, supplies digitized measurement data to some combination of external communication interface, data storage device, and data display device depending upon the specific application for which the instrument is intended. In the case of an oscilloscope or strip chart recorder, the ADC result is periodically obtained and keyed to time when stored for later production of an amplitude-versus-time display of the measurement. Rapid multiplexing between the taking of data and production of displays is used to simulate real-time instrument operation. Common external communication interfaces are digital single-bit or multibit serial data ports conforming to industry standards such as RS-232, RS-422, and GPIB. Data storage devices such as any form of integrated-circuit (IC) random-access memory (RAM), disk drives, and tape drives are often used. Display devices range from multidigit numeric displays for digital multimeters (DMMs) to cathode ray tubes (CRTs) for oscilloscopes. Even in the most economical digital instruments, the operations of these functional blocks as well as its ADC are usually controlled by a microprocessor.

2.1.3 Instrument Resolution. All ADC circuits function to produce a binary code that represents an input signal level. The form of code most frequently used is a binary-base numeric representation because of the simple bistate (high or low) possibility for each digit of the code. Many different types of ADC circuits are in use today. Dual-slope integrator or successive-approximation types are examples of conversion techniques that might be utilized for high resolution but usually are not suitable for the fastest signal measurement applications requiring millions or more of conversions per second. Digital oscilloscopes are available with flash ADC circuits that can sample electrical signals at rates exceeding a billion samples per second, but at the cost of reduced resolution. The operation of ADCs is discussed further in Sec. 3.3.2.

Resolution requirements, specified by the user and depending upon the particular application, determine the number of binary bits the ADC must use to code the voltage level from the preamplifier. Resolution is defined as the smallest change in voltage that can be detected by the measurement system. For example, an 8-bit binary code gives a maximum possible resolution of 1 part in 255, or 0.4% of the full-scale range. In general, an N-bit binary code gives a maximum number of increments within the ADC range given by

$$2^N - 1. \tag{4}$$

The resolution in volts for a given range is then this number of steps divided into the largest magnitude voltage or full-scale range.

The nature and purpose of a measurement determine the resolution requirements of a digital conversion system to be used for displaying or recording data. For example, a temperature detection instrument with a 0–5-V full-scale output corresponding to a 0–100 °C temperature detection range requires at least a 10-bit ADC if the temperature is to be known to within 0.1 °C. On the other hand, a switch used to detect the closure of a cover might be operated so that 5 V is connected to the input of a measurement system only when the cover is secured. The measurement system will receive either 5 or 0 V in this case for the cover closed or open, respectively. Such a measurement system need have only a 1-bit digital conversion code to utilize fully the available signal. Individual signal inputs within any electronic binary logic circuit can be thought of as inputs of 1-bit ADCs.

2.2 Charge Measurement

One coulomb of electrical charge is the quantity of electricity transported in 1 s by 1 A of electrical current. Charge is typically measured by an electrical circuit with an integrating mathematical characteristic.

Electronic instruments specifically for measuring electrical charge are referred to as electrometers. Conceptually, such an instrument consists of an extremely high-input-impedance electronic differential amplifier with a capacitive negative-feedback path and grounded positive-input terminal as shown in Fig. 1.

The capacitance of the feedback path determines a constant of proportionality between the amplifier output voltage and the net charge that has flowed from the amplifier negative-input node during the time since the amplifier output voltage was last zero. The high differential gain of the amplifier forces nearly all of the measured charge to be stored by the feedback capacitor, giving rise to a potential across the capacitor, which appears at the amplifier output. Under ideal circumstances, the voltage output is determined by the familiar equation (5), where Q is the measured charge in coulombs, V is the amplifier output in volts, and C is the feedback capacitance in farads:

$$V = -Q/C. \tag{5}$$

A measurement with such a circuit will be accurate as long as several conditions are

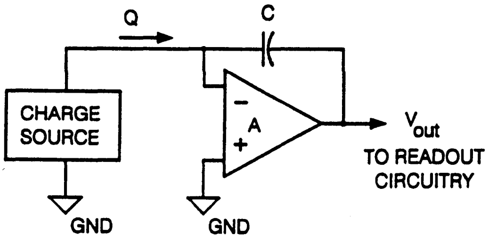

FIG. 1. Typical electrometer (charge amplifier) configuration; the large gain A of the amplifier forces any charge Q entering the input node to be stored on the capacitor C, forcing the magnitude of V_{out} equal to Q/C.

satisfied. First, the charge to be measured must be much greater in magnitude than stray charge introduced by amplifier input bias current and feedback capacitor leakage current. Second, the amplifier output must at all times during the measurement interval remain within its linear range. Third, the variations with time in the measured charge flow rate must not be faster than the gain–bandwidth product (small output signal) or slew rate (large output signal) of the operational amplifier. Otherwise, the amplifier could not "keep up" and would become nonlinear in its response.

2.3 Voltage Measurement

One volt is classically defined as the difference in potential between two points along a conductor with 1 A of electrical current flowing through the conductor and 1 W of power dissipated between the two points. Contrary to this basic definition, a voltage measurement usually does not involve a power measurement except for some types of true-rms instruments described later.

2.3.1 dc Measurements. Numerous methods of measuring voltage are in use today for applications ranging from the precise measurement of millivolt analog sensor outputs to measurement of high-voltage ac power bus levels to bistate digital level sensing. The most modern methods nearly always involve a high-input-impedance preamplifier to sense the voltage without loading the source of the voltage; i.e., without drawing significant current from the source. Typical input impedance values for modern digital voltmeters are over 10 MΩ.

Electronic voltage measurements can be classified into one of two broad categories: analog and digital. Both analog and digital meters require an analog preamplifier at the input for sensing the voltage to be measured. In the case of the analog meter, it is the presence of the preamplifier that has modernized the meter relative to purely electromechanical analog meters and placed new analog meters into the class of electronic instruments.

For analog measurement and display of voltage levels, the preamplifier referred to above is used to sense the voltage and produce a proportional analog current signal suitable for driving an analog display such as the galvanometric needle movement of a d'Arsonval meter. This type of measurement representation is classified as analog because of its continuous indication throughout the measurement range. The use of analog meters has declined in recent years because of readily available digital voltmeters that have greater accuracy, lower power consumption, and easier reading, all at comparable cost. The advantages and disadvantages of analog versus digital instruments are discussed further in Sec. 3.4.

For digital (numeric) display of voltage levels, the front-end circuitry again comprises a linear preamplifier as in the analog case, but now is used to drive an ADC circuit instead of the galvanometric movement (see Sec. 3.3.2 for information on ADCs). The measurement is then displayed from the ADC output code by appropriate logic circuitry driving a display device such as a liquid-crystal display (LCD) multidigit numeric display. This type of measurement is classified as digital because of its discrete nature, as only a finite number of readings are possible.

Measurement ranging is typically accomplished with a resistive voltage divider ahead of the preamplifier for high-level (greater than 1 V) dc measurements; with a divider and/or transformer for high-level ac voltage measurements; and with variable preamplifier gain or sensitivity. When a resistive divider is used, the total resistance of the divider circuit is maximized, again, to minimize measurement error due to loading effects upon the voltage source. Resistance values as large as the low-megohm range typically can be used without introducing other errors due to preamplifier imperfections such as bias currents, noise, and dc drift.

2.3.2 ac Measurements. The measurement of ac (rms) voltage pertains to the measurement of a characteristic value that is proportional to the root of the power in a signal. The rms value of a signal is quite different from the direct average value of the signal, although both determine power dissipated when the signal is applied to a resistive load. The direct average value is the dc component of a signal and is readily obtained by an averaging low-pass filter, a rather simple operation to implement electronically. The true rms value is much more difficult to obtain electronically because of the required nonlinear mathematical operations as well as the need for high electronic speed. Great speed is needed in certain true rms measurements because many signals of interest have an energy spectrum that extends into the megahertz range.

One of the best techniques for measurement of the true rms of an arbitrary periodic wave form with high-frequency spectral components is based upon establishing a balance between two temperatures, one due to the heating power of the signal under test and another due to the heating power of a dc test signal generated by the instrument. This instrument is called a thermal rms voltmeter and is illustrated in Fig. 2.

The thermal meter illustrated in Fig. 2 operates as follows. The input side of the balance circuit consists of an amplifier that provides drive current as required to reproduce precisely the signal under test across a heater element (resistive load) in direct thermal contact with a thermocouple. The output of this, the test thermocouple, is compared to a second, identical thermocouple and heater element. A balance control circuit produces a dc signal that is applied to the second heater element at whatever amplitude is required to make the second thermocouple output equal to the first. Under this balanced condition, the dc control signal applied to the second heater element is equivalent to the rms of the signal under test as long as several conditions are satisfied. First, the amplifier of the signal under test must exactly reproduce the wave form of the test signal across the first heater element. This means that the amplifier's bandwidth and slew rate must not be exceeded by the input signal, thus placing constraints upon the signal's crest factor and spectral extent. Also, the two heater element and thermocouple assemblies must share the same thermal ambient conditions, yet be thermally isolated from each other and have power responses that match very closely. Accurate (5% of full scale) rms measurements can be made of signals with frequency range to 10 MHz, full-scale amplitude range from 1 mV to 300 V, and crest factor (ratio of signal peak to rms values) of 10 to 1 with commercially available instruments. Thermal rms calibration standards for laboratory use are capable of accuracies on the order of a few parts per million.

2.4 Current Measurement

Electrical current is quantified in engineering units of amperes. One ampere is defined classically as the quantity of electrical current that, if flowing in two infinitely long parallel wires spaced 1 m apart in a vacuum, would produce a force of 2×10^{-7} N/m of length between the wires. Just as voltage measurement usually does not involve a power measurement, current measurement by electronic instruments typically does not involve a force measurement.

Most electronic current measurement techniques involve various operations that result in the production of a voltage signal proportional to the current signal to be measured. The resulting voltage signal is measured and scaled according to the current-to-voltage constant of proportionality of the conversion operation so that a reading calibrated in engineering units of amperes is obtained. These voltage signals can be measured by the techniques discussed in Sec. 2.3.

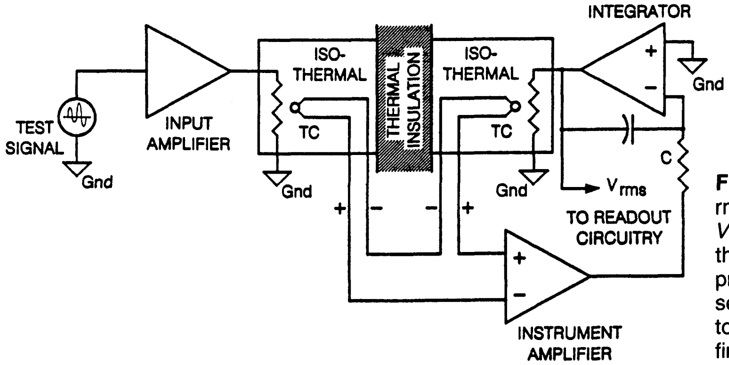

FIG. 2. Example of typical thermal rms converter; the integrator output V_{rms} is a dc voltage necessary to zero the instrument amplifier output, thus producing a heating power in the second isothermal box exactly equal to the heating power produced in the first isothermal box by the test signal.

The particular method of current-to-voltage conversion used depends upon the form of the current signal to be measured. If the current signal is ac (see Sec. 2.1.1), then linear transducers such as a resistive shunt, Hall device, or current transformer may be employed to detect the current and produce a proportional, similarly shaped voltage wave form so long as the power spectral extent of the ac current to be measured does not exceed the frequency response of the transducer. dc current signals (see Sec. 2.1.1) can be detected only by shunt or Hall-effect transducers since the voltage output of the current transformer is proportional to the derivative of the current signal.

2.4.1 Resistance Shunts. A shunt transducer is simply a resistance with a very stable and well-known value, usually very small (< 1 Ω). The shunt must be serially inserted into the circuit within which the current to be measured flows. The fact that the circuit must be broken when connecting or disconnecting the shunt is a potential disadvantage of the shunt transducer. The resistance of the shunt must also be small enough not to affect the circuit operation. When current flows through the shunt, a voltage is developed across the shunt. This voltage is usually very small because of the small resistance of the shunt. This voltage is then measured by one of the systems described in Sec. 2.3.

Note that, depending upon where within the circuit the shunt is placed, large voltages may be present relative to some reference point such as earth ground. Therefore floating instruments such as battery-powered digital multimeters are typically used with the shunt to avoid inadvertently affecting circuit current being measured by the measurement itself. Another precaution is that the current in the shunt must not be so large that the power dissipation produces thermal gradients or temperature rises that affect the shunt resistance.

2.4.2 Hall-Effect Transducers. The Hall-effect transducer operates by detecting the magnetic field produced by and proportional to the current to be measured. A Hall transducer, illustrated in Fig. 3, is a semiconductor with two pairs of plates electrically connected (resistive path) to surfaces of the semiconductor block. The plates are positioned such that a drift current due to a bias voltage between

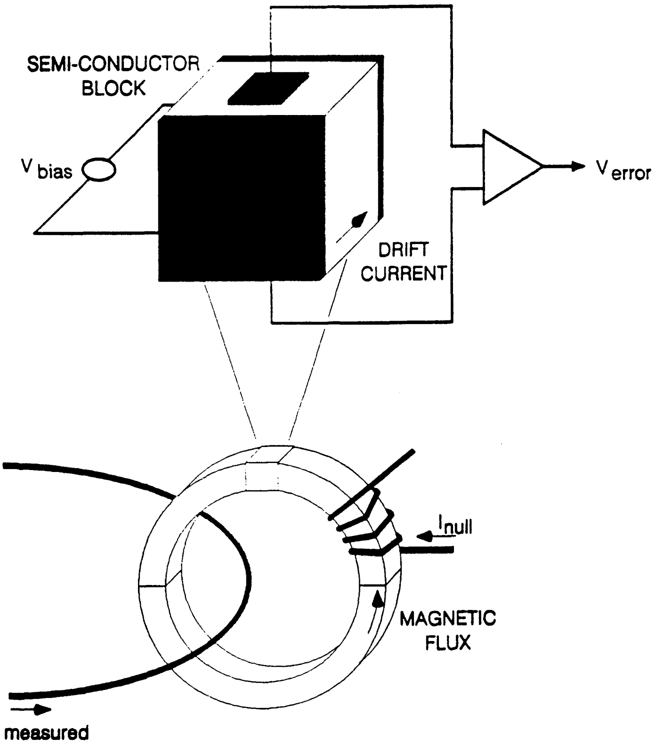

FIG. 3. Hall current transducer in a feedback control system; I_{null} is electronically controlled such that V_{error} is kept equal to zero, forcing I_{null} to be proportional to $I_{measured}$.

one pair flows orthogonally between the other pair. With no applied magnetic field, there will be no change in charge density between the second pair of plates due to the drift current. When a magnetic field resulting from proximal current flow is applied, the path of the drift current is altered, resulting in a charge density gradient and an associated voltage drop between the second pair of plates. This differential voltage can be used in a feedback system with a magnetic toroid encircling the conductor carrying the applied field current to create another magnetic field within the Hall device equal and opposite to the applied field so that a signal proportional to only the current creating the applied magnetic field is obtained.

2.4.3 Current Transformers. A current transformer is also based on magnetic field theory but is a passive device requiring no applied potential to operate. The current transformer consists of a magnetic material formed usually in a toroid shape with insulated wire wound to form a number of turns around the toroid body. This winding serves as the secondary circuit of the transformer. The conductor carrying the current to be measured is passed through the toroid center and represents a single-turn primary circuit. The flux of the magnetic field resulting from the conductor current concentrates within the magnetic material of the toroid. ac conductor current produces alternating magnetic flux within the toroid which, in turn, induces an alternating current in the secondary winding when a small resistance such as a shunt is connected between the winding terminals. If the secondary terminals are not connected to a low-resistance load, very large ac voltages can appear between them when current flows in the primary circuit, making the current transformer very sensitive but potentially very dangerous.

Current transformers have a long history of application in power measurements where they function to facilitate the measurement of very large, low-frequency sinusoidal ac currents (>10 A) by producing a much smaller but proportional ac current suitable for direct reading by ammeter instruments, historically the electromechanical d'Arsonval type. Secondary current is related to primary current by the inverse of the number of secondary turns. Since the primary is usually only a single turn, the secondary current can be no larger than the primary current. This makes the current transformer unsuitable for the measurement of low-level ac currents, although it does find some application in milliampere range measurements.

2.4.4 Active Shunts. Low-level current signals (<1 mA), both ac and dc, are typically measured by either Hall devices or active shunts. The lowest-level measurements (<1 μA) are typically made with active shunts that are similar to basic shunts in operation except that much larger proportional voltage levels can be obtained without increase in the effective resistance of the shunt. Instead of a discrete resistance, active shunts are composed of an extremely-low-noise feedback amplifier circuit similar to that described in Sec. 2.2, except that a large resistance is used in the amplifier feedback path in place of the capacitor. A typical arrangement is illustrated in Fig. 4.

The output voltage V_{out} is the product of the current flowing out of the shunt's positive terminal and the feedback resistance R except for the polarity change. Active shunts are also known as current amplifiers or picoammeters.

2.5 ac Impedance Measurement

The impedance of a circuit element is defined as the ratio of the voltage drop across the element to the current flowing through the element. In dc circuits, this ratio is the resistance of the element. In ac circuits, some elements produce not only a voltage drop, but also a phase shift between the voltage and current. In this case, the ratio (impedance) is represented by a complex number that defines both the magnitude and the phase shift. An element that produces only a voltage drop is called *resistive*. An element that produces a phase shift is called *reactive*. There are two common types of reactive elements: *capacitance*, in which the current leads the voltage by a phase angle of 90°, and *inductance*, in which the current lags the voltage by 90°.

The complex-number representation of an impedance element is given by

$$Z=R+jX, \tag{6}$$

where the resistive element (R) is in series with a reactive element (X). The "reactance"

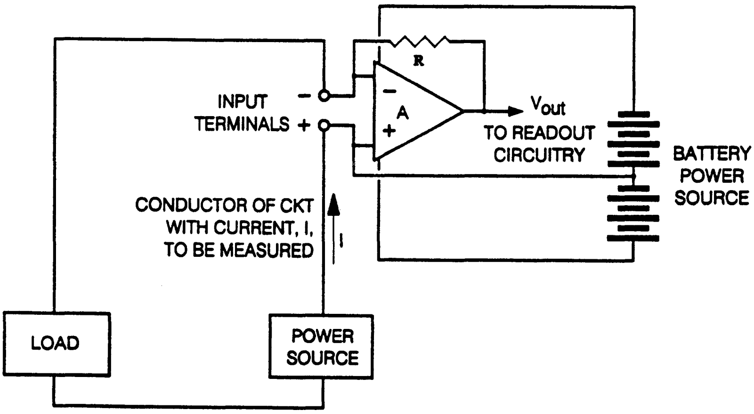

FIG. 4. Active shunt for measuring low-level currents I; the amplifier gain A and the feedback resistance R are made very large to give a large output voltage V_{out} (equal to IR) but with a negligible voltage drop between the input terminals.

of a capacitance element (X_c) or an inductance element (X_l) is

$$X_c = -1/\omega C, \tag{7}$$

$$X_l = \omega L, \tag{8}$$

where ω is the angular frequency of the signal.

dc resistance can be accurately measured by digital multimeters using the techniques described in Secs. 2.3 and 2.4. These involve measuring the voltage developed across the resistor when a fixed dc current is applied. For the most accurate dc measurements, the same current flows through the resistor being measured and a known (standard) resistor. The ratio of the two voltage measurements is the same as the ratio of resistance values. A network of resistors in which voltage measurements can be used to determine resistance values accurately is referred to as a *bridge* circuit. Bridge circuits can also be used to measure ac impedance, but the procedures are complicated by the phase shifts between the voltage and current that occur in reactive impedance elements. Bridge circuits for measuring dc and ac impedance will be described in the following section.

2.5.1 Bridge Measurements. Various forms of bridges have been used for many years to make high-precision measurements of ac and dc circuit elements. Although their use has diminished somewhat because of the capabilities available in modern digital multimeters, they are still needed for some kinds of specialized measurements, such as high-frequency impedance, or extremely precise resistance measurements. Bridge circuits still form the basis of many of the modern digital instruments, in which the operation of the bridge is automated and the associated calculations are done by an internal microprocessor. The basic principles of bridge measurements are reviewed here along with the concepts of guarded circuits and three-terminal measurements.

2.5.1.1 dc Bridges. Figure 5 shows the basic configuration of a *Wheatstone bridge.* The bridge has four resistive arms and is excited across a pair of opposite corners by a dc voltage source, usually 5–10 V. The unknown resistor is connected in one leg as shown, and the standard resistor is adjusted to give a null (0 V) across the galvanometer

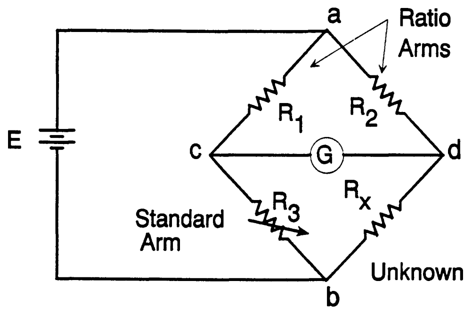

FIG. 5. The Wheatstone bridge is the basic configuration for precision measurement of dc resistance for values ranging from 1 Ω to several megohms. Lower resistance values (down to 0.000 01 Ω) can be measured with a modification called a Kelvin bridge.

(null detector). The unknown resistor can be determined from the other bridge elements as follows:

$$R_x = R_3\,(R_2/R_1). \qquad (9)$$

The measurement of the unknown resistor is independent of the excitation voltage or the calibration of the null detector. The Wheatstone bridge has been widely used in precision dc resistance measurements for values between approximately 1 Ω and 2 or 3 MΩ.

For lower resistance values, the errors due to lead resistance and contact resistance become significant for the Wheatstone bridge. A variation known as the *Kelvin bridge* (Helfrick and Cooper, 1990) can be used to measure resistance values as low as 0.000 01 Ω.

For higher resistance values (above 1 MΩ), the shunting effects of insulation resistance and leakage current can become significant. The concepts of guarded measurements and three-terminal resistance measurements were developed to overcome these problems with bridge measurements. These concepts are also used in other kinds of modern electronic instruments for measuring high resistance or ac impedance. Figure 6 illustrates a guarded bridge circuit and a three-terminal resistance measurement.

The unknown resistor R_x is connected to a pair of terminals mounted on insulating posts attached to a metal plate. A third terminal, called the guard, is connected to the metal plate. The main terminals of the resistor are connected to the bridge in the usual manner, sometimes using shielded leads whose shields are tied to the metal plate. R_1 and R_2 represent leakage paths and insulation resistance of the insulators and connecting cables. These resistances may be very high, but the shunting effect will be significant if R_x is also very high. To make the bridge measurement, the guard terminal of the resistor is connected to the guard terminal of the bridge as shown. In the bridge circuit R_2 is in parallel with R_a, but since R_a is so much smaller, the effect is negligible. Similarly R_1 is in parallel with the null detector whose resistance is also very much smaller. This effectively eliminates the effects of external leakage paths from the bridge balance condition.

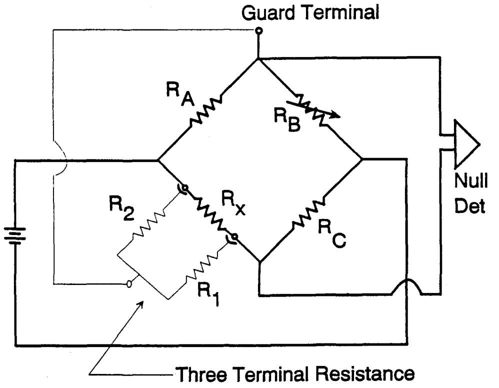

FIG. 6. Guarded three-terminal resistance measurements reduce the shunting effects of terminal insulation resistances (R_1 and R_2) in a high-voltage megohm bridge.

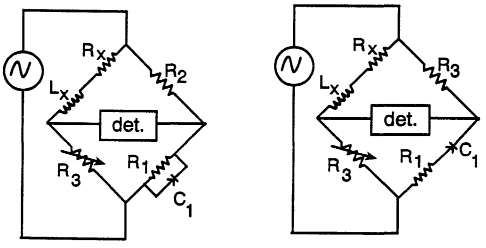
2.5.1.2 ac Bridges. The bridge configurations discussed in Sec. 2.5.1.1 are used to measure resistance. They are normally excited with a dc voltage source or an ac voltage source at a low frequency where the effects of reactive elements are negligible. At higher frequencies, the reactive phase shifts can produce significant effects in the operation of the bridge. By adding known reactive elements to the standard and ratio arms of the bridge (Fig. 5), the magnitude and phase of an unknown impedance can be determined by the balance condition of Eq. (9) using the complex impedance values in place of the resistance values. This, of course, means that both magnitude and phase conditions must be satisfied to balance the bridge. It also means that there may be component values for which there is no balance condition. For example, in Fig. 5, an inductive element in the R_x leg could not be balanced by an inductive element in the R_1 leg because the phase shifts are in the same direction. A capacitive element would be required in one of the legs.

Because the null condition requires balancing of both magnitude and phase, different configurations of ac bridges are used for measuring inductive and capacitive impedance values. The *Maxwell bridge* configuration is used for measuring inductance coils with phase shifts ranging from about 45° to 85° ($1 < Q < 10$). The *Hay bridge* is used for inductors with phase angles approaching 90° (high Q). The Q value of a reactive element is a measure of the ratio of stored to dissipated power and can be shown to be equal to the tangent of the phase angle of the impedance. From Eqs. (6) and (8) it is seen that the Q value of a series resistance and inductance element is



MAXWELL BRIDGE

HAY BRIDGE

FIG. 7. ac bridge configurations used for low-Q (Maxwell) and high-Q (Hay) inductance measurements.

$$Q = \omega L/R. \tag{10}$$

The *Schering bridge* is a widely used configuration for measuring capacitance values, particularly for well-insulated low-loss capacitors. Figures 7 and 8 illustrate the configurations of these three common ac bridge circuits.

2.5.2 Active Guard Circuits. The problem of leakage currents in measuring very high resistance values was discussed in Sec. 2.5.1. This problem is even more troublesome when trying to measure small capacitance values with an ac bridge. In many cases the capacitance of the connecting leads and other stray capacitances are much larger than the capacitor being measured. The *Wagner ground connection* (Fig. 9) is used for elimination of stray capacitance in ac bridges. The Wagner ground circuit consists of the resistor R_W and the capacitor C_W, which are adjusted manually until no change in the bridge balance is observed when switch S is moved from position 1 to position 2. In this condition, point A of the bridge is at ground potential, and essentially no current can flow through the stray capacitances represented by C_1 and C_2. There are also capacitances from the excited corners of the bridge to the Wagner ground, but the balancing procedure minimizes their effect. Many electronic instruments use the method shown in Fig. 10 to reduce the effect of stray capacitance. The critical parts of the circuit are surrounded by a guard (or shield) structure. The amplifier circuit serves to maintain the guard at the same potential as some point in the bridge, which eliminates any current flow through the stray capacitance to the guard. This concept is referred to as an active (or driven) shield and is often used to eliminate the effects of cable capacitance.

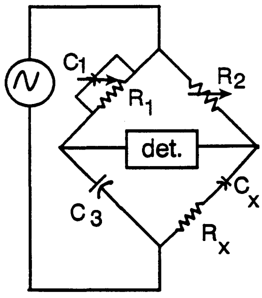


FIG. 8. The Schering bridge is used for low-loss capacitance measurements.

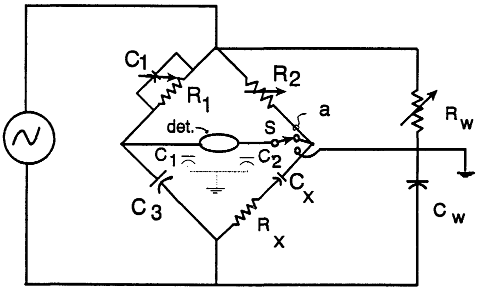

FIG. 9. The Wagner ground connection between R_W and C_W eliminates the effect of stray capacitance whenever the bridge is balanced so that no change is observed whenever switch S is moved.

2.5.3 Electronic Impedance Instruments. General purpose bridges are seldom used today because of the availability of microprocessor-based electronic instruments. Bridge instruments are still used, but the bridge functions are completely automated. Measurement results are computed and displayed in the desired units by the internal microproces-

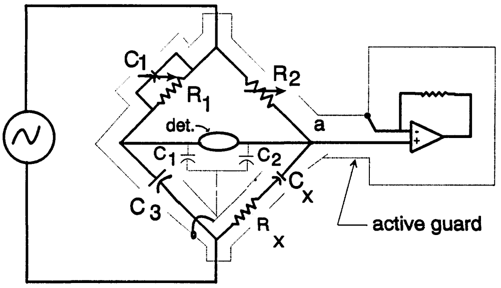

FIG. 10. Illustration of an active (driven) guard circuit. The amplifier acts to drive the guard to the same potential as point a, thereby greatly reducing the current flow through stray capacitances C_1 and C_2.

sor. There are other kinds of electronic instruments that measure impedance and phase relationships over a wide range of frequencies. The *vector impedance meter* measures impedance at frequencies below 100 kHz by direct measurement of the voltage and current magnitude and phase difference. The phase difference is measured by means of timing circuits that determine the time between zero crossings of the two signals. For higher frequencies the *vector voltmeter* converts the input signals to two heterodyne intermediate frequencies (IF) that have the same amplitude and phase relationships as the original signals. Ratio and phase measurements are made on the low-frequency (IF) signals.

2.6 Electrical Power Measurement

The current, I in amperes, through a resistive load, R in ohms, and the voltage, V in volts, across the load are related by

$$V=IR, \tag{11}$$

which arises from the basic definition of resistance. The power dissipated (or consumed) by the load is determined by the product of the current and the voltage drop. Using Eq. (11) the following simple relationships for power P are obtained:

$$P=VI=V^2/R=I^2R. \tag{12}$$

The power can be determined by measuring the voltage across the load and the current through the load. In a dc circuit, the power is calculated by the product of the voltage and current (VI) as shown in Eq. (12). The VI product represents the instantaneous power flow to the load. In an ac circuit, the VI product must be averaged over a cycle to obtain the net power dissipated by the load. If the load has a reactive component [see Eq. (6)] the voltage and current will not be in phase. In this case, the average power over a cycle is

$$P_{\mathrm{av}}=V_{\mathrm{rms}}I_{\mathrm{rms}}\cos(\phi), \tag{13}$$

where ϕ is the phase angle between the voltage and the current. The cosine of the phase angle in Eq. (13) is called the power factor.

For purely reactive loads the phase angle is 90° and the average power is zero. In this case, the load is storing energy for part of the cycle and returning it to the circuit during the remaining part. This part of the power is called reactive power and is given the units of vars (volt-amperes reactive). The quantity calculated by Eq. (13) is called the active power (watts) and represents the power actually consumed by the load. The product of rms voltage and rms current is called the apparent power. The relationship between apparent power (S), active power (P, watts), and reactive power (Q, vars) is

$$S=\sqrt{P^2+Q^2}. \tag{14}$$

ac power measurements and the application of Eqs. (13) and (14) are fairly simple for single-phase circuits with a single load. The relationships are more complex for multiple-phase, multiple-load circuits. For further information the reader should consult a textbook on electrical power engineering (e.g., Wildi, 1981).

The terminology and concepts described above are more widely used with electrical power applications than with electronic instrumentation, but there are a variety of instruments available for measuring these quantities.

2.6.1 Electrodynamometer Power Measurements. The electrodynamometer movement is used extensively in making direct-reading wattmeters. This movement is similar to the familiar d'Arsonval movement, which uses a moving armature coil in a permanent-magnet stator field. In the electrodynamometer movement, the stator field is generated by a set of windings that are excited by the load current. The armature coil is excited by the voltage drop across the load, connected with a fairly large current-limiting resistance in series. The torque on the armature coil is proportional to the product of the load voltage and the load current. The slow dynamic response for the movement provides averaging, so that the steady-state position of the coil is an indication of the power being measured. By changing the configuration of the stator coils or shifting the phase of the armature voltage, these instruments can be made to indicate other parameters such as power factor or reactive power (vars).

2.6.2 Watt-Hour Meters. One of the most common and familiar instruments for electrical power measurement is the watt-hour meter, which is used by electric utilities for metering power to customers. This instrument is essentially a small induction motor. The rotor is an aluminum disk in which eddy currents are induced by a fixed coil excited by the voltage signal. The stator field is generated by another set of fixed coils that are excited by the load current. The torque on the disk is proportional to the voltage–current product. The disk is damped by permanent magnets, which induce eddy currents as the disk rotates. This gives an arrangement in which the speed of rotation of the disk is proportional to the power. A set of gear-driven mechanical counters provide a totalized measurement of the electrical energy (watt-hours) delivered to the load.

2.6.3 Electronic Power Measuring Instruments. Electronic power transducers based on the Hall effect described in Sec. 2.4.2 are used in many industrial or laboratory instrument systems. Referring to Fig. 3, if I_{measured} is proportional to the load current and V_{bias} is proportional to the load voltage, then V_{error} will be proportional to the power. This provides an analog multiplication of the two signals in a manner similar to the electrodynamometer instruments described above.

Microprocessor-based digital power analyzers are available that can make measurements in a variety of multiphase and multiload circuits. These instruments digitize and store the voltage and current wave forms at a very fast sampling rate. All of the desired parameters are calculated and displayed by the internal computer.

3. INSTRUMENT INTERFACES

For a measurement made by an instrument to be useful, its data must be presented for interpretation by a person or by another piece of equipment.

3.1 Instrument-to-Human Interfaces

3.1.1 Visual Display. Instruments present data to a person through the use of one or more of the person's senses. The most often used sense is that of sight. In addition to the wide variety of precise and nonambiguous means to convey information visually, people have remarkable abilities to filter spatially (i.e., to focus attention on a single visual indication while ignoring other indications and distractions in the vicinity).

Some instruments are inherently sight-oriented. Galvanometers, mercury-in-glass thermometers, and Bourdon tubes exhibit deflections that reflect the value of the parameter being measured and can be observed visually. Electronic instrumentation usually involves the use of a transducer to convert the parameter being measured to an electrical signal and requires a means of displaying the amplitude of this signal.

Analog electrical interfaces usually communicate the measured value by controlling the displacement of one or more mechanical (or simulated mechanical) indicators along a scale. For many situations this type of indication is preferable to a purely digital (numeric) display. These include instances in which

1. the relative value (e.g., percentage of the full scale or relationship to alarm points) of the measured variable is more important than the precise value of the variable or the units in which it is being measured (as in an automobile fuel gauge);
2. the polarity and/or rate of change of the measured variable is important (as in meters used for tuning musical instruments);
3. fluctuations in the measured variable are so rapid that reading a numeric display is difficult (as in record level indicators on audio equipment).

Although analog indications typically have lower resolution than digital displays, this is not always the case. The hour, minute, and second hands on a clock, for instance, together provide a time measurement with nearly 0.001% resolution; yet an experienced user can read and interpret the measurement with only a casual glance. A commonly used analog visual interface that does not employ or simulate mechanical indicators is the cathode ray tube. In such a device, the amplitude of the input electrical signal controls the deflection of an electron beam. The amount of deflection is observed by placing a phosphor-covered sheet of glass in the path of the beam so that light is given off at the point of impact. Up to three measurements can be displayed by a single beam if the vertical deflection, horizontal deflection, and intensity of the beam are controlled simultaneously. This interface device is useful for signals that change too rapidly for display with mechanical devices. It is also used to display simple graphs (e.g., histograms or frequency spectra) in real time.

Digital indicators are used when high resolution is required, when errors inherent in the interpretation of analog displays (e.g., parallax and interpolation) are undesirable, when data are inherently discrete in nature (e.g., event counts), or when digitized data are required for other reasons (e.g., for transfer to a computer). With recent advances in analog-to-digital conversion and numeric display technologies, simple digital displays may cost no more than inexpensive analog mechanisms with comparable resolution and accuracy. The simplest and lowest-resolution digital display, the two-state (on–off) indicator lamp, is usually reserved for status displays and alarm indicators.

Displays of digitized data often mimic analog instruments and can provide valuable features their purely analog counterparts cannot. Bar graphs, for instance, can include peak-hold functions, or can change colors under predetermined conditions. And while numeric displays become difficult to read when updated too rapidly, the readability of digitally synthesized analog indications usually improves as update rates increase.

The use of imaging as a real-time operator interface is growing in many industrial, commercial, and research areas. Two-dimensional maps (using color to indicate measured values), surface plots, and other types of graphs can be displayed on data terminals with the assistance of computer-based data acquisition systems.

3.1.2 Audio Signaling. Audio transducers are also used as operator interfaces but are usually reserved for alarms and discrete event indications in order to avoid overwhelming the operator with more audio input than humans can readily process.

Information can be conveyed audibly by controlling a sound's amplitude, repetition rate, or frequency content. An alarm buzzer is turned on (a form of discrete amplitude control) to indicate a condition that requires the operator's attention. The repetition rate of clicks from a Geiger counter indicates the intensity of an ionizing radiation field. The varying pitch of a metal detector's audio output is a function of the distance to and size of a metal object. In speech synthesis, control over amplitude, spectral content, and temporal duration are combined to create intelligible phrases.

3.2 Human-to-Instrument Interfaces

The interfaces discussed in Sec. 3.1 address the communication of measurement information to people. Most instruments also require instruction or adjustment by their operators. Input devices seldom use visual or audio techniques, relying instead on some sort of mechanical-to-electronic transducer. Knobs, switches, touchscreens, keypads and keyboards, mice, joysticks, and trackballs all provide this function. Input devices can be grouped into analog and digital categories, and each has advantages and disadvantages for any given application. Some have built-in visual feedback of their current setting, and some retain their settings after instrument power has been removed and restored.

3.3 Instrument-to-Equipment Interfaces

When a signal from an electronic instrument is to be used by another piece of equipment, it must be in a format compatible with the target system's input. Data can be communicated in analog form using signal voltage, current, phase, and frequency, or in digital form by a wide variety of different formats and protocols. Fortunately, standards exist in the research, industrial, and consumer markets that simplify the chore of electronic interfacing. In the analog domain, 0–1-V, 0–5-V, 0–10-V, 0–20-mA, 4–20-mA, 10–50-mA, and 0–10-kHz ranges are used, and devices are available for converting from one standard range to another. Few applications will require custom-developed data transmission techniques.

The term *signal conditioning* is used to refer to the processing usually required to translate the signal from the transducer, which is usually much lower in level, into one of these commonly used ranges and may also include filtering or other manipulation of the transducer's output.

Data can also be transmitted digitally in bit-serial formats (e.g., RS-232, RS-422, RS-423, or RS-485) or in byte- or word-serial formats (e.g., general-purpose instrument bus, parallel binary or binary-coded decimal, or Centronics). Some standards cover little more than signal levels or transmission media, and the user must know how much of the interfacing task is covered by the particular standard being considered.

Digital data streams have the advantage of being able to include information other than signal amplitudes (e.g., engineering units) if their data bandwidths are sufficient. Some industrial instruments now feature hybrid data interfaces that superimpose digital data on top of the analog measured-variable signal.

When harsh electrical environments, long transmission distances, or other factors make interfacing via electrical conductors impractical or unreliable, optical data interfaces (usually via optical fibers) provide an alternative that can solve attenuation and noise problems while providing high data throughput.

3.3.1 Multiplexing. To reduce the reliability and expense penalties associated with extensive field wiring, measurements from several instruments can be transmitted over a single signal path using one of several techniques collectively referred to as multiplexing. With time-division multiplexing, signal streams (whether analog or digital) are successively connected to the transmission medium in a predetermined sequence. A demultiplexer at the other end of the cable separates and sorts the signals and applies them to the appropriate outputs. Two conditions must be met for proper time-division multiplexing. First, the demultiplexer unit must be synchronized carefully to the multiplexer so that the incoming signals are routed to the correct outputs at the correct times. Secondly, because each of the signals transmitted is now being sampled, the Nyquist sampling criteria must be met: each signal must be sampled at a rate at least twice the frequency of the highest-frequency component in that signal (Oppenheim and Schafer, 1989). Otherwise, an error-producing effect known as *aliasing* will occur. Antialias filtering may be required to limit the frequency content of the signals to be digitized. Latches (for digital signals) and sample-and-hold amplifiers (for analog signals) can be used to eliminate the time gaps in the sampled data at the output of the demultiplexer.

Frequency multiplexing permits the simultaneous transmission of several continuous signals. Baseband signals modulate carrier signals of different and properly spaced frequencies. These composite signals are combined by a mixer. At the receiving end of the transmission system, bandpass filters separate the carrier signals and feed each to a demodulator. If the system has been properly designed and implemented, the action of the multiplexer and demultiplexer circuitry is completely transparent to the end devices.

Optical data transmission systems can use wavelength multiplexing to send several signals down a single optical fiber. Input signals modulate optical sources (light-emitting diodes or lasers) having different output wavelengths. These light signals are combined using optical mixers and launched into one end of the fiber. Optical splitters (filters or prism-like devices) are used at the receiving end to separate the colors, and optoelectronic devices (usually light-sensitive diodes) convert the optical energy back into electronic signals.

In broadband transmission systems, time-division multiplexing is combined with either frequency or wavelength multiplexing to increase the number of channels of information that can be transmitted simultaneously.

3.3.2 Analog-to-Digital Conversion. Continuous electronic signals are digitized (converted to digital form) by analog-to-digital converters (ADCs). An ADC operates on one of several different principles, each of which has its unique advantages and characteristics. These features are summarized in Table 1; the following is a brief description of the operating principles.

Successive approximation ADCs determine the digital value corresponding to the analog input voltage by repetitively comparing the input to the output of an internal digital-to-analog converter (DAC) and adjusting the code fed to the DAC for a better match. An N-bit ADC requires N compare–adjust cycles to obtain the optimum digital representation. That code is then applied to the device's digital output and a conversion-complete indication is given. Accuracy depends on the accuracies of the internal comparator and DAC. By making the reference input to the internal DAC an

Table 1. Comparison of the features of common analog-to-digital conversion techniques.

Analog-to-digital technique	Accuracy	Speed	Power Use	Cost
Successive approximation	Medium	Medium	Low to medium	Low
Integrating	High	Low	Medium	Medium
Flash	Low	High	High	Medium to high
Sigma-Delta	Medium	Medium	Medium	Medium

analog input to the device, a multiplying converter is created—the output count will be proportional to the product of the analog input voltage and the DAC reference voltage.

Integrating ADCs contain a constant-current source connected to the input of an analog integrator. An internal counter measures the time required for the integrator to ramp up to a voltage matching the input signal. The required time is proportional to the input voltage. Variations on the basic integrating converter design can compensate for internal offsets and integrator leakage. Errors introduced by noise having frequency content higher than 1/(integrating period) are reduced with integrating ADCs.

Flash ADCs consist of a 2^N-element voltage divider string with one of the inputs of a differential comparator connected to each node of the string. One end of the string is grounded and the other is connected to a voltage reference. The remaining inputs of the comparators are connected to the input signal. Thus the output of all comparators with string-connected inputs at a voltage higher than the input signal will assume one output state and the outputs of remaining comparators will assume the other. Decoding circuitry converts the pattern of converter outputs into an N-bit output word. Flash converter resolution is limited by the number of comparators that can be incorporated into a single device. Power considerations presently limit output resolution to 8 bits or less.

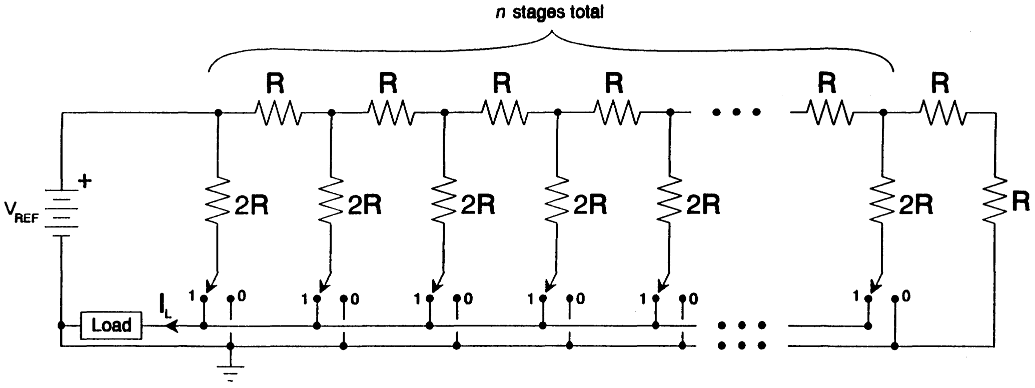
Sigma-delta conversion is a relatively new technology. Although the technique has been known for approximately 25 years, only recently have advances in digital signal processing technology made it practical to fabricate these converters in integrated-circuit form. Sigma-delta converters oversample the input signal by a high factor (usually 32 or 64), produce a one-bit stream of digital data at this high rate, and then process this stream with digital decimation filters that produce high-resolution (14-, 16-, or 18-bit) data streams at reduced sample rates. The highly oversampled inputs reduce the requirements on antialias filters substantially and usually eliminate requirements for sample-and-hold amplifiers.

Digitization techniques also differ in their requirements for antialias filtering and for external control signals. Some must follow sample-and-hold amplifiers for optimum performance while others require additional external electronic components. Some are easy to implement in miniature, integrated-circuit form and others must be built with larger hybrid circuits and/or discrete components. The proper selection and application of ADCs are among the most critical and challenging issues in high-performance instrument design.

3.3.3 Digital-to-Analog Conversion. Performing the inverse of the ADC function, digital-to-analog converters (DACs) accept data from digital devices (conventional computers, digital signal processors, or more specialized circuits) and transform them into a continuous analog output signal. The vast majority of DACs are based on the same internal architecture: a resistor "ladder" network (Fig. 11) in which resistors or capacitors are switched in and out of a current-summing network according to the digital input code (Sheingold, 1986). DACs have either current or voltage outputs and are usually less complex and less expensive than ADCs of comparable resolution, accuracy, and speed.

3.4 Recording

We will use the term *recording* to mean the preservation of experimental data for subsequent inspection, analysis, or presentation. A recorder, therefore, is a device for copying measurements made by electrical instrumentation to a physical medium in a useful for-



$$I_L = \frac{V_{REF}}{R} \cdot \frac{x}{2^n}$$

FIG. 11. *n*-stage *R*-2*R* resistor ladder as applied to digital-to-analog conversion. The term *x* in the equation is an integer determined by summing the binary-weighted values of the switch settings.

mat. The resulting record can be read (interpreted) by a person or by a processing system or translated into a format suitable for this purpose. Recordings, like the user interfaces described above, can be in either analog or digital form.

3.4.1 Analog Recorders. True analog recorders make continuous time records of measured variables. Strip chart recorders make such records by passing long sheets of paper beneath one or more marking pens that are deflected in a direction perpendicular to the direction of paper travel by an electrical signal corresponding to the magnitude of the variables. In this manner, the pens make traces on the chart that show how the measurements vary with time. Strip chart recorders also serve as useful real-time interfaces because data trends and rates of variable changes are readily apparent. These recorders have accuracy and resolution limitations similar to mechanical meter movements described above (the pens are often mounted on the end of galvanometer "needles") with additional limits imposed by the accuracies of the chart grid and the paper transport mechanism. Inertia in the pens and their deflection mechanisms restrict the use of strip chart recorders to signals that have no frequency content above a few hundred hertz. Electrocardiographs and seismographs are familiar examples of strip chart recorders.

Short segments of rapidly changing analog signals can be captured on photographic film by using especially designed cameras to take pictures of cathode ray tube displays or by using film recorders. Magnetic tape recorders can be used to record experimental data just as they are used to capture wave forms generated by microphones and electronic musical instruments in audio recording. Low-frequency limitations inherent in direct recording of signals can be circumvented by using the input signals to frequency-modulate carrier signals. In this technique, the deviation of the carrier signal from its center frequency corresponds to the instantaneous amplitude of the signal being recorded, and signals with frequency components down to and including dc can be preserved. Pulse-width modulation can also be used for recording signals with important low-frequency information. Both of these modulation techniques require more high-frequency bandwidth than would be required by direct recording.

Recent announcements of semiconductor devices (analog electrically erasable programmable read-only memories) that capture fragments of analog signals and preserve them indefinitely foretell of a new technology that could have a major effect in analog signal processing (Pell, 1991).

3.4.2 Digital Recorders. Digitized data can be recorded using techniques similar to the analog methods described above and can take advantage of other methods not applicable to analog signals. Conventional data loggers are the digital counterparts to analog strip chart recorders. Numeric values and/or simulated analog curves representing input signals are printed on long strips of paper.

Data can be preserved magnetically on tape, disks, and cards. Because digital data can be stored temporarily (buffered) and recorded in bursts of high-frequency signals, special modulation techniques are not required for recording low-frequency data.

Equipment for recording data on optical disks has recently become available for high-density recording of digitized experimental data. Some of this equipment has analog inputs and outputs—the digitization of the stored data is transparent to the user. Once written, data on most optical disks cannot be altered, but new devices incorporating magneto-optical technology allow users to erase and modify stored information.

Semiconductor memory preserves digital data in memory cells made up of transistors and diodes. Volatile memory can retain information only as long as power is applied to the devices. Nonvolatile memory preserves the information after power has been removed and even after the devices have been extracted from the circuitry that supplied the information. Alhough it lacks the large storage capacities of some magnetic and optical storage devices, random-access semiconductor memory can be written to and read from more quickly than any other type of storage media.

Magnetic bubble memory is an alternative technique for nonvolatile storage of data. Bubble memory devices may be similar to large integrated circuits in appearance and in fabrication techniques, but they are not semiconductor devices. Data cannot be accessed randomly as in semiconductor memories, but access times rival that of the fastest fixed-disk storage systems. Data can be stored indefinitely with or without power applied and the devices are more immune to shock, vibration, and other environmental effects than other magnetic storage systems.

4. NOISE AND OTHER SOURCES OF ERROR

Many of the electronic instruments discussed in Sec. 2 are designed to measure signals of less than 1 μV. High-gain amplifiers enable these signals to be displayed on an oscilloscope. It is usually the case that whenever the most sensitive ranges of an electronic instrument such as an oscilloscope are used, the signal becomes corrupted with "noise" signals, which may appear spurious or random in nature. The level of the noise limits the minimum signal that can be measured with the instrument; therefore, it is desirable to minimize the noise as much as possible. There are two basic sources of noise that can occur in electronic systems: induced noise and inherent noise.

4.1 Induced Noise

Induced noise is picked up in an electronic circuit from external sources, such as 60-Hz power lines or high-frequency (rf) equipment. This type of noise is referred to as electromagnetic interference (EMI) and can be quite large. Fortunately EMI can be reduced or eliminated by proper shielding and grounding of circuit components and signal leads. Shielding and grounding considerations can become quite complex; however, a few simple rules can help reduce or eliminate many common problems.

Many modern electronic instruments are designed with shielded circuits that reduce both noise pickup and noise emissions. In most cases the use of shielded signal cables and proper connections to the instrument as recommended by the manufacturer will produce acceptable results, especially in a laboratory environment. Two common types of input configurations are used for test instruments: differential and single-ended. A differential input has two terminals (plus and minus) for the signal leads and, sometimes, a third terminal for the shield. A single-ended input usually has one coax connector terminal with the center conductor for the signal lead and the outer shell for the shield. The shield serves as the "common" or "negative" lead for the signal and the measurement circuit.

For single-ended measurements, the shield is part of the circuit and is always connected at both ends. For differential measurements, the user must make a choice as to how to connect the shield. In most cases the best practice is to connect the shield to the test instrument shield or ground terminal and leave it unconnected ("floating") at the other end. Connecting the shield at only one point serves the purpose of breaking any possible circuits (called *ground loops*) through which large noise currents might flow. These currents, if present, might induce additional noise voltages into the measuring circuit. For additional information on shielding and grounding techniques, the reader is referred to textbooks [see, e.g., Morrison (1986) or Ott (1976)].

Induced noise is usually coupled into the measuring circuit by capacitive or inductive impedances, which implies that it is alternating or transient in nature. It is very difficult to eliminate induced signals completely, especially at the ac power line frequency (50 or 60 Hz). Instrument designers use various methods to reduce the effects of the noise. A common practice in instruments that make low-level dc measurements is to integrate (or average) the signal over a time interval that is a multiple of the period of the power line frequency. The induced noise at this frequency will then average to zero. Averaging also helps reduce the effects of any random noise that might be present since it also tends to average to zero.

There is another form of induced noise that can be particularly troublesome in making low-level dc measurements. These are small dc voltages which are produced by the Seebeck effect whenever conductors of different materials are joined together in the presence of temperature gradients. This is the principle upon which a thermocouple functions as a temperature measuring device. This voltage (called thermal emf) is very difficult to eliminate completely and therefore must be considered when errors on the order of a microvolt might be significant. It is easy to detect the presence of a thermal emf by simply reversing the polarity of the signal leads at the test instrument. Since the polarity of the thermal emf does not change, it will add to the measurement signal in one case and subtract in the other.

4.2 Inherent Noise

Inherent noise is generated by random molecular and atomic processes within individual circuit elements such as resistors, diodes, transistors, or any other active device. It appears in several different forms depending upon the dominant mechanism of generation. It is inherent in all electronic devices and will always be present at some level. It can be controlled to a certain extent by circuit designers with the use of low-noise components and careful placement in the circuit. This section will present a brief description of the basic types of inherent noise that might be observed when making measurements with certain kinds of electronic instruments.

Inherent noise is generally random in nature and is present over a broad range of frequencies. One of the most commonly observed is *thermal noise,* also referred to as *Johnson noise* or *Nyquist noise.* Thermal noise results from the motion of free charge carriers (electrons) due to thermal energy and is present in all resistors. The basic description of thermal noise was originated by Nyquist in 1928. Using the second law of thermodynamics, he showed that the noise power spectral density of a resistor R in thermal equilibrium at temperature T was given by

$$S_v(f)=\frac{4hfR}{\exp(hf/kT)-1}, \tag{15}$$

where

h=Planck's constant=$6.624\text{x}10^{-34}$ J s

k=Boltzmann's constant

=1.38×10^{-23} J/K

f=frequency (Hz)

S_v=power spectral density

(mean square V/Hz).

For frequencies below approximately 10^{11} Hz, Eq. (15) reduces to

$$S_v=4kTR. \tag{16}$$

Note that in Eq. (16), the noise power is constant with frequency, a condition that is referred to as "white" noise. As an example of the order of magnitude of thermal noise, a 10 000-Ω resistor at room temperature (27 °C) generates an rms signal of 1.3 μV over a bandwidth of 10 kHz.

Other types of noise are observed in different electronic devices. "Shot" noise, first studied by Schottky, is caused by the motion of charge carriers in a drift current as in a vacuum tube or semiconductor diode. Shot noise, like thermal noise, also has a white spectrum. In vacuum tubes and semiconductor devices the observed noise at low frequencies is much higher than that predicted by the Nyquist equation (15) for thermal noise. This is called "flicker" noise and has a spectrum characterized by

$$S_f(f) = K I_{\mathrm{dc}}^n / f^\alpha, \tag{17}$$

where K is a constant dependent on the material, n is approximately 2, and α varies between 0.5 and 2. S_f is the noise (mean square A/Hz) observed on the dc current flowing through the device. Flicker noise is sometimes called $1/f$ noise or pink noise. It has been observed at frequencies as low as 10^{-6} Hz, and, in carbon-composition resistors, can exhibit power spectral densities over 10 times greater than thermal noise below 100 Hz (Kennedy, 1988). The major cause of $1/f$ noise in semiconductor devices appears to be traceable to surface properties of the material. The generation and recombination of carriers in surface energy states and the density of surface states are important factors. Improved surface treatment during manufacturing has been able to reduce $1/f$ noise in semiconductors.

Other noise-generation mechanisms have been observed in various kinds of semiconductor devices, but the ones described above are the most common. Although electronic noise is of primary interest to electronics designers and researchers, the user of electronic instruments will find it useful to be aware that it is always present, and at what level it might start to affect the measurements being made.

5. CONCLUSION

Many changes in electronic instrumentation have resulted from advances in integrated-circuit and microprocessor technology. The pocket-sized digital multimeters in common use today combine many of the capabilities that required several specialized laboratory devices only a few years ago. Modern laboratory instruments also provide many combined functions in a single device able to make routine measurements at levels that formerly required careful and skillful techniques. Many laboratory instruments are becoming available as plug-in cards for personal computers. The general trend is toward greater levels of capability being available in simpler and easier to use forms. This permits the user to make difficult measurements without having to become an electronics expert. It will always be necessary for the user to have an understanding of the basic principles and the possible "pitfalls" involved in these measurements. It is hoped that the information provided herein is useful in serving that purpose.

GLOSSARY

ac: Originally an initialism for *alternating current.* Modern usage as an adjective indicates the presence of periodic variations.

Aliasing: A type of distortion caused by sampling a signal at a rate lower than the Nyquist frequency.

Charge: A quantity of electricity. The smallest identified increment of charge is that amount associated with a single electron.

Crest Factor: The ratio of the peak value to the rms value in a periodic wave form.

Current: The net flow of electronic charge past a certain point in a circuit.

dc: Originally an initialism for *direct current.* Modern usage as an adjective means nonvarying or varying slowly in a nonperiodic manner. dc often is used to refer to a frequency of zero.

Instrument: A device used for quantifying a measured variable.

Load: A device that draws current from an electrical circuit.

Noise: Signal corruption resulting from the addition of components not related to the desired information being transmitted.

Nyquist Frequency: A frequency equal to twice the frequency of the highest-frequency significant spectral component of a signal. Signals sampled at rates higher than the Nyquist frequency theoretically can be accurately reconstructed from the sampled data.

Sine wave: A single-frequency wave form that varies according to the general function

$$F(x) = A \sin(2\pi f x),$$

where A is the peak amplitude of the function and f is the frequency (in cycles per unit of x). In electronic instrumentation, x usually represents time and f is in units of hertz (cycles per second).

Slew Rate: The rate of change of a measured variable. A common, but not strictly correct, usage of slew rate refers to the maximum rate of change of an output that a device is capable of.

Transducer: A device that converts energy from one form to another. In electronic instrumentation, transducers convert measured physical stimuli into electrical signals or electrical signals into radiated energy.

Voltage: The difference in electromotive force (also called electrical potential) between two points in a circuit or an environment.

INTRODUCTION

Electrochemistry, one of the oldest areas of the physical sciences, is undergoing rapid development. With important advances in concepts, instrumentation, and methodology, electrochemistry now extends into many other diverse fields. In general terms, electrochemistry is concerned principally with chemical reactions that are associated with the transfer of electrons or ions across interfaces. The most typical electrochemical interface is that between a solid metal and a liquid solution of an electrolyte (ionic conductor), but any interface involving a predominantly electronic conductor and a predominantly ionic conductor is considered to be an electrochemical interface.

Interfacial reactions are governed by the potential distribution across the interface in a so-called electric double layer. It is formed by the accumulation of excess charges of equal but opposite signs on the two sides of the interface. Many models of the double-layer structures and theories for charge-transfer kinetics across electrochemical interfaces have been developed since the fundamental aspects of electrochemical reactions were first studied in 1796 by Alessandro Volta.

In this short article only essential aspects of electrochemistry are covered, with emphasis on interfacial phenomena. These phenomena are currently attracting much attention of electrochemists and also of workers from other fields, including physics and biology. Several important areas of electrochemistry such as the conductivity of electrolytes, mass transport phenomena, electrodeposition of metals, electrochemical corrosion, electrochemical machining, and some aspects of thermodynamics have been omitted.

Electrochemistry has important applications in various areas of technology such as energy storage and conversion, large-scale production and refining of almost all nonferrous metals, production of inorganic chemicals, organic synthesis, corrosion prevention, electrochemical sensors, and biomedical applications.

1. THE STRUCTURE OF ELECTRODE–ELECTROLYTE INTERFACES

1.1 Potential Concepts in Electrochemistry

Consider a metal electrode in equilibrium with an electrolytic solution containing the ion $M_1^{z_1^+}$ resulting from the dissolution of the metal; e.g.,

$$M_1 \rightleftarrows M_1^{z_1^+} + z_1 e^-, \tag{1}$$

where the electrons then accumulate on or come from the metal M_1. On the basis of thermodynamics the electrical work W_e available from this process is

$$W_e = E z_1 F = -\Delta G, \tag{2}$$

where ΔG is the Gibbs free energy change per mole of M_1 converted to $M_1^{z_1}$, F is the Faraday, z_1 is the number of electrons per metal ion in Eq. (1), and E is the thermodynamic electrode potential. Reaction (1), however, does not fully represent the situation. The cationic charge must be compensated by the generation of an equal amount of charge of opposite sign or the consumption of an equal charge of the same sign. Thus a second reaction must attend reaction (1); e.g.,

$$M_2^{z_2^+} + z_2 e^- \rightleftarrows M_2. \tag{3}$$

Multiplying Eq. (3) by z_1/z_2 and adding Eq. (1), one obtains

$$M_1 + (z_1/z_2) M_2^{z_2^+} \rightleftarrows M_1^{z_1^+} + (z_1/z_2) M_2. \tag{4}$$

Virtually no net charge can be generated in or on the metal or electrolyte phases.

The difference in the electrode potentials for Reactions (1) and (3) is determined experimentally with a voltage measuring device (e.g., a voltameter or potentiometer) connected by two metal leads M and M' (usually copper) to electrodes M_1 and M_2. This is denoted symbolically by

$$M \,|\, M_1 \,|\, s \,|\, M_2 \,|\, M'; \tag{5}$$

Then $\Delta_{m'}^{M}\phi = \Delta_{M_1}^{M}\phi + \Delta_{s}^{M_1}\phi + \Delta_{M_2}^{s}\phi + \Delta_{M'}^{M_2}\phi$, where $\Delta_b^a\phi$ is the potential difference between the bulk of the indicated phases. The voltage difference $\Delta_{M'}^{M}\phi$ on the two identical metal leads M and M' can be shown to correspond to the difference in the thermodynamic electrode potentials E_1 and E_2 (see, e.g., Trasatti, 1980). The individual values of E_1 and E_2 cannot be determined by direct measurement.

Some researchers have considered the potential difference $\Delta_s^M\phi$ between the bulk of the metal and bulk of the solution to correspond to the absolute value of the electrode potential on the thermodynamic scale. This is conceptually misleading. This potential difference term ($\Delta_s^M\phi$) is known as the Galvani potential and corresponds to the electric work to transport a unit positive test charge from the bulk of the solution phase into the metal. The electrode work term involved with the thermodynamic electrode potential, however, includes additional energy terms such as the charging of the ions in a dielectric medium and other chemical interactions associated with the accumulation of the electrons in the electron orbitals of the metal near the Fermi level.

The Galvani potential is of interest in its own right in understanding the structure of electrochemical interfaces. The potentials involved in the Galvani potential correspond to the *inner* potentials of the metal (ϕ_M) and solution (ϕ_s) phases (see Fig. 1). The inner potential is in general defined as the work to transport a unit positive test charge from an infinite distance away in a vacuum to a position within a particular phase a. The inner potential is given by

$$\phi_a=\psi_a+\chi_a, \qquad (6)$$

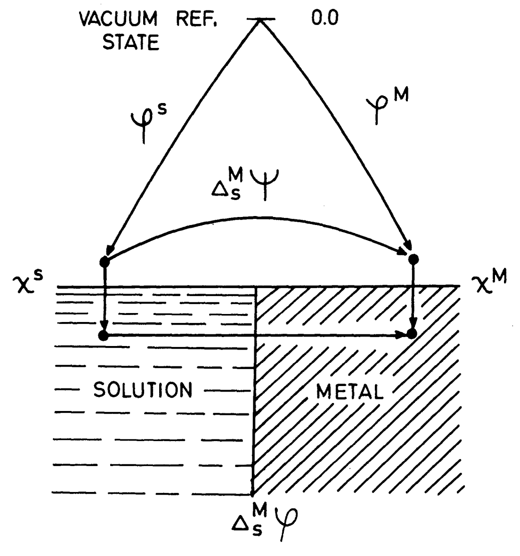

FIG. 1. Galvani ($\Delta_s^M\phi$), Volta ($\Delta_s^M\psi$), and surface (χ^s and χ^M) potentials at the metal–solution interface.

where ψ_a is the outer potential and χ_a is the surface potential. The former is a function of the net charge on the phase a and the latter is a function of dipoles at the surface of phase a. In turn, the Galvani potential may be given as

$$E_G=\Delta_s^M\phi=\Delta_s^M\psi+\Delta_s^M\chi=E_V+\Delta_s^M\chi, \qquad (7)$$

where $E_V=\Delta_s^M$ is the Volta potential. The Volta potential E_V can be determined experimentally while the surface potential difference $\Delta_x^M\chi$, and hence the Galvani potential, cannot. Any potential measuring device introduces a new interface whose Galvani potential combines with the potential difference being measured. The difference of the inner potentials between two metal leads of the same metal $\Delta_M^{M'}\chi$, however, can be measured since the surface potentials are the same for each lead. Then the Galvani potential difference reduces to a Volta potential difference which is measurable (Bockris and Reddy, 1970; Trasatti, 1980).

The difference in the thermodynamic electrode potentials ($E-E_2$) of two electrodes in a galvanic cell $M|M_1|s|M_2|M'$ corresponds to $\phi_{M'}-\phi_M$ [see Eq. (5) and the cell with which it corresponds]. Therefore it is possible to set up a relative scale of thermodynamic electrode potentials on which one electrode system is taken as the zero of the scale. For protic solvent systems such as water, the reference electrode establishing the zero of the electrode potential scale is the reversible hydrogen electrode involving the process

$$H_2 \rightleftarrows 2H^+ + 2e^-, \qquad (8)$$

occurring on a metal surface such as platinum which catalyzes this reaction. The H_2 and H^+ activities for the hydrogen reference electrode are usually not for standard-state conditions but the measured values of $E-E_{ref}$ can be easily corrected to standard state conditions for E_{ref}. Therefore we deal with

$$M|M_1|s|M_{ref}|M'$$

and

$$\Delta_{M'}^M\phi=E_1-E_{ref}.$$

For example, for a zinc electrode with a standard hydrogen reference electrode

$$M|Zn|Zn^{2+},H^+|H_2,Pt|M',$$

$$\Delta_{M'}^{M}\phi = E_{Zn/Zn^{2+}} - E_{SHE}, \qquad (9)$$

where E_{SHE} corresponds to the standard hydrogen reference electrode and the cell is isothermal and thermodynamically reversible. The electrochemical reactions are

$$Zn \rightleftharpoons Zn^{2+} + 2e^- \qquad (10)$$

$$\underline{2H^+ + 2e^- \rightleftharpoons H_2(Pt)} \qquad (11)$$

$$Zn + 2H^+ \rightleftharpoons Zn^{2+} + H_2 \qquad (12)$$

where Reactions (10) and (11) are often referred to as the half-cell reactions and Reaction (12) is the cell reaction.

The potential of this cell ($E_{Zn/Zn^{+2}} - E_{H_2/H^+}$) is a function of the concentrations of Zn^{2+} and H^+ and also the saturation pressure of H_2. From thermodynamics, it can be shown that

$$E_{Zn/Zn^{2+}} - E_{H_2/H^+} = E^0_{Zn/Zn^{2+}} - E^0_{H_2/H^+} - \frac{RT}{2F} \ln \frac{a_{Zn^{2+}} P_{H_2}}{a_{Zn}(a_{H^+})^2}, \qquad (13)$$

where R is the gas constant, T is the absolute temperature, $a_{Zn^{2+}}$, a_{Zn}, and a_{H^+} are the activities (effective concentrations) of the indicated species, and P_{H_2} is the H_2 saturation pressure. The quantities with the superscript 0 corresponds to the standard-state values.

The potential difference between the conventional electrochemical scale with $E_{SHE} = E^0_{H^+/H_2} = 0$ and the physicists' scale with a vacuum reference state for $\phi = 0$ can be calculated from various models of the electrode process occurring at the SHE reference electrode. The difference between the two scales corresponds to the removal of an electron from the Fermi level of the reference electrode to the vacuum level and for the standard hydrogen reference is about 4.5 eV. Figure 2 gives a comparison of the two scales of potentials (Gerischer, 1990).

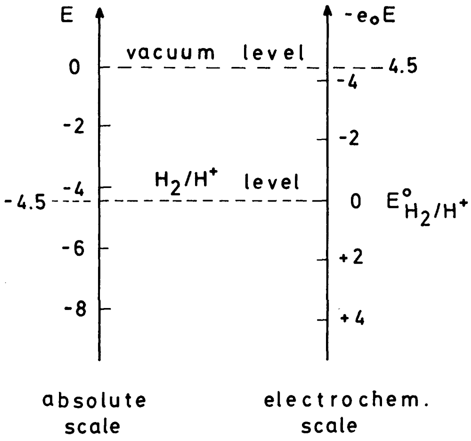

FIG. 2. Comparison of the electrochemical and absolute (vacuum) scale of potentials [adapted from Gerischer (1990), reproduced with permission of Pergamon Press].

1.2 The Electrical Double Layer

To a first approximation, the electrode–electrolyte interface can be represented as a parallel-plate condenser with one plate through the centers of the ions separated by a monolayer of solvent molecules from the electrode surface, and the second plate at the metal surface. The solvated ions, whose centers define the outer Helmholtz plane (OHP), interact with the electrode surface through electrostatic forces only. Most of the cations, e.g., Na^+, K^+, and Li^+, and anions, e.g., F^- and ClO_4^-, which have solvation shells, generally do not approach the electrode surface closer than the OHP. Some weakly solvated anions, such as Cl^-, Br^-, and I^-, are chemisorbed on the electrode surface, undergoing a chemical bonding to the surface. A partial charge transfer takes place in this interaction. The coverage of these "specifically" adsorbed ions can be substantial if a large charge transfer takes place and strong chemical bonding occurs. Their centers define the inner Helmholtz plane (IHP). The coverage of electrostatically adsorbed ions does not usually exceed 0.1–0.2 of a full monolayer.

Figure 3 gives a schematic representation of the double layer. The potential at which the net charge of the metal is zero is termed the potential of zero charge (PZC) and is characteristic of the metal as well as the electrolytic solution. The field across the double layer at the PZC is dependent on the orientation of dipoles, including water molecules at the surface. The model of an electrical double layer as a condenser with a fixed plane of charge in the electrolyte (inner layer) is due to Helmholtz (1853). Gouy (1903) and Chapman (1913) took into account the ion concentration gradient extending from the electrode surface into the solution (diffuse layer) caused by the charge in the double layer. Stern (1924)

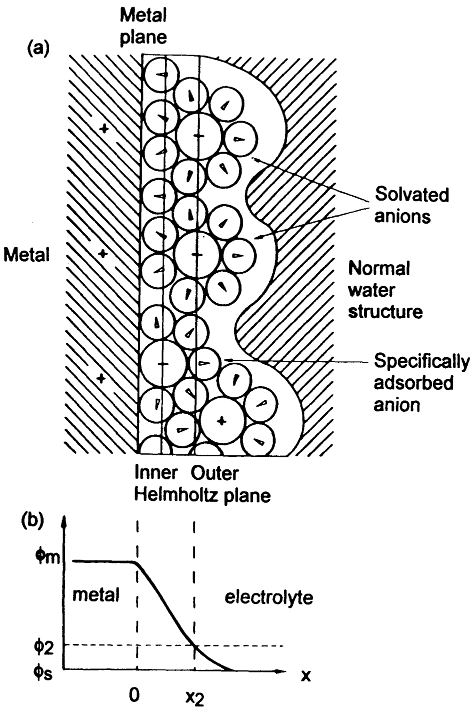

FIG. 3. Model of the electrochemical double layer.

modified this model by taking into account that the finite size of ions results in a limiting distance of closest approach to the electrode surface. The double-layer capacitance is a series combination of the capacitance of the compact and diffuse layers, and the total capacitance of the metal–solution interface, $C_{M\text{-}s}$, is given by

$$1/C_{M\text{-}s} = 1/C_{M\text{-}2} + 1/C_{2\text{-}s}, \qquad (14)$$

where $C_{M\text{-}2}$ and $C_{2\text{-}s}$ are the capacitances between the metal and the outer Helmholtz plane and for the diffuse ionic layer, respectively. The capacitance of the diffuse ionic layer depends on the potential drop $\phi_2 - \phi_s$, [see Fig. 3(b)] where ϕ_2 is the potential of the outer Helmholtz plane and ϕ_s is the potential of the bulk solution (Delahay, 1965). For a symmetrical electrolyte $C^{z+}A^{z-}$,

$$C_{2\text{-}s} = |z| fA \cosh[|z| f(\phi_2 - \phi_s)/2], \qquad (15)$$

where $A = (RT\epsilon c_s/2\pi)^{1/2}$, $f = F/RT$, F is the faraday, T is the absolute temperature, R is the gas constant, c_s is the ion concentration, and ϵ is the dielectric constant of the solvent. At potentials not far from E_{PZC} the equation predicts the shape of the capacitance potential curve for low concentrations (Fig. 4). $C_{2\text{-}s}$ passes through a minimum as ϕ_2-ϕ_s approaches zero. The measurement of the differential double-layer capacitance is used for the determination of E_{PZC}. The pronounced minimum at the PZC for low concentrations disappears at higher electrolyte concentrations because the value of the term $1/C_{2\text{-}s}$ still remains small compared to $1/C_{M\text{-}2}$ even at the PZC. In the presence of specifically adsorbed anions, the PZC is shifted to more negative values. At high positive charges on the electrode the anions become partially desolvated, and this reduces the distance of closest approach to the surface, causing a large increase of $C_{M\text{-}2}$. At high negative charges, the water structure around only the cations is changed, causing a relatively small increase of the capacitance. The Gouy–Chapman–Stern model only partially accounts for some features of the capacitance–potential curves. Some of the refinements of this model take into account the structure of the dielectric in the compact layer, dielectric saturation in the strong electric field, differences in the outer Helmholtz plane for cations and anions, and the penetration of the electric field into the metal electrode.

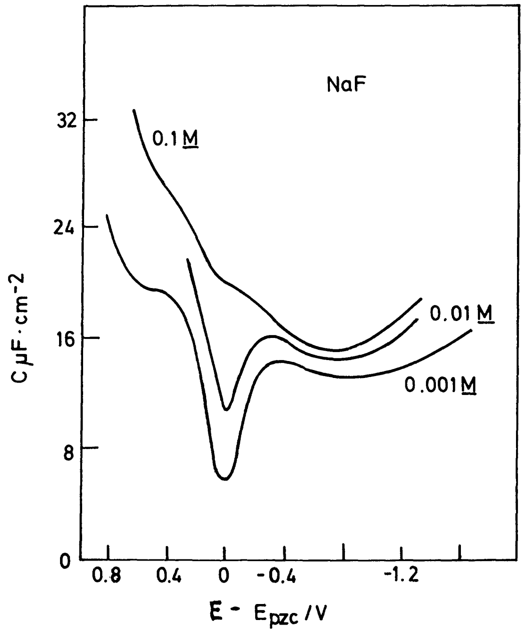

FIG. 4. Double-layer capacitance for Hg in NaF solution at 25 °C, vs $E - E_{PZC}$ (rational potential) [reproduced from Conway (1965) with permission of Ronald Press].

The potential of zero charge is related to the modified (electrochemical) work function for electrons in the electrode since zero charge conditions are required for determination of both quantities. (The Kelvin probe measures the disappearance of excess charge.) The Fermi level of an electrode at E_{PZC} correlates with the work function Φ. The relationship

$$E_{\mathrm{PZC}} = -\Phi + \mathrm{const} \qquad (16)$$

with a unit slope holds for the transition metals (Fig. 5). For *sp* metals the slope is not unity because of the metal-dependent water orientation (Trasatti, 1977). Deviations from Eq. (16) may arise from different dipole structure and ion adsorption at the metal–electrolyte interface, particularly the latter. The work function as well as the PZC depends on the crystal orientation. This means that even the concept of a PZC for a polycrystalline electrode may be undefined. The majority of more recent double-layer studies with solid metal electrodes have been done with single-crystal surfaces (Hamelin, 1985).

1.2.1 New Models. The theoretical analysis of the metal/liquid-electrolyte interface has been the subject of much study over the last two decades. In general, the models avoid some of the oversimplifications of earlier treatments. They take into account the ion size, the effect of solvent molecule size and its dipole moment, and the contribution of the metal valence-electron orbitals to the double-layer behavior. The full role of the metal in this context was not realized before recent calculations using the methods of surface physics. The penetration of the field into the metal electrode (the Thomas–Fermi screening distance) appears more important than heretofore realized.

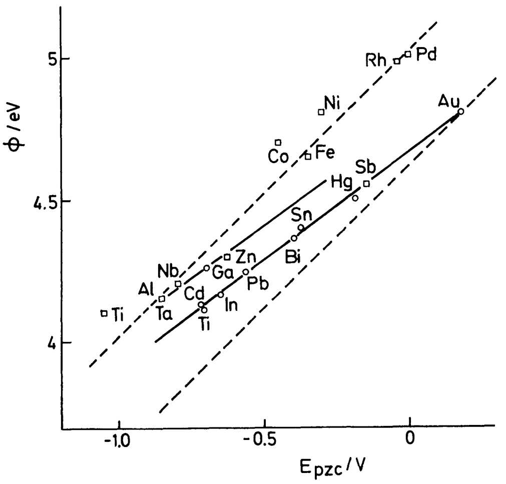

FIG. 5. Correlation of E_{PZC} with work function for various metals [reproduced from Trasatti (1977) with permission of John Wiley and Sons].

A model using hard spheres for ions and solvent with a point dipole at the center of the solvent spheres gives the following expression for the total interfacial capacitance at low concentrations (Blum and Henderson, 1981):

$$\frac{1}{C} = \frac{L_D}{\epsilon} + \frac{1}{\epsilon}\left[\frac{d}{2} + \left(\frac{\epsilon}{\epsilon_0} - 1\right)\frac{1}{\lambda}\frac{d_s}{2}\right] + \cdots , \qquad (17)$$

where d is the ionic diameter (assumed to be the same for the cations and anions), d_s is the solvent diameter, L_{D} is the Debye length, and λ is a function of the permittivities of the solution and of free space. The result may be viewed as a Gouy–Chapman capacitance (ϵ/L_{D}) in series with a second capacitance which takes into account changes in the local dielectric constant that are underestimated in this model.

Several variations of a lattice-gas model, which also allow for the effects of ionic size and solvent-molecule dipoles, produce a reasonable capacitance–potential curve if a lower dipole moment is taken for the first layer of water than for bulk water. A treatment of the monolayer of solvent separately is able to account for the shapes of capacitance curves on different metals, the temperature dependence, the H/D isotopic effect, and the effects of organic molecules. These results have been reviewed by Parsons (1990).

The role of the metal phase, ignored in the above models, has been considered with the jellium model for the metal. A substantial metal contribution to the capacitance arises from the tailing off of the electron density versus distance into the interface. The metal phase also modifies the polarization of the solvent in the IHP layer by affecting the distance of closest approach, d_i (determined by metal–solution coupling), and the relaxation of the electronic structure with charge on the metal which gives the series capacitance component C^M(dip). At the PZC, for several models, C can be approximated by

$$1/C \approx 1/C_0 + 4\pi d + 1/C^M(\mathrm{dip}), \qquad (18)$$

where C_0 is the capacitance corresponding to the solution side. The comparison with experimental data has so far been made at the PZC and not with the capacitance–potential curve over a wide range of potentials (Badialli, 1986).

2. CHARGE-TRANSFER REACTIONS

Electrochemical reactions can be divided into two classes: (I) outer-sphere one-electron transfer with the solution-phase electron donors or acceptors in the OHP when the electron transfer occurs, and (II) more complex electron-transfer processes where more than one electron may be transferred. The adsorption of reactants, products, and/or intermediates may be involved and the reactions are generally more complex. Class I electron transfer involves a simple ionic redox process in which only a change of the oxidation state of reactants positioned in the OHP is involved. Class II electrochemical reactions are often multiple steps with some chemical steps taking place before, between, or after the electron transfer steps. Under some circumstances, one step, called the rate-determining step (RDS), limits the rate, while all other preceding and following steps can be considered to be in equilibrium. Many electrochemical reactions of organic molecules and reactions accompanied by gas evolution or dissolution are in class II.

Just as for chemical reactions in general, the charge transfer is controlled by the existence of an energy barrier between the oxidized and reduced states. A unique feature of electrode reactions is that the height of this barrier can be decreased or increased by changing the potential across the metal–electrolyte interface.

2.1 Phenomenological Description of the Kinetics of Charge-Transfer Processes

Because of the heterogeneous nature of electrode reactions, the rate of the charge transfer across the electrochemical interface depends not only on the potential but also on the double-layer structure and the adsorption of reactants, intermediates, products, and other constituents of the solution either intentionally or nonintentionally present. Mass-transport limitations will not be considered here. The expression relating the current (the rate of reaction) to the electrode potential can be obtained from the absolute rate theory applied to the electrochemical interface. For electrochemical reactions the heights of the free-energy barriers are functions of the potential drop across the interface in accordance with absolute rate theory. For a one-electron transfer reaction,

$$R \rightleftarrows O + e^-, \tag{19}$$

a shift in the electrode potential from 0 to a value E causes the changes depicted in Fig. 6. The barrier for the oxidation $\Delta G_a^\ddagger$ is decreased by a fraction α of the energy change nFE, while the barrier for reduction is increased by $(1-\alpha)nFE$. The current–potential relationship is given by

$$\begin{aligned} i &= i^{\rightarrow} - i^{\leftarrow} \\ &= nF\{k^{\rightarrow} C_R \exp(+\alpha nfE) \\ &\quad - k^{\leftarrow} C_O \exp[-(1-\alpha)nfE]\}, \end{aligned} \tag{20}$$

where $i^{\rightarrow}$ and $i^{\leftarrow}$ are the anodic (oxidation) and cathodic (reduction) current densities (A/cm^2), C_R and C_O are the concentrations of reactant and product, respectively, $k^{\rightarrow}$ and $k^{\leftarrow}$ are the corresponding rate constants, E is the electrode potential versus a reference electrode, α is the anodic transfer coefficient, and $1-\alpha$ is the cathodic transfer coefficient. For a one-step single-electron transfer, α is equal to the symmetry factor β, which reflects the symmetry of the energy barrier (Fig. 6). When the slopes of the free-energy curves at their intersection are equal numerically but opposite in sign, then $\alpha=\beta=\frac{1}{2}$.

At equilibrium, the net current density is zero, and the anodic and cathodic currents are of equal magnitude. This current density at the reversible potential is termed the exchange-current density, i_0. If the potentials are taken relative to the reversible value, one obtains the current-density–overpotential equation (the Butler–Volmer equation):

$$i = i_0\{\exp(+\alpha nf\eta) - \exp[-(1-\alpha)nf\eta]\}, \tag{21}$$

where η is the overpotential $\eta = E - E_{\text{rev}}$. This is one of the fundamental relationships in electrochemistry. For $|\eta| > 0.118/n$ V the anodic or the cathodic current density becomes predominant and Eq. (21) reduces to one term. Overpotentials of 1 V are frequently

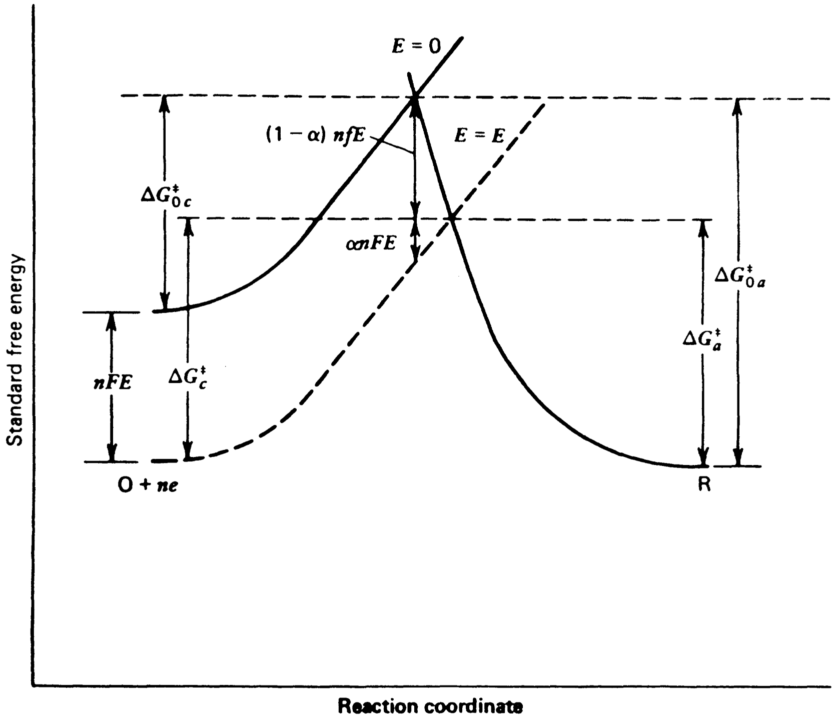

FIG. 6. A detailed picture of the change of free energy of activation caused by change of potential [reproduced from Bard and Faulkner (1980) with permission of John Wiley and Sons].

encountered experimentally. Over the 1.0-V range, the reaction rate may change by a factor 10^8. Such large changes in rates are a unique feature of electrochemical reactions. Such large changes for chemical reactions usually require extreme changes in temperature and pressure.

The double-layer structure can affect the kinetics of electrode reactions in two ways for a class I reaction. First, because of the presence of the diffuse ionic layer, the concentration of ions C_2 in the outer Helmholtz plane differs from the value of C_s in the bulk solution. Second, the overpotential η in Eq. (21) should be corrected for changes in the potential drop across the diffuse layer, $\phi_2 - \phi_s$. This effect is known as the Frumkin effect (Frumkin, 1933). With a concentrated supporting electrolyte and reactants and products of low charge (0 or ±1), these double-layer effects may be quite small. For class I reactions, corrections for these double-layer effects are relatively easily calculated, particularly when a large concentration of a supporting electrolyte is used to reduce the double-layer effects.

2.2 Theories of Electron Transfer

Theoretical descriptions of charge transfer (electrons or protons) in electrochemical reactions have been a subject of much interest since the work of Gurney (1931) who suggested that electron-transfer reactions at electrodes as well as between redox couples in solutions can be interpreted in terms of electron tunneling. Microscopic aspects of the charge transfer in the phenomenological treatment are contained in the rate constants k and the transfer coefficient α.

There have been two main approaches to the problem. In the first, which can be termed "molecular," attention is focused on the behavior of one chemical bond that is modified in the interfacial reaction. The theory assumes that the energy of activation is determined by the distribution of thermal energy in the various internal modes of the reacting species, but ignores the dynamic behavior and dielectric relaxational properties of the solvent (Horiuti and Polanyi, 1935; Bockris and Matthews, 1966; Christov, 1961).

The second approach, referred to as "continuum" theory, has been pursued by various theorists using classical and quantum statistical mechanics with a common focus on solvent dipole fluctuations as a major factor controlling the rate of charge transfer. According to the Franck–Condon principle, the electronic transition occurs in a time too short for changes in the nuclear positions and moments within the restraints of the uncertainty principle. The electron is transferred by tunneling without any change in the total energy. This is accomplished by thermal fluctuations in the solvent molecules surrounding the central ions. If, as a result of solvent fluctuations, the dipole distribution around the reacting particle is such that at the same time the energy is equal for the initial and final states, the quantum-mechanical tunneling of electrons from the metal to the reacting species can take place. Following the electron transfer, the system then relaxes to the equilibrium dipole distribution. Therefore, for simple reactions, the activation energy should be determined by the reorganization of the solvent dipoles required for quantum-mechanical electron transfer.

A particular feature of electrode reactions is that the electron energy level can be varied over a wide range by changing the electrode potential. Levich and Dogonadze (1959), using a full quantum-mechanical treatment, have shown that the variation of potential energy with displacement is parabolic, equivalent to a simple harmonic oscillation of the solvent. The solvent contribution to the potential energy is of the form

$$U_n = U_0 + \tfrac{1}{2}(h\nu_s) \sum (x_n - x_{n,0})^2, \qquad (22)$$

where x_n is a solvent coordinate, $x_{n,0}$ is the equilibrium value, U_0 is the energy when all x_n have the values $x_{n,0}$, and ν_s is the frequency of the solvent motion. The three-dimensional representation of Eq. (24) is given in Fig. 7. The electron transfer occurs at the lowest energy at which the paraboloids intersect. The intersection gives the same picture as that with the two coordinates also given in Fig. 7. The energy of activation is required for the movement of the system along the solvent coordinate from A to B. The Levich–Dogonadze–Kuznetsov treatment [see, e.g., Levich (1970)] for the heterogeneous reduction process [Eq. (21)] gives

$$i = \int \int c_0(x)\,[n(E)\rho(E)]\,W(E,x)\,de\,dx, \qquad (23)$$

where $c(x)$ is the concentration of the reacting ion at the distance x from the electrode, $\rho(e)$ is the electronic density of states in the metal, $n(E)$ is the Fermi distribution function, and $W(E,x)$ is the transition probability for the system to pass from the initial (i) to the final (f) state.

A simpler and easier-to-follow treatment of the role of solvent fluctuations in electron-transfer reactions at interfaces is due to Marcus (1964), who also gave much attention to the homogeneous redox reactions. He used only classical statistical thermodynamics. The theory gives an expression similar to Eq. (23) but based on free-energy considerations. The Marcus treatment works reasonably well for homogeneous electron-transfer reactions involving a single-electron transfer and to a somewhat lesser extent for heterogeneous redox reactions (Albery, 1975).

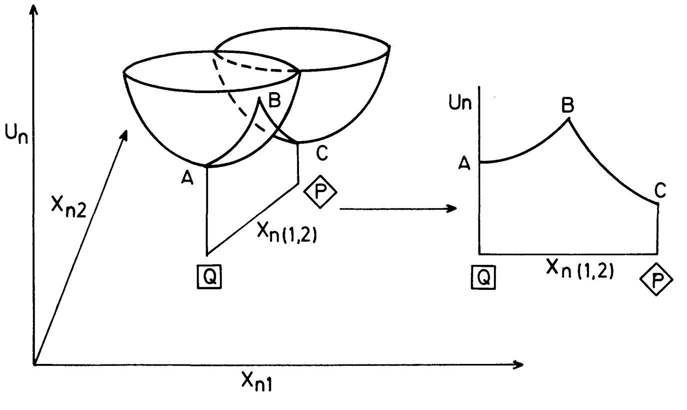

FIG. 7. Three-dimensional representation of Eq. (14). The electron transfer occurs at the lowest energy at which the two parabolic bowls intersect [reproduced from Albery (1975) with permission of Clarendon Press].

Neither Marcus nor the Levich–Dogonadze group in their initial work considered the contributions of the vibrational modes of the inner coordination sphere ligands to the free energy of activation. Marcus rather quickly recognized the importance of this contribution, which is usually considerably larger than that of the solvent continuum, and added a term to the activation free energy to take this contribution into account. The Levich–Dogonadze group felt that the vibrational modes associated with the nearest neighbors of the reacting ions would require far too large a quantum of energy to be excited at room temperatures. This was not true, and in more recent years this contribution to the reorganizational energy has been taken into account.

For a heterogeneous one-electron transfer from the metal electrode to a redox species in solution, the Marcus treatment indicates the potential dependence of the rate constant to have the form

$$i=\kappa(kT/2\pi\rho)^{1/2}c\,\exp(-\Delta G^{*}/RT), \tag{24}$$

$$\begin{aligned}\Delta G^{*}=&(W_R+W_p)/2+(\lambda_i+\lambda_0)/4\\&+(E-E_r^0)e/2+(eE-eE_r^0+W_P\\&-W_R)^{2/4}(\lambda_i+\lambda_0),\end{aligned} \tag{25}$$

where ρ is the reduced mass in the activated state, λ_0 and λ_i are reorganizational energy terms, W_P and W_R are the work to the bring reactants and products to the most probable charge-transfer distance (transmission probability), E and E_r are the electrode potential and the reversible value, and κ is the electron tunneling probability.

At low overpotentials the last term in Eq. (25) is small. In this case Eq. (25) gives $\alpha=\frac{1}{2}$ and a linear η-log$i$ curve with a slope (Tafel slope) of $2RT/F$. At higher overpotentials $\alpha\rightarrow1$ and the curve departs from linearity. The experimental results of simple redox reactions confirm the predictions of Eqs. (24) and (25) in regard to $\alpha=\frac{1}{2}$ and the existence of barrierless and activationless processes (Krishtalik, 1983). The finding of a linear η-log$i$ curve as evidence in support of the theoretical treatments has been questioned by Bockris and Khan (1979) on the grounds that most electrode reactions give linear η-log$i$ plots over a wide range of overpotentials, with a slope of 0.12 V/decade at 25 °C, corresponding to $\alpha=\frac{1}{2}$, even when the reactions do not meet the conditions for Eqs. (24) and (25) to be applicable. The Marcus theory, however, also has yielded interesting interrelations between the rate constants for similar homogeneous and heterogeneous reactions.

2.3 Theories of Proton Transfer

Of special interest to electrochemists is the discharge of the hydronium ion to form H_2 gas at the cathode surface. The rate-determining step (rds) on *sp* metal surfaces such as mercury is the formation of adsorbed H; i.e.,

$$M+H_3O^{+}+e^{-}\rightleftarrows M-H_{ads}+H_2O. \tag{26}$$

This reaction is then followed by either a recombination reaction

$$2M-H_{ads}\rightarrow 2M+H_2 \tag{27}$$

or an electrochemical desorption reaction

$$M-H_{ads}+H_3O^{+}+e^{-}\rightleftarrows M+H_2+H_2O. \tag{28}$$

The idea of a quantum-mechanical model involving tunneling for the proton transfer can be traced back to Gurney (1931). Models based on Gurney's approach assume the existence of a classical distribution of states in the reacting species and the surrounding solution. On the basis of the changes in the isotopic separation factors for H_2 and D_2 evolution on the Hg electrode over the wide potential range in which the transfer coefficient α is constant, Bockris and Matthews (1966) concluded that up to 70% of the observed current is due to proton tunneling at low overpotentials. Proton transfer takes place from the H_3O^{+} ion in the OHP to an adsorbed state. Bockris and Matthews (1966) used an asymmetric Eckart potential-energy barrier for the tunneling. The calculation of the potential-energy profile for this model is highly dependent on the models for H_2O and H_3O^{+} at the electrode surface and particularly the potential-energy contours in reaction-coordinate space as discussed by Marcus (1964). In the tunneling calculation, the assumption is made that the initial and final states do not fluctuate during the tunneling. This work has been reviewed by Bockris and Kahn (1979).

A quantum-statistical-mechanical treatment of proton transfer has been carried out by Dogonadze *et al.* (1968). They extended the formalism of outer-sphere electron transfer to proton transfer. The reaction is considered to take place as a result of a continuum of solvent polarization fluctuations. These theorists assumed that activation by stretching of the $(\text{H–OH}_2)^+$ and *M*–H bonds is sufficiently improbable to be neglected on the basis that $h\nu \gg kT$, where ν is the frequency of the vibrational modes involved in the reacting species. They take into account only the outer-sphere reorganization of the solvent and assume that activation can only occur because of nonequilibrium solvent polarization in this treatment.

This treatment reveals three distinct potential regions with different transfer coefficients, viz., $\alpha=1$ for low η (difficult to check experimentally), $\alpha \approx \frac{1}{2}$ for intermediate η (supported by experiments), and at high η a proposed barrierless region where $\alpha=0$, for which Krishtalik (1983) claims experimental evidence support.

A particularly questionable feature of this model is the assumption that the activation occurs only through the phonon interactions in a solvent volume large compared to that of H_3O^+, and particularly the neglect of internal modes involved directly in the proton transfer (H–OH_2 and $M\text{–H}_{\text{ads}}$). Kuznetsov (1987) has further developed this model by suggesting a charge-variation model for electrochemical discharge of proton donors. The model takes into account the variation of charge of the adsorbed atom in the activation–deactivation process. Experimental isotopic effects with various metals are in line with the theory.

2.4 Electrosorption Reactions

Adsorption of species from solution on an electrode surface is a replacement process in which usually the solvent is replaced by the adsorbate. The solvent molecules, however, will also interact with the adsorbate. The adsorption depends on the interaction energies at the electrode surface, the composition of the electrolyte, and the electrode potential. A strong interaction of the adsorbed species with the electrode surface usually involves direct orbital interactions with the electrode and is referred to as chemisorption. For many ions, especially anions, the adsorption energy exceeds that expected on the basis of just electrostatics. Such adsorption is referred to as specific ionic adsorption. Chemisorption is often found also with atoms and molecules and on surfaces in general.

For the ideal polarized interface, there is no electrochemical reaction occurring at a significant rate. For such an electrochemical interface the sum of the charge on the metal electrode, σ_M, and on the solution side of the interface, σ_s, must be zero because of the neutrality restriction; therefore, $\sigma_M=\sigma_s$. The charge density (charge per unit area of the electrochemical interface) can be calculated from measurements of the interfacial capacitance per unit area (C) as a function of the potential of the metal electrode E relative to a reference electrode whose potential is constant; i.e.,

$$\sigma_M=\int_{E_{\text{PZC}}}^{E} C\,dE, \tag{29}$$

where E_{PZC} corresponds to the PZC at which $\sigma_M(\text{PZC}) = 0$. The charge density on the metal can also be determined from the interfacial surface tension γ. From the well-known Gibbs adsorption equation, it can be shown that

$$\sigma_M=\left(\frac{\partial\gamma}{\partial E}\right)_{\mu,p,t}, \tag{30}$$

where E is the potential of the metal relative to a reference electrode, μ is the chemical potential of any solution phase component, p is the pressure, and t is the temperature. The derivative $(\partial\gamma/\partial E)_{\mu,p,t}$ is relatively easily obtained with a liquid-metal electrode such as mercury but is somewhat more difficult to obtain for a solid metal electrode. At the PZC, σ_M and hence $(\partial\gamma/\partial E)$ go to zero and γ passes through a maximum.

2.4.1 Partial Charge Transfer During Specific Ionic Adsorption.

When orbital overlap occurs between the electron orbitals of the adsorbed ion and the metal electrode, the bonding of the ion to the electrode is not purely electrostatic and partial charge transfer is expected. Lorenz and Salie (1961) proposed that

$$x^z \rightarrow x_{\text{ads}}^{z(1-\lambda)} + \lambda z e^-, \tag{31}$$

where λ is the partial-charge-transfer coefficient. If the adsorption is purely electrostatic, $\lambda=0$, while if the adsorption is almost entirely through covalent bonding, $\lambda=1$. The term λ cannot be determined by just measuring the charge through the external circuit since the double-layer charge also is involved.

Lorenz and Salie (1961) have attempted to derive equations relating λ to experimentally measurable quantities, principally the high-frequency differential capacitance of the interface and the excess charge on the metal when $\lambda = 0$. Despite serious questions and criticisms of the Lorenz approach to the measurement of λ, the qualitative concept of partial charge transfer between the chemisorbed ion and the metal has gained some acceptance.

An alternative approach proposed by Vetter and Schultze (1972) defines the concept of "electrosorption valency," given by the relation

$$\gamma' = -\frac{1}{F}\left(\frac{\partial \sigma_m}{\partial \Gamma}\right)_{\Delta\phi} = \frac{1}{F}\left(\frac{\partial \mu_{\mathrm{ad}}}{\partial \Delta\phi}\right)_{\Gamma}, \qquad (32)$$

where σ_m is the charge provided by the external circuit, $\Delta\phi$ is the potential drop $\phi_M - \phi_2$, and Γ is the surface excess of the absorbate per unit area of the interface.

The quantities in the first term of Eq. (32) are all directly measurable. Experimentally, Schultze and Vetter (1973) obtained, for Hg at $\Delta\phi = 0$, the values $\gamma'_{\mathrm{Cl}^-} = -0.16$, $\gamma'_{\mathrm{Br}^-} = -0.33$, and $\gamma'_{\mathrm{I}^-} = -0.40$. Despite some approximations and estimations the electrosorption valency clearly provides evidence for partial charge transfer. The quantum-mechanical calculations of Kornyshev and Schmickler (1985) support the partial-charge-transfer concept while calculations based on the "jellium" model by Lang (1983) do not. The latter is not surprising since the jellium model does not handle properly the localized covalent binding of the adsorbed ion with the electron orbitals of the metal.

3. ELECTROCHEMISTRY ON WELL-DEFINED SINGLE-CRYSTAL SURFACES

Very substantial progress has been made in the last several years in studying electrochemical reactions on single-crystal surfaces. This parallels the progress in surface science and the surface characterization of solid–vacuum and solid–gas interfaces. Double-layer properties, electrosorption reactions, and the kinetics and pathways of electrocatalytic reactions have been found to be dependent on the crystallographic orientation of the electrode, i.e., on the local symmetry of surface atoms. Single-crystal electrode studies are essential to an understanding of the various processes occurring at electrode surfaces.

3.1 Double-Layer Capacitance Studies

A large body of experimental data on the double-layer properties of single-crystal electrode surfaces exists for the *sp* metals gold, silver, and copper but only one *d* metal, iron. Striking differences in the double-layer properties of the low-index planes have been found for Au, Ag, Bi, Zn, and Sn in weakly adsorbed electrolytes as well as with specifically adsorbed halides (Hamelin, 1985). The potential of zero charge differs by several hundred millivolts from one face to the other, indicating that the kinetics of various electrochemical reactions should also be strongly affected by the crystallographic orientation of the electrode surface. For example, the PZC values for Ag(111), Ag(100), and Ag(110) are −0.45, −0.67, and −0.77 V, respectively. This indicates that even the concept of the PZC may not be valid for a polycrystalline electrode.

Note should be taken, however, of the strong possibility that restructuring of the surface occurs after the metal electrode is introduced into the electrolyte, particularly with the more active metals such as Bi, Zn, Sn, Cu, and Fe.

The linear relationship between the work function and the PZC values holds also for single-crystal electrodes* [see Eq.(17)]. The close-packed planes have higher work functions and more positive PZC values. *In situ* studies of the vibrational properties of water molecules in the compact layer on single-crystal surfaces would help to advance the understanding of the compact layer and the symmetry elements.

---

*The work function of a phase *a* is defined as the work necessary to transport an electron from within the phase to an infinite distance away *in vacuo* (vacuum reference) when there is no net charge on the surface through which the electron is removed. Since the potentials of zero charge differ for the various crystal surfaces, their work functions will also differ.

3.2 Electrosorption of Hydrogen and Oxygen on Noble-Metal Electrodes

The electrosorption of hydrogen occurs on platinum metal in a reversible manner at potentials more positive than the reversible potential for hydrogen gas evolution. This is an example of so-called underpotential deposition (UPD) (Sec. 3.3). Hydrogen adsorption can be represented by the reaction (26). A monolayer of adsorbed hydrogen forms before H_2 evolution commences, according to reaction (27). Anion adsorption has a substantial effect on the hydrogen adsorption reaction. Hydrogen adsorption exhibits a pronounced dependence on the crystallographic orientation of the electrode surface. This has been established with well-ordered single-crystal surfaces, particularly platinum. Recent data for surfaces prepared in ultrahigh-vacuum (UHV) systems, characterized with low-energy electron diffraction (LEED) and Auger electron spectroscopy (AES), and transferred to a thin-layer electrochemical cell [see Yeager *et al.* (1978) and Ross (1979)], agree reasonably well with the data obtained by a special flame annealing method of Clavilier *et al.* (1980).

Linear-sweep voltammetry curves are shown in Fig. 8 for the adsorption and desorption of hydrogen atoms on the three low-index planes of platinum in sulfuric acid. The potential is linearly swept in the positive and then the negative directions, and the current is recorded as a function of the electrode potential. By integrating the current–voltage curves, it is possible to calculate the adsorption iso-

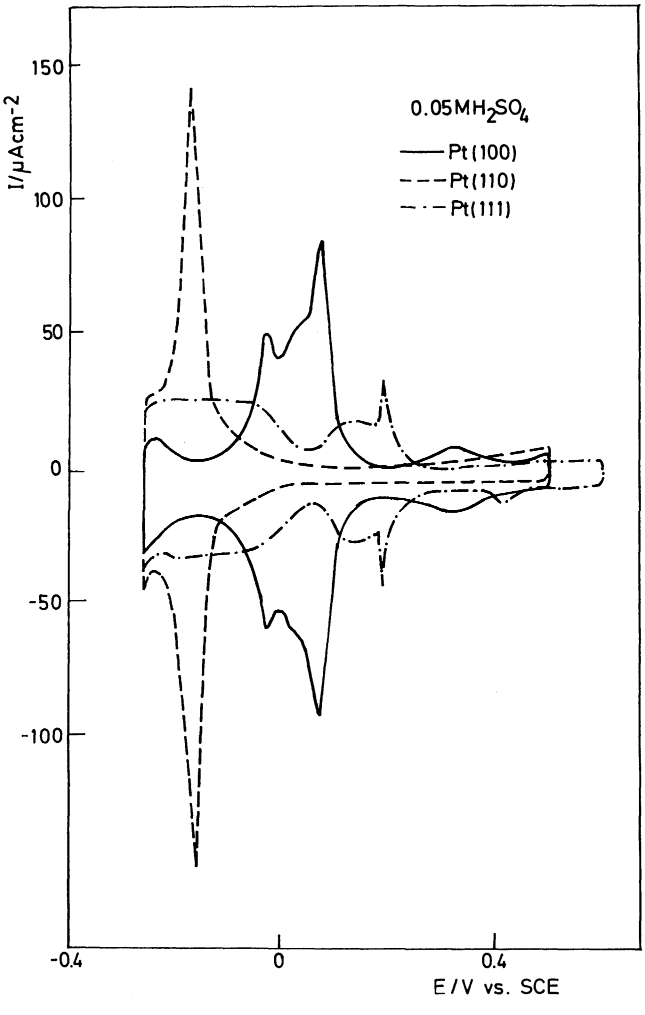

FIG. 8. Electrosorption of H on Pt single-crystal electrodes in 0.50*M* H_2SO_4. Sweep rate 50 mV s^{-1}. The potential scale is given vs saturated calomel reference electrode [adapted from Markovic *et al.* (1988) with permission of the Americal Chemical Society].

therms (surface coverage versus electrode potential) provided the electrosorption valence is known. The strong dependence of the electrochemical properties on the crystallographic orientation of the electrode surface is also supported by results obtained on high-index stepped surfaces which show a dependence on the step orientation and step density.

The interpretation of the hydrogen adsorption curves for platinum is a matter of some controversy. The behavior of the Pt(111) surface is less understood than the other two low-index planes—in particular, the more positive peak in Fig. 8. The exact location of the hydrogen atoms on the platinum surfaces is not yet well established. This was a matter of controversy for many years in gas-phase studies (Christmann, 1988). The infrared studies of Bewick *et al.* (1988) provide some evidence that on the Pt(111) and polycrystalline Pt surfaces, the bonding of H with Pt may be similar to that in metal hydrides.

The adsorption of *M*-OH and *M*-O occurs on noble metals such as platinum at potentials much less positive than the potential for oxygen evolution and leads to the formation of submonolayers or monolayers of these species. Thicker layers can be formed at such potentials on most less noble metals, such as ruthenium. The reaction is very irreversible except at the onset of the oxidation. It is also strongly dependent on the crystallographic orientation of the surface. The differences in the voltammetry curves in the early stages of the formation of the *M*-OH and *M*-O layers have been proposed by Angerstein-Kozlowska *et al.* (1987) to be due to the different strengths of adsorption and the extent to which these processes are coupled with the desorption–adsorption process of anions having tetrahedral structure (SO_4^{2-}, ClO_4^-).

3.3 Formation of Metal Monolayers

In the electrodeposition of metals onto foreign metal substrates, e.g., Pb on Pt, the formation of a monolayer of metal may take place at potentials more positive than the potential required for the reversible deposition. This phenomenon is another illustration of underpotential deposition (UPD) (see Sec. 3.2). This occurrence of UPD implies that the chemical potential of the adatoms deposited in the UPD layer (μ_{ads}) is different from that of the corresponding bulk metal (μ_{bulk}). The adatoms are more strongly bound to the surface of the foreign substrate than to the surface of their own species. The difference in the electrode potentials for reversible UPD and reversible deposition of the bulk metal corresponds to the differences in chemical potentials

$$[\mu(\theta)]_{\mathrm{ads}}-\mu_{\mathrm{bulk}}=-ze[E(\theta)_{\mathrm{ads}}-E_r] \\ =-ze\Delta E_p, \qquad (33)$$

where E_r is the reversible electrode potential for the bulk metal and $E(\theta)_{\mathrm{ads}}$ that for the UPD layer at the coverage θ. The difference $[E(\theta)_{\mathrm{ads}}-E_r]$ is a measure of the binding energy of the UPD layer to the foreign metal substrate. The electrosorption valency has been taken to be close to the Faradaic valence.

On the basis of data for polycrystalline electrodes, Kolb *et al.* (1974) found a linear relationship between the UPD effect at $\theta=0.2$ and the difference in work functions of the substrate and the adsorbate bulk metal, of the form $\Delta E_p(\theta=0.2)=s\Delta\Phi$, where $s\cong\frac{1}{2}$. This correlation does not seem to be applicable in this simple form for single-crystal electrodes (Bewick and Thomas, 1975). A necessary condition for UPD to occur is $\Phi_{\mathrm{substrate}}>\Phi_{\mathrm{adsorbate}}$. Trasatti (1975) found a linear correlation also between $\Delta E_p(\theta=0)$ and $\Delta\Phi$ by taking the potential onset ΔE_p at the UPD, i.e., $\theta=0$. The electrosorption valency of foreign adatoms is in the majority of the cases close to the Faradaic valence, i.e., only a small charge may be retained on the adsorbate. Table 1 gives a list of the relative binding energies and electrosorption valencies for various pairs of substrate and adsorbate metals.

Figure 9 shows the voltammetry curves for the formation and dissolution of a monolayer of Pb on gold single-crystal electrodes. Adžić *et al.* (1974) have shown that the UPD of metals strongly depends on the crystallographic orientation of the electrode surface. The coverage of foreign adatoms is determined by the electrode potential and concentration of cations in solution. The properties of adatoms have been studied at a constant potential by various *in situ* optical techniques, scanning tunneling and atomic force microscopies, and *ex situ* surface-physics techniques (Sec. 5.3). Kolb (1978) has reviewed the work on the UPD of metals.

Various overlayer lattices have been identified for different coverages of adatoms cor-

Table 1. Relative binding energies and the electrosorption valencies for some metal adatoms on various polycrystalline substrates.[a]

System, substrate/ adatom	Relative binding-energy valence, $ze_0\Delta E_p$ (eV)	Electrosorption	
		γ^1	γ^1/z
Pt/Pb	1.74	2	1
Pt/Bi	1.77	3	1
Pt/Cu	0.82	1.8	0.9
P/Tl	1.3	0.85	0.85
Pt/Cd	1.92	0.3	0.15
Au/Pb	0.80	1.95	0.97
Au/Tl	0.69	1	1
Au/Cu	0.44	2	1
Au/Bi	0.75	3	1
Ag/Pb	0.160	1.9	0.95
Ag/Tl	0.28	1	1

[a]Relative binding energies obtained from ΔE_p at $\theta \sim 0.1$–0.2, and electrosorption valences obtained at $\theta \sim 0.1$. Reproduced from Adžić (1984) with permission of John Wiley and Sons.

responding to the multiple peaks observed in many systems. Half-widths of the voltammetry peaks smaller than (90 mV)/z indicate attractive interaction between adatoms, while larger values indicate repulsion or irreversibility. The sharp UPD peaks observed with some systems at certain coverages have been interpreted by Adžić *et al.* (1974) in terms of structural phase transitions in the UPD layer, but attractive terms in the adsorption isotherm may also result in narrow peaks.

The UPD of metals offers a unique opportunity to modify in a controlled way the electronic and catalytic properties of electrode surfaces by changing the adatoms and their coverage from 0 to 1. Large catalytic effects occur with foreign adatoms in the oxidation of organic molecules and oxygen reduction on some noble metals; see the review by Adžić (1984) and Sec. 3.4.

3.4 Electrocatalytic Reactions

Electrocatalytic reactions involve the strong interaction of reactants and/or intermediates with the electrode surface and usually are very dependent on the nature of the electrode material. A good example is H_2 evolution, for which the exchange-current density of various metals varies by 11 orders of magnitude. Therefore the subject of electrocatalysis is principally concerned with the role of the electrode material in determining the kinetics of electrode reactions and is a subpart of heterogeneous catalysis. Electrocatalysis is a complex area since electrocatalytic reactions are often multistep reactions which are additionally complicated by the role of the electrode material and its surface properties. In general, a detailed understanding at a molecular level of the elementary steps in electrocatalytic reactions has not yet been attained. Recent advances in the *in situ* identification of reaction intermediates and products and the proper characterization of electrode surfaces are improving this situation (Sec. 5).

Many electrocatalytic reactions have great technological importance and an even larger number have the potential for such. Consequently, they have been studied in detail. These include hydrogen, oxygen, and chlorine evolution; oxygen reduction; the oxidation of small organic molecules suitable for energy conversion (e.g., alcohols, hydrocarbons, carbon monoxide); and various organic reactions for synthetic purposes. Electrocatalytic studies can be divided into studies of the electronic factor, which depends on the nature of the electrode material, and the structural factor, including the symmetry of surface sites [see Bockris and Reddy (1970), Yeager (1981), and Appleby (1983)].

3.4.1 Electronic Factors. Much effort has been directed to the correlation of the kinetics of the H_2 evolution reaction with the nature of the electrode material. Proposed mechanisms for hydrogen generation on various metals are still open to some questions.

It is believed that for Pt and platinum metals the following mechanism is operative:

$$H_3O^+ + e^- \rightleftarrows H_{ads} \quad \text{(fast)}, \tag{34}$$

$$2H_{ads} \rightarrow H_2 \quad \text{(rds)}. \tag{35}$$

On the other hand, for metals such as Hg and Pb, reaction (34) is the rds, while for Au and Ni the rds is the reaction (Bockris and Reddy, 1970)

$$H_{ads} + H_3O^+ + e^- \rightarrow H_2 + H_2O. \tag{36}$$

The kinetics of these electrocatalytic reactions have been correlated with the free energies of adsorption of the reactants. This results in the so-called "volcano" plots, discussed for heterogeneous catalysis by Balandin (1958) and by Parsons (1958) and Gerischer (1958)

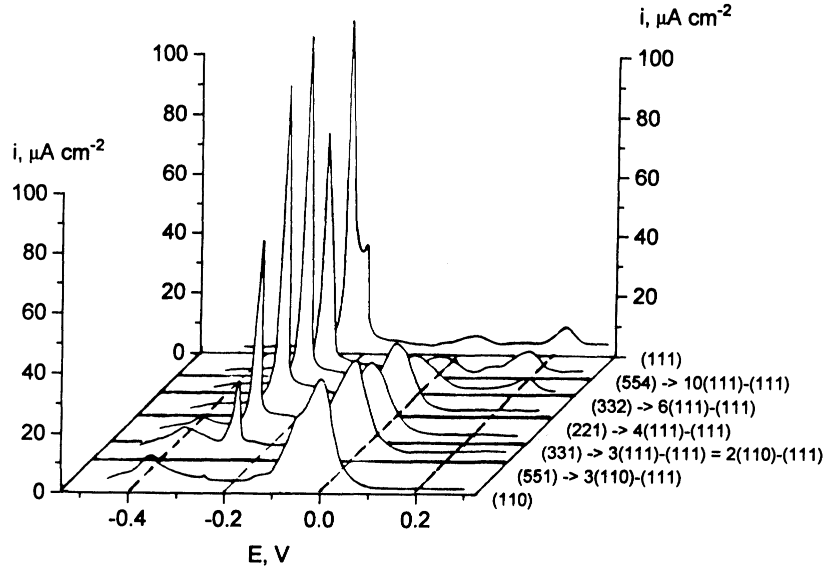

FIG. 9. UPD (anodic sweeps) of Pb on Au single-crystal electrodes in 10 m*M* $HClO_4$+1 m*M* $Pb(ClO_4)_2$ [reproduced from Hamelin and Lipkovski (1984) with permission of Elsevier Sequoia Press].

for electrocatalysis. Figure 10 shows a plot of logi_0 vs *M*–H bond strength calculated from the overvoltage data of Krishtalik (1970) (i_0 corresponds to the exchange-current densities for the overall reaction). For the left-hand branch of the volcano curve, the rate of reaction increases with the *M*–H bond strength for nontransition metals, for which the reaction (34) is the rds. For the right-hand branch, the rate decreases with the bond strength for transition metals, for which reaction (35) and, in some cases, reaction (36) are the rds. According to Khan (1985), these volcano plots support the bond-stretching model for the proton transfer (Sec. 2.3).

The oxygen evolution and reduction reactions also are electrocatalytic reactions that are of critical importance for a number of applied aspects of electrochemistry. The mechanisms of these reactions are still uncertain

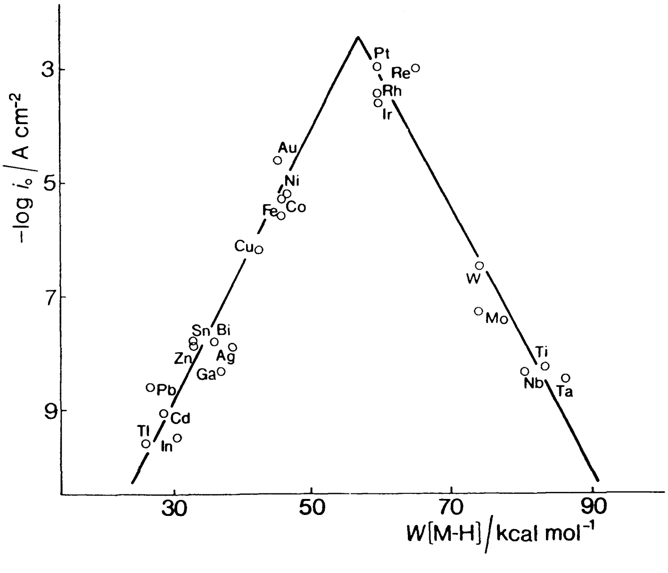

FIG. 10. Equilibrium rate for hydrogen evolution as a function of *M*–H bond strength [reproduced from Trasatti (1977) with *M*–H from Krishtalik (1970) with permission of John Wiley and Sons].

on most electrode surfaces, despite extensive studies. This is a consequence of the pronounced irreversibility at moderate temperatures and the fact that the reaction may proceed through a large number of pathways. Furthermore, the pathways for the O_2 reduction and generation are usually quite different and not just the reverse of each other. The range of potentials over which these two processes occur on a given electrode are widely separated from each other, and consequently the states of the electrocatalytic surfaces also are usually quite different for the O_2 reduction and generation processes.

The reduction of O_2 in aqueous solution, depending on the electrode material, appears to occur by two pathways overall. For acid solutions, these are

$$O_2+4H^+ +4e^- \rightarrow 2H_2O \tag{37}$$

and

$$O_2+2H^+ +2e^- \rightarrow H_2O_2. \tag{38}$$

The four-electron pathway may involve H_2O_2 as an intermediate, while for the two-electron pathway H_2O_2 is a product (Yeager, 1986). In general, little H_2O_2 is observed on Pt-group metals as a reaction product. As the peroxide builds up in concentration in the electrolyte, it undergoes further reduction,

$$H_2O_2+2H^+ +2e^- \rightarrow 2H_2O, \tag{39}$$

and/or decomposition,

$$2H_2O_2 \rightarrow 2H_2O+O_2. \tag{40}$$

The extent to which each of these pathways is involved at a particular electrode surface is usually established with the rotating-disk-ring electrode. Both the four-electron reduction and the reduction beyond the peroxide stage require the rupture of the O–O bond. A sufficiently strong interaction with a proper surface spacing of adsorbent sites is necessary for these reactions to occur (Terasevich *et al.*, 1983). A volcanolike relationship has been reported in plots of η vs ΔG_{ads} at constant current for oxygen reduction in acid solutions (Appleby, 1983). Electrocatalysis for oxygen reduction involves a number of materials, which are listed in Table 2 (Yeager, 1986).

Table 2. Electrode surfaces for O_2 reduction in aqueous solutions.[a]

Class I	Reduction predominantly through HO_2^--formation 1. Graphite, most carbons 2. Metals: gold, mercury, most oxide-covered metals (e.g., Ni, Co) 3. Oxides: most transition-metal oxides (e.g., NiO, spinels) 4. Transition-metal macrocycles: e.g., Co-TsPc, Co-TMPP
Class II	Reduction by both $4e^-$ and peroxide pathways 1. Platinum, platinum alloys, platinum-family metals 2. Other metals: silver, palladium 3. Oxides: pyrochlores (e.g., lead ruthenate) 4. Some transition-metal macrocycles (e.g., dicobalt face-to-face porphyrins, dicobalt pyridyl planar complexes, Fe-TsPc, Fe-TPyPz)
Class III	Heterogeneous peroxide decomposition catalysts 1. Metals: silver, platinum 2. Oxides: spinels, perovskites, MnO_2 3. Transition-metal macrocycles

[a] Reproduced from Yeager (1986) with permission of Elsevier Sequoia Press.

An interesting class of catalytic materials for O_2 reduction comprises the transition-metal macrocycle complexes attached to high-surface-area carbon electrodes. Their activity, but not stability, may come close to the activity of highly dispersed platinum, the best catalyst for O_2 reduction. They provide an opportunity to study the interaction of O_2 molecules with the transition metals. The various types of interactions are shown in Fig. 11 in terms of the molecular orbitals of the O_2 and the transition metal in the complex (Yeager 1986). The side-on and bridge-type interactions should be conductive to the dissociation of O_2 and hence the direct four-electron reduction. There is evidence for such with some complexes.

The oxidation of small organic molecules is of interest for electrochemical energy conversion in fuel cells. The most studied reactions have been methanol and formic acid oxidation. Volcano relations have been observed for formic acid and ethylene oxidation. The reactions are slow, even with the best catalyst, platinum. Strongly bound intermediates block the catalyst sites and make the surfaces inactive. The modification of the platinum surface

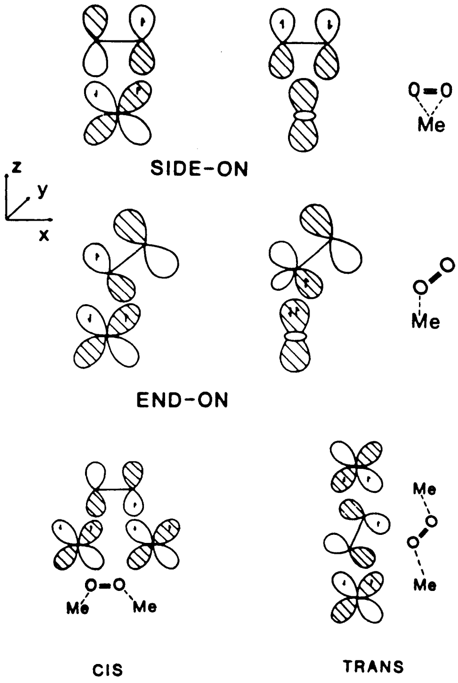

FIG. 11. Various types of interactions of O_2 with transition-metal species [reproduced from Yeager (1986) with permission of Elsevier Sequoia Press].

by alloying, UPD of foreign atoms, and the designing of bifunctional catalysts do increase somewhat the kinetics of these reactions. These modifications prevent the formation of high coverage of such intermediates as CO or facilitate their oxidation at potentials less positive than those required on platinum (Adžić, 1984; Parsons and VanderNoot, 1988).

3.4.2 Structural Factors in Electrocatalysis. The importance of the surface structure was controversial in heterogeneous catalysis as a whole, including electrocatalysis, for many years. During the last ten years or so, the results obtained with well-ordered single-crystal surfaces have demonstrated clearly the importance of structural factors. The coordination of surface atoms, interatomic distances, distance between adsorption sites, and surface energies all depend on the plane exposed. For a typical electrocatalytic reaction, the adsorption of reactants and intermediates, adsorbate surface migration, surface chemical reactions, and product desorption depend on the atomic arrangement of the electrode surface and not just on the electronic properties.

The oxidation of formic acid on single-crystal platinum surfaces is a good illustration of a striking structural effect. Linear-sweep voltammetry curves for the low-index planes of platinum are shown in Fig. 12. The reaction proceeds through two pathways after the rupture of the C–H bond:

$$\mathrm{HCOOH} \rightarrow \text{-}\mathrm{COOH}_{\mathrm{ads}} + \mathrm{H}^+ + e^-, \tag{41}$$

$$\text{-}\mathrm{COOH}_{\mathrm{ads}} \begin{cases} \nearrow \mathrm{CO}_2 + \mathrm{H}^+ + e^- & (42) \\ \searrow \text{strongly bound species.} & (43) \end{cases}$$

This strongly bound species is a matter of some controversy. On the basis of *in situ* Fourier-transform infrared spectroscopic measurements, it appears that the species is linearly bonded and bridge-bonded CO, as has also been found to be formed during the oxidation of CH_3OH. This species causes a complete blocking of the Pt(100) surface in the anodic scan. The least adsorption of CO takes place on the Pt(111) surface, which as a consequence appears to be the most active surface (see Adžić, 1990).

A strong structural dependence is characteristic of O_2 reduction on Au(*hkl*). In alkaline solutions not only the rate but also the reaction mechanism depends on the crystallographic orientation of the electrode surface. The four-electron reduction occurs on the Au(100) surface, but only the two-electron reduction takes place on Au(110) and Au(111) surfaces. The Au(100) surface is the best catalyst for O_2 reduction in alkaline solutions (Adžić *et al.*, 1984).

Many organic reactions, such as the oxidation of methanol, formaldehyde, ethylene glycol, glucose, and others, depend strongly on the crystallographic orientation of the surface. Hydrogen evolution in general has only a small dependence on the surface structure, as well as oxygen reduction on platinum [see the reviews of Adžić (1990) and Parsons (1990)]. The structural effects can be very important and as large as the electronic effects. Current research with stepped surfaces will help to rationalize the concept of "active sites." The data with stepped surfaces show that each crystallographic orientation gives the electrode surface a distinct electrochemical identity. This suggests that most of studies

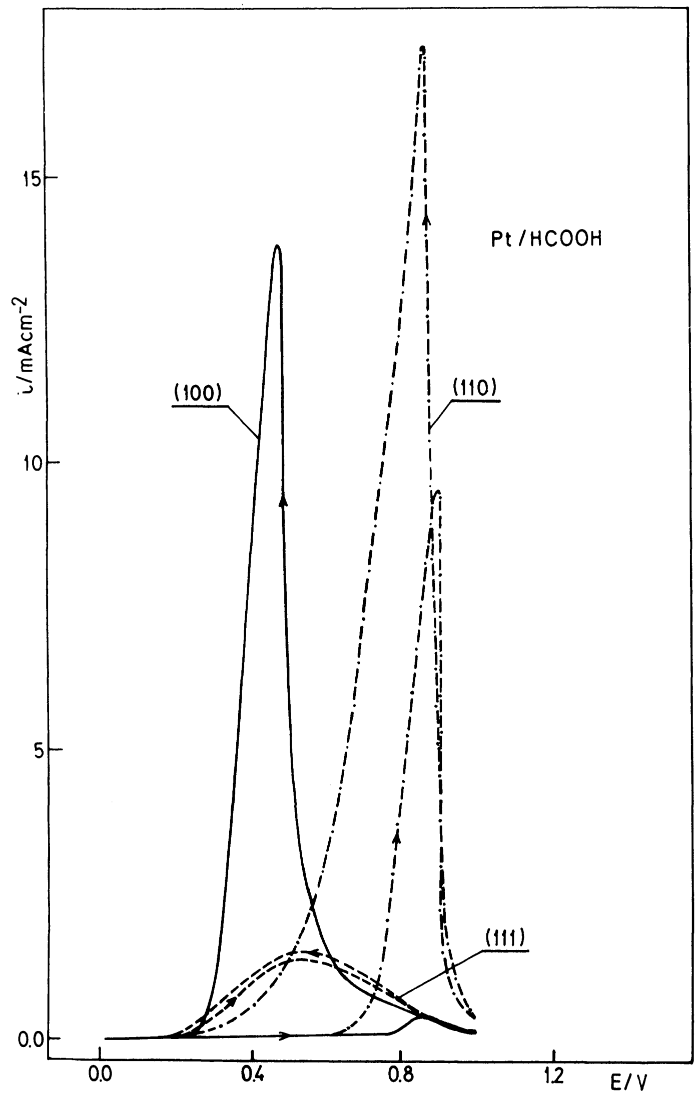

FIG. 12. Oxidation of HCOOH on Pt single-crystal electrodes in 0.1*M* $HClO_4+0.3M$ HCOOH. Sweep rate 50 mV s^{-1} [reproduced from Adžić (1990) with permission of Plenum Press].

in electrocatalysis should involve single-crystal surfaces.

4. SEMICONDUCTOR ELECTRODES

4.1 Space-Charge Effects

In general, the electrochemical properties of semiconductor electrodes are the result of a low concentration of free electrons and the presence of two types of charge carriers, conduction-band electrons (negative) and holes (positive) in the valence bands. The excess charge in the semiconductor is not located just within a fraction of an angstrom from the surface, as it is in a metal. Instead, its distribution extends into the bulk, thus making a space-charge region like the diffuse part of the ionic double layer at a metal–solution interface. The electrode potential at which the space charge in the semiconductor is zero corresponds to the PZC. For semiconductor electrodes it is called the flat-band potential, E_{fb}, since under these conditions there is no electric field and no band bending. Figure 13 shows the energy levels of the band edges and potential distributions for an *n*-type semiconductor in contact with an electrolyte for (a) no excess charge corresponding to $E=E_{fb}$, (b) positive excess charge (electron depletion); and (c) negative excess charge (electron accumulation).

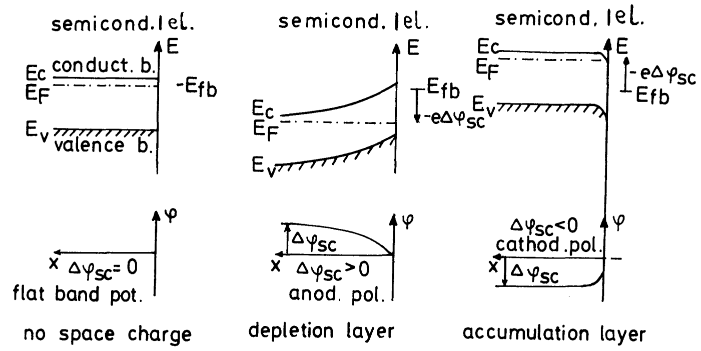

FIG. 13. Effects of space charge in an *n*-type semiconductor on the course of band edges and electric potential [adapted from Gerischer (1990) with permission of Pergamon Press].

Differential-capacitance measurements provide information on the charge distribution across the interface. When specific adsorption does not occur, the overall capacitance of the interface C is given by

$$C^{-1}=(C_{sc})^{-1}+(C_{-2})^{-1}+(C_{dif})^{-1}, \qquad (44)$$

where C_{sc} is the space-charge capacitance in the semiconductor and C_{-2} and C_{dif} are the capacitances of the outer Helmholtz layer and the diffuse ionic layers on the electrolyte side of the interface, respectively. For low and moderate carrier concentrations ($n_0<10^{16}$ carriers/cm^3) the predominant term on the right-hand side of Eq. (44) is $(C_{sc})^{-1}$ and hence $C \cong C_{sc}$.

For an extrinsic semiconductor the space-charge capacitance, C_{sc}, is given *mutatis mutandis* by Eq. (6) for the metal–diffuse-layer capacitance. For an extrinsic (e.g., *n*-type) semiconductor under depletion-layer conditions [Fig. 13(b)], C_{sc} is given by the Mott–Schottky equation, which was first derived for the metal–semiconductor interface:

$$1/C_{sc}^2=[2/(e\epsilon\epsilon_0 N_D)])(-\Delta\phi-kT/e), \qquad (45)$$

where $\Delta\phi$ is the potential drop across the space-charge layer and N_D is the density of donors. From the linear plots of $1/C_{cs}^2$ vs E one obtains E_{fb} and the doping level N_D, since $-\Delta\phi=E-E_{fb}$.

Specific ion adsorption has a pronounced effect on semiconducting oxides. The potential drop in the inner Helmholtz layer varies with the *p*H of the solution because of the interaction of the surface with H$^+$ and OH$^-$ ions.

4.2 Electrons, Holes, and Surface States in Electrode Reactions

A special feature of the semiconductor–electrolyte interface is that the charge transfer can occur to energy levels in the conduction band and in the valence band of the semiconductor. This is distinctly different than with metal electrodes, for which only the electronic levels near the Fermi level are involved. Electron transfer across the semiconductor–electrolyte interface can be treated using the theories of the electron-transfer discussion earlier in Sec. 2.2. When any change in the electrode potential occurs entirely across the space-charge layer, $\Delta\phi_{sc}$ and with not too high a doping level, then according to Gerischer (1958, 1990), the electron-transfer kinetics can be described by the current density via the conduction band:

$$i_c=k_c^+N_cN_{red}-k_cn_sN_{ox}, \qquad (46)$$

where $n_s=n_0\exp(e\Delta\phi_{sc}/kT)$ is the surface concentration of electrons and n_0 is the bulk concentration. The current density via the valence band is

$$i_v=k_v^+p_sN_{ox}-k_v^-N_vN_{ox}, \qquad (47)$$

where $p_s=p_0\exp(e\Delta\phi_{sc}/kT)$ is the surface concentration of holes, p_0 is the bulk value, N_{ox} and N_{red} are the number of solution-phase reactants per unit volume, N_c and N_v are effective densities of states in the conduction and valence bands, respectively, k_c^+ and k_v^- are the respective rate constants of the anodic and cathodic reactions involving electrons, and k_v^+ and k_v^- are the respective rate constants involving holes. In contrast to metals, all of the change in electrode potential is across the space-charge region and none between the semiconductor surface and the in-

ner or outer Helmholtz plane when the carrier concentration is low ($<10^{-16}/\text{cm}^3$) in the semiconductor. Consequently, there is no variation of the activation barrier for electron transfer. The applied potential causes only a change in concentration of electrons or holes in the space-charge region in the semiconductor. The surface concentration of the electrons determines the rate of electron transfer from an *n*-type semiconductor to the solution-phase redox system. The rate of electron injection into the conduction band from a redox system is constant and independent of the potential. For a *p*-type semiconductor and hole transfer, the relation are reversed. This is shown schematically in Fig. 14 together with the current–potential curves. The Helmholtz layer may change with potential, as a result of the presence of surface states or chemical changes of the composition of the interface. The current–potential curves approach to a certain extent those of metal electrodes. The electrolytic decomposition and photodecomposition of semiconductors are to a large extent controlled by the electron and hole concentrations (see Gerischer, 1990).

Surface states are a well-established feature of semiconductors, resulting from dangling bands or different bond structures at the surface. A large number of surface states in a narrow energy range can be detected by means of capacitance measurements. They can act as a bridge for electron transfer and accelerate the rate enormously.

4.3 Photoeffects at Semiconductor Electrodes

Light of energy greater than the band gap ($h\nu > E_g$) creates electron–hole pairs, the majority of which are separated into individual electrons and holes by the space-charge field. For *n*-type semiconductors the holes may reach the electrode surface at a potential equivalent to the valence-band edge and there oxidize a solution-phase species. Photo-oxidation processes are promoted by irradiation of an *n*-type semiconductor electrode. For a *p*-type semiconductor electrode, the electric field is of opposite sign in the space-charge region, and the electrons produced by irradiation migrate toward the surface, while the holes migrate toward the bulk. At the surface, the electron can cause a photoassisted reduction of species in the solution phase.

The generation of photocurrents and photovoltages at semiconductor–solution interfaces has facilitated the development of three types of photoelectrochemical cells (Bard and Faulkner, 1980). These are photovoltaic, photoelectrosynthetic, and photocatalytic cells. In photovoltaic cells the photovoltaic effect is used to generate electric power as in solid-state photovoltaic cells. The reaction at the counterelectrode is simply the reverse of the photoassisted reaction at the semiconductor electrode. Corrosion problems and limited efficiency restrict the applicability of these cells. In photoelectrosynthetic cells the reaction at the counterelectrode differs from that at the semiconductor. In a typical cell with an *n*-type semiconductor, H_2O can be oxidized; or CO_2 can be reduced with a *p*-type semiconductor. In the first reaction, O_2 evolution takes place at the semiconductor electrode and H_2 evolves at the counterelectrode. The energy is stored in the form of H_2. The report by Fujishima and Honda (1972) on the limited photoelectrolysis of water with *n*-type TiO_2 attracted much attention. The photoreduction of H_2O can be performed with *p*-type semiconductors.

The semiconductors suitable for producing these reactions are poor electrocatalysts. Even so, these systems have a strong competition from the combination of solid-state photovoltaic cells with conventional electrochemical H_2 generation by water electrolysis. Colloidal semiconductor particles are being studied for use in these cells (Bard, 1980; Grätzel, 1981). This research led to the discovery of a quantum size effect, a new phenomenon in small dimensions reported by Rosetti *et al.* (1984) and Fojtik *et al.* (1984). Photocatalytic cells are similar to the photoelectrosynthetic cells, except that the reaction usually proceeds slowly even in the dark and the light energy is used to overcome the energy of activation of the reaction. The efficiency of these cells is also very low.

In overall perspective, photoelectrochemical cells are not yet ready for practical applications because of low efficiency, limited operating life, and high costs.

5. TECHNIQUES FOR THE STUDY OF ELECTROCHEMICAL INTERFACES AND ELECTRODE PROCESSES

5.1 Electrochemical Techniques

Electrochemical techniques will be only briefly summarized. A good description of these techniques can be found in the text by Bard and Faulkner (1980). Electrochemical techniques form the basis of the broad field of electroanalytical chemistry. Most of the methods involve the perturbation of the electrode system from its equilibrium state and the measurement of the steady-state or nonsteady-state response. The perturbation methods include

1. displacement of the electrode potential from the reversible value,
2. passage of a net current or charge,
3. changes in the concentrations of species involved in the electrode reaction, and
4. pressure, temperature, and area changes.

Upon perturbation, the potential, current, or impedance of the electrode systems is controlled. The transport of the reacting species from the bulk of the solution to the electrode surface is well defined and easy to treat quantitatively for the rotating-disk electrode (Levich, 1962; Pleskov and Filinovskii, 1976).

A common characteristic of most electrochemical techniques is high sensitivity. One percent of a monolayer can be easily determined, linear sweep rates of 10^6 V/s can be used with ultramicroelectrodes, and the modulation of the potential can extend into the megahertz range. Very high pressures and low temperatures have been used with electrochemical cells. Rate constants have been examined on a submicrosecond time scale directly and even on a nanosecond time scale with redox catalyst techniques (Andrieux *et al.*, 1990).

5.2 *In Situ* and *Ex Situ* Spectroscopic and Surface-Physics Techniques

Although very sensitive, electrochemical techniques often are not sufficient to determine the mechanisms of electrode reactions and the properties of the electrode–solution interface. These techniques lack the molecular-level specificity to identify adsorbed intermediates and products of the reaction. In order to overcome this problem, a large effort is being made to combine various spectroscopic techniques, capable of providing molecular-level information, with electrochemical ones. While optical spectroscopic techniques (e.g., uv–visible, infrared, Raman) have been used to examine various species adsorbed on single-crystal electrode surfaces in electrolytes (i.e., *in situ*), this is not true of many of the surface-sensitive electron physics techniques which require a vacuum environment, e.g., x-ray photoelectron spectroscopy, Auger electron spectroscopy, or low-energy electron diffraction (LEED). Special transfer systems have been developed to facilitate the transfer of single-crystal electrode surfaces between the electrochemical and UHV environments, but surface changes can occur even with the noble metals. This makes the *ex situ* approach less attractive. Some examples of both approaches are discussed below.

5.2.1 uv–Visible Reflectance Spectroscopy and Ellipsometry. Studies of electrode surfaces with reflectance spectroscopy involve the measurements of the intensity of light reflected from the electrode surface as a function of the wavelength. There are several variations of this technique, such as the wavelength dependence of the electroreflectance coefficient $R^{-1}(dR/dE)$, differential reflectance studies of surface plasmon excitation, and Fourier-transform infrared reflectance. Several properties of the electrode–electrolyte interface, not accessible by standard electrochemical techniques, can be probed by reflectance techniques. These include the electronic properties of metal surfaces and adsorption-induced changes; structural and electronic properties of adsorbates and thin oxide films; surface states on metal electrodes; and surface reconstruction. See, e.g., the reviews by McIntyre (1973) and Kolb (1988). The use of single-crystal electrodes has given considerable impetus to some of these studies.

The reflectivity of a metal–electrolyte interface depends on the electrode potential, even in the absence of charge-transfer or partial-charge-transfer reactions. This change of reflectance with potential, $R^{-1}(dR/dE)$, is referred to as the electroreflectance. Changes in electrode potential change the electron density extending into the interface. This transition region acts like an optical adlayer of thickness small compared to the wavelength, and its optical properties are functions of the surface charge which in turn depends on the electrode potential. The technique is surface sensitive and suitable for studying the electronic properties of metal surfaces. Figure 15 shows the normal-incidence electroreflectance spectra of Au(100) for various bias potentials. The potential dependence of the spectra has been interpreted in terms of the optical transition from an occupied bulk state into an empty surface state. The transition energy increases as the potential is changed in the positive direction.

Reflectance studies of adsorbed layer usually consider the interface to be composed of three regions: the bulk electrolyte, the interfacial region, and the bulk electrode. Quantitative treatments involve the calculation of the relative change of reflectance,

$$\Delta R/R=[R-R(0)]/R(0), \tag{48}$$

where $R(0)$ and R are the reflectances of the bare and adsorbate-covered surfaces. In a three-region model, $\Delta R/R$ for *s*-polarized light is given by

$$(\Delta R/R)_{\perp}=\frac{8\pi d(\epsilon_1)^{1/2}\cos\phi_1}{\lambda}\,Im\left(\frac{\epsilon_2-\epsilon_3}{\epsilon_1-\epsilon_3}\right), \tag{49}$$

where ϵ_1, ϵ_2, and ϵ_e are the dielectric constants of the bulk solution, adsorbed layer, and electrode substrate, respectively; d is the effective thickness of the layer; λ is the vacuum wavelength; and ϕ_1 is the angle of incidence. The significance of ϵ_2 and d for a monolayer or submonolayer is open to question and Eq. (49) is only qualitatively significant when applied to such layers.

Typical systems studied by reflectance spectroscopy include metal monolayers obtained by UPD, oxygen adsorption and oxide formation, halide adsorption on metals, hydrogen adsorption on platinum, and the adsorption of transition-metal complexes and dyes on metals, graphite, and semiconductors (McIntyre, 1973; Kolb, 1988).

A related technique involves the transmission of light through an electrochemical cell with optically transparent electrodes (electronically conducting SnO_2 or thin layers of Au or Pt on quartz or minigrids) and mea-

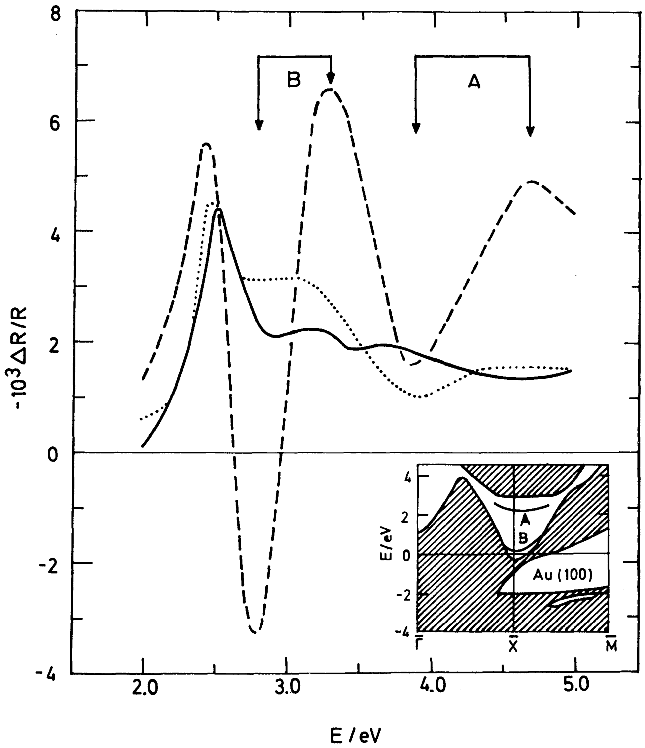

FIG. 15. Normal-incidence ER spectra of reconstructed Au(100)-(5×20) (solid), Au(100)-(1×1) (dashed), and Au(111) (dotted) in 0.01*M* $HClO_4$ caused by potential change from −0.2 to +0.3 V vs standard calomel reference electrode. surements of the absorbance changes resulting from species produced or consumed at the electrode.

Ellipsometry and ellipsometric spectroscopy have been used to investigate the same or similar systems as reflectance spectroscopy. This work has been reviewed by Muller (1973) and Gottesfeld (1989). Reflection of linearly polarized light from a surface produces elliptically polarized light because of different amplitude reduction of the parallel and perpendicular optical components and phase retardation. The difference in phase angle defines one ellipsometric parameter, Δ, and the ratio of the amplitudes of parallel and perpendicular components of the electric field defines $\tan\psi$, the second parameter. From the changes in Δ and ψ upon reflectance, the two optical constants of a film between two bulk phases can be determined if the film thickness is known. Often the film thickness as well as the two optical constants (the real and imaginary components of the refractive index of the film) need to be determined. This problem has been solved with the automatic ellipsometer developed by Cahan and Spanier (1969), which measures the three parameters Δ, ψ, and $\Delta R/R$. Ellipsometry is widely used to study film growth on electrode surfaces. Its sensitivity to a small fraction of a monolayer makes it attractive for such studies even though the quantitative interpretation of optical data for submonolayers is a problem. Automatic instruments can be used for spectroscopic measurements, i.e., the dependence of the optical constants on wavelength (Wheeler *et al.,* 1978).

5.2.2 Infrared Reflectance Spectroscopy and Raman Scattering from Electrode Surfaces. Vibrational properties of species adsorbed at the electrode–aqueous-solution interface can be obtained by infrared reflectance spectroscopy. This was shown by Bewick (1983), who reduced the light path through the aqueous solution to approximately 1 μm by moving the reflecting electron surface close to the infrared-transparent window. Modulation of the electrode potential was necessary with a dispersive infrared spectrometer in order to achieve sufficient sensitivity. This technique is known as electrochemically modulated infrared spectroscopy (EMIRS). The use of potential-modulation techniques is difficult with Fourier-transform techniques because of the overlaps of the band pass of the

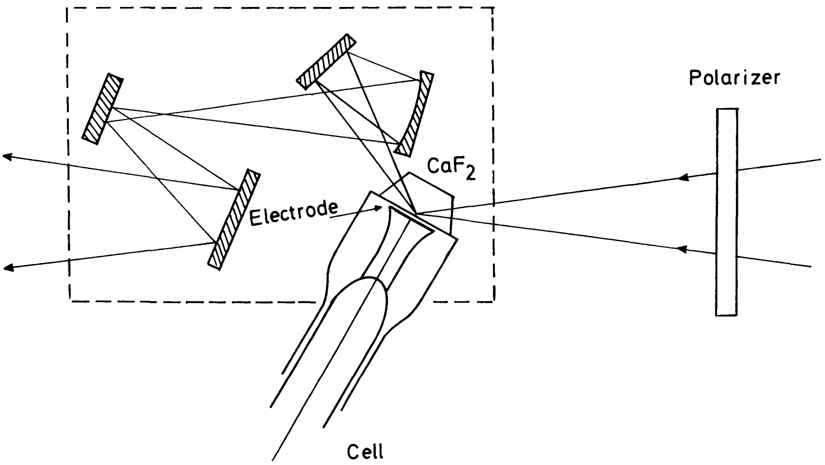

FIG. 16. Schematic diagram of ir spectroelectrochemical cell [reproduced from Kunimatsu *et al.* (1985) with permission of The American Chemical Society].

frequencies needed for the potential modulation and the interferometer. With Fourier-transform infrared (FTIR) spectroscopy, the signal-to-noise ratio is satisfactory even without such potential modulation(Bewick and Pons, 1985). One type of ir spectroelectrochemical cell using external reflectance is shown in Fig. 16. In order to eliminate the unwanted water bands from the ir spectrum, two series of interferograms at two different potentials are normalized relative to each other. This is the SNIFTIRS (subtractively normalized Fourier-transform infrared spectroscopy) technique, which has proved useful for the detection of the species generated or adsorbed on electrode surfaces.

These infrared techniques show great promise for obtaining information on a molecular level about species adsorbed at the electrode–electrolyte interface as well as in the thin electrolyte layer, and are helpful in establishing pathways for various electrode processes. Typical applications include studies of intermediates and products in the oxidation of organic molecules such as methanol, formic acid, and glucose; the reduction of CO_2; and the adsorption of CO, hydrogen, and anions. The identification of adsorbed intermediates and products has been reported in several instances. The interaction of adsorbates with the electrode surface and the potential dependence have been followed. Figure 17 gives the FTIR spectra obtained for the reduction of CO_2 on single-crystal platinum surfaces. The negative band for solution-phase CO_2 results from the consumption of this species in the thin layer of solution during its reduction to CO. The bands for bridge-bonded and linearly bonded CO are seen, i.e.,

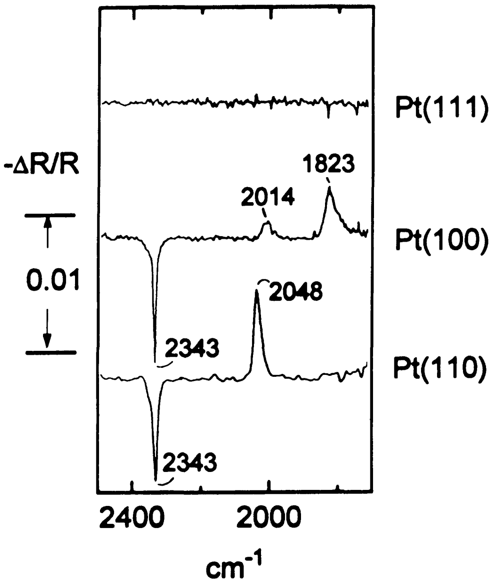

FIG. 17. Potential-difference FTIR spectra for CO_2 reduction at Pt single-crystal electrodes in CO_2-saturated 0.1 *M* $HClO_4$. No reduction occurs on Pt(111); bridge-bonded and linearly bonded CO are reduction products on Pt (100) while linearly bonded CO predominates on Pt(110) [reproduced from Nikolic *et al.* (1990) with permission of Elsevier Sequoia Press].

CO is the product of the CO_2 reduction in the hydrogen adsorption region on Pt(100) and Pt(110). The Pt(111) surface is inactive for CO_2 reduction (Nikolic *et al.* 1990).

The Raman signals from adsorbed species at monolayer levels on most substrates are ordinarily very low, in fact too low for Raman scattering to be very useful in routine studies of adsorbed species. Amazingly large Raman scattering, however, was obtained by Fleischmann *et al.* (1973), and subsequently recognized as a tremendous enhancement of the Raman signals for adsorbates on silver, copper, and gold by Jeanmaire and VanDuyne (1975). This effect is known as surface-enhanced Raman scattering (SERS) and requires that the metal have very high conductivity at the optical frequency of the laser beam used to produce the Raman scattering. With gold and copper this means that the enhancement is large only at laser frequencies in the red below that of the interband transition responsible for their color. A second requirement is that the surface have a certain amount of roughness. Under optimum conditions, the enhancement can be by 10^6-fold on silver.

During the 1970s and early 1980s SERS attracted the attention of a large number of workers from various fields. This work has been reviewed by Fleischmann and Hill (1982) and by Chang and Laube (1984). There is not yet a consensus on the theory of the SERS effect. In general, roughened surfaces are used, but in some cases intentional roughening of the silver single-crystal surfaces is not necessary to achieve very substantial enhancement. Figure 18 shows the SERS spectra of Fe(III)-tetrasulfonated phthalocyanines (FeTsPc) adsorbed on the single-crystal silver electrode surfaces. These spectra have similarity with the solution-phase spectra, indicating that there is no change in the symmetry of the molecule upon adsorption and that the planes of the TsPc ligands are not oriented parallel to the surface (Adžić *et al.*, 1984). This information is of considerable help in understanding how the adsorbed FeTsPc functions as a four-electron O_2-reduction electrocatalyst.

5.2.3 EXAFS and Surface X-Ray Diffraction.

EXAFS, or extended x-ray absorption fine-structure, spectroscopy yields information concerning the radial distribution func-

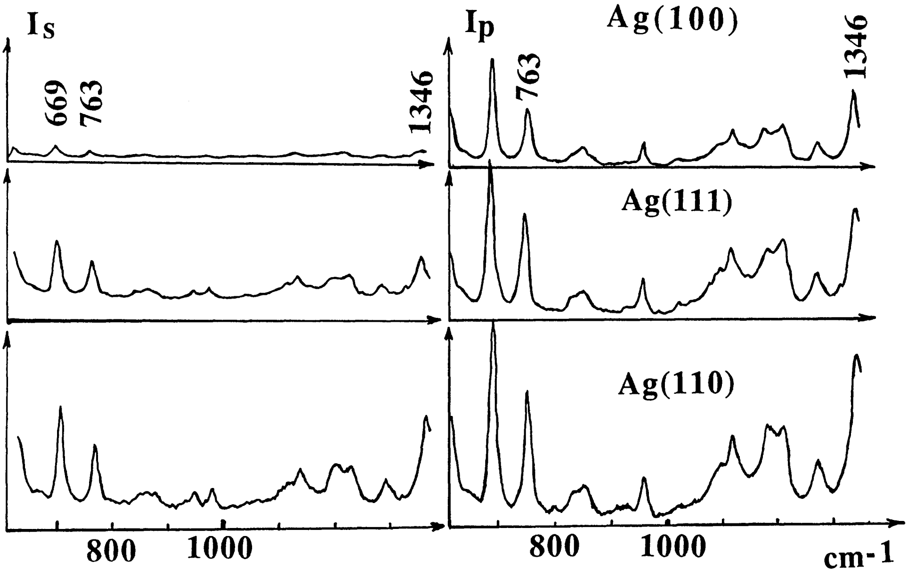

FIG. 18. Resonant surface-enhanced Raman spectra obtained from Fe-TsPc adsorbed on silver single-crystal interfaces. Electrolyte 0.1*M* $HClO_4+H_2O$ saturated with argon gases at $T=20\,°C$. tion for neighboring atoms; i.e., the number and types of neighboring atoms and the corresponding interatomic distances can be determined. In some instances the oxidation state can also be obtained. This information is obtained by analyzing the oscillatory fine structure in the x-ray absorption spectra.

The x-ray absorption can be obtained directly from the measurement of absorption, but it can also be obtained from the fluorescence radiation or electron yield. *In situ* applications in electrochemical systems are possible since the aqueous solutions are relatively transparent to the "hard" x rays. Generally, thin layer cells are used. Synchrotron radiation is preferred to conventional x-ray sources because of the much higher intensities obtained with the former. In electrochemical experiments, EXAFS permits the changes in bond length and coordination number with change in oxidation state to be examined *in situ*. A variety of electrochemical systems has been studied. These include dispersed electrocatalysts, polymeric films on electrodes, ions in solution, ion-exchange polymers, passivation and oxide films on metals, battery oxides, and UPD layers on gold and silver (see the review by Sharpe *et al.*, 1990).

Surface x-ray scattering, using synchrotron radiation, has been recently applied for *in situ* determination of structures of the electrochemical interface. This technique provides a direct determination of the position of atoms at the electrode surface and shows a considerable potential for improving our knowledge of electrochemical interfaces. Surface reconstruction phenomena and structures of UPD metal monolayers have been reported (Toney and Melroy, 1991; Ocko *et al.*, 1990).

5.2.4 Photoemission of Electrons from a Metal into Solution. Photoelectronic emission from metals into solutions can also provide information on the structure of the electrode–electrolyte interface. Photoemission of electrons occurs upon illumination of a metal electrode with light whose energy exceeds the work function of the metal–solution interface (Barker *et al.*, 1965). After injection of the electrons into the liquid phase, the subsequent interactions lead to the thermalization and solvation of the electron. This is followed by reaction with electron acceptors at distances of the order of 1–10 nm from the electrode. Suitable scavengers include H^+, CO_2, O_2, N_2O, NO_3^-, etc. Cathodic polarization of the interface decreases the work function and consequently increases the photoemission. Brodsky *et al.* (1974) gave the following equation for the total photoemission current for dilute solutions when the de Broglie wavelength of the electron is less than the thickness of the diffuse part of the double layer:

$$I=A[h\nu-h\nu_0-e(E-\phi_2)]^{5/2}, \tag{50}$$

where A is a constant, $h\nu$ is the light quantum energy, $h\nu_0$ is the work function of the metal–solution interface at the potential $E=0$ versus the reference electrode, and ϕ_2 is the potential of the outer Helmholtz plane. This equation, referred to as the "$\frac{5}{2}$-power law," has been found to be followed experimentally for a series of metals. At the PZC, $\phi_2=0$ and the photocurrent–potential curves for solutions of different concentrations should intersect. This method of determination of the PZC yields results in good agreement with PZC data obtained from the differential-capacitance minima within a possible error of 0.02–0.03 V (Frumkin *et al.*, 1980).

5.2.5 Scanning Tunneling Microscopy. Scanning tunneling microscopy (STM), developed by Binnig *et al.* (1982), is operative not only in vacuum but also with the samples in air or covered with electrolytes. A sharp probe of a metal such as W or Pt is scanned parallel to the surface using the electron tunneling current to establish the surface profile with atomic-level or near–atomic-level resolution. Since the electrolytic solutions are not electronic conductors, electron tunneling can occur between the tip and electrode surface that is being examined. Images with close to atomic resolution have been reported for single-crystal Au surfaces and also for the initial stages of metal deposition on metals and graphite. This work has been reviewed by Sonnenfeld *et al.* (1990). Atomic-resolution images have been reported for Au(100) and the UPD of Cu on Au(100) by Magnussen *et al.* (1990). Ordered structures of Cu adatoms have been found and the structure-determining role of the coadsorbed anions has been discussed. Figure 19 shows the ordered structure of a Cu adlayer on Au(100).

Manne *et al.* (1991) have used the atomic force microscope (AFM) to image a UPD layer of Cu at Au(111) with atomic resolution. The AFM relies on the intrinsic forces be-

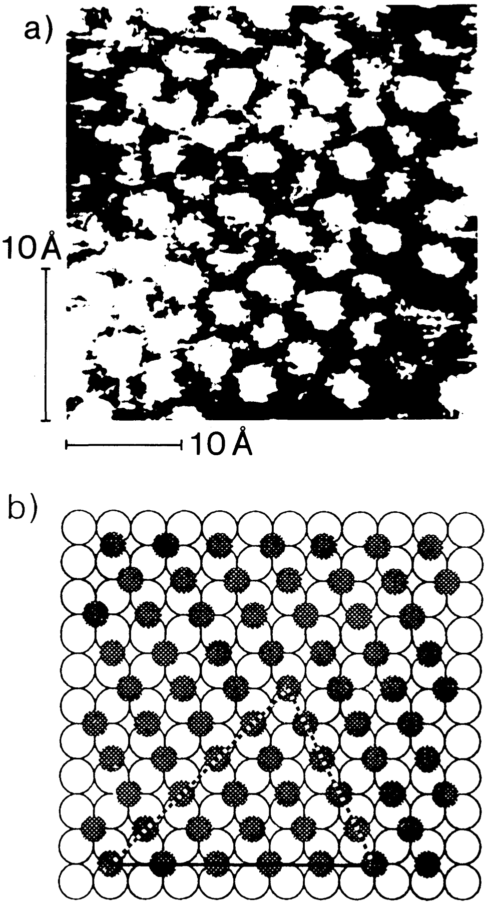

FIG. 19. (a) STM image of ordered structure of a Cu adlayer on Au(100) in 0.05*M* H_2SO_4+5 m*M* $CuSO_4$. (b) Model of the adlayer structure. Filled circles, Cu adatoms; solid line, well-aligned along [110]; dashed lines, less-ordered adlayer lattice directions [reproduced from Magnussen *et al.* (1990) with permission of The American Physical Society].

tween the tip and the surface to cause the tip to be displaced as it is scanned parallel to the surface. The displacements perpendicular to the surface are then sensed with an optical lever (see Binnig *et al.*, 1986). These results confirmed the STM data and established that the Cu atoms are in a close-packed lattice with a spacing of 0.29±0.02 nm in perchloric acid but 0.49±0.02 nm in a sulfate electrolyte.

5.3 *Ex Situ* Studies by Surface-Physics Techniques

Techniques that require vacuum or ultrahigh vacuum (UHV) cannot be applied directly to electrode–liquid-solution interfaces. In order to make use of several UHV techniques for the characterization of electrode surfaces, Hubbard *et al.* (1988), Yeager *et al.* (1978), and Ross (1979) designed systems for the transfer of the electrode from the electrolyte environment into a UHV chamber and vice vera. These systems have been designed to minimize restructuring and contamination of the single-crystal surfaces during transfer. The UHV techniques used most often by electrochemists include Auger electron spectroscopy (AES), low-energy electron diffraction (LEED), x-ray photoelectron spectroscopy (XPS), and electron energy-loss spectroscopy (EELS).

In the transfer system developed at Case Western Reserve University (Yeager *et al.*, 1978), the electrode is cleaned and annealed in a UHV chamber, characterized with AES-LEED-XPS, transferred into a second chamber, and made part of a thin-layer electrochemical cell. Following the electrochemical measurements, the electrode is transferred back into the vacuum chamber for reexamination with UHV techniques.

There is, however, always a question of the relevance of measurements in which the electrode surface is in high vacuum to those in the electrochemical environment (see Sec. 5.2). The importance of knowing the crystallographic orientation of the surface from LEED measurements before and after the electrochemical measurements is not questioned, but restructuring of the surface is possible during the transfers. This type of measurement has helped to establish the voltammetric profiles of well-ordered single-crystal surfaces for various adsorption reactions. LEED measurements in UHV have been used to confirm the validity of various methods of surface preparation. One such method is the annealing of noble-metal crystals in a hydrogen–air flame followed by quenching of the crystal in ultrapure water (Clavilier *et al.*, 1981). An improvement in this method is the cooling of the hot crystal in H_2 gas before contact with the ultrapure water (Markovic *et al.*, 1986). These methods apparently give well-ordered platinum and gold single-crystal surfaces. Zurawski *et al.* (1987) have suggested the adsorption of CO to protect the Pt surfaces from other impurities during the transfer from the ultrahigh-vacuum environment into the electrolytic solutions. The CO is easily removed from the surface by oxidative desorption.

This approach has been used for the study of hydrogen adsorption on the low-index planes of Pt (Sec. 3.2), UPD of several metals on Pt and Au, and the oxidation of a large number of organic molecules. Ordered layers were found with LEED-AES techniques for the UPD of Ag, Cu, and Pb on iodine-pretreated Pt(*hkl*) (Stickney *et al.,* 1986), Pb on Ag(*hkl*) (Hanson and Yeager, 1988), and Cu on Pt(111) (Aberdam *et al.,* 1985). Using EELS, Hubbard *et al.* (1988) have identified products and fragments of the oxidation of a large number of organic molecules on Pt(*hkl*).

Bange *et al.* (1987) have recently studied Br adsorption on Ag(110) by progressively replacing a monolayer of H_2O by Br. This approach allows a direct comparison of the potential drop in the double layer at the metal–electrolyte and the metal–vacuum interfaces.

6. APPLIED ELECTROCHEMISTRY

6.1 Batteries

Batteries are electrochemical devices for energy storage in the form of chemical energy. The main feature of the electrochemical energy conversion is its high efficiency, which explains the widespread use of batteries and continuing interest in fuel cells. A variety of electrochemical systems are used in a large number of primary and secondary (rechargeable) batteries. These include the commonly used lead–acid, nickel–cadmium, silver–zinc, nickel–iron, nickel–zinc secondary and the manganese dioxide–zinc, air–zinc and lithium primary batteries. Various metal–air systems are being considered as future electrochemical storage devices. During the last ten years primary lithium batteries, with aprotic nonaqueous solvents, have become widely used principally because of their high energy per unit weight, their high cell voltage (3.0 V), and their long life. A large effort is under way in the U.S. to improve the performance of several existing batteries and to develop new storage batteries for use in electric cars. A good survey of the battery systems is available in the book edited by Bockris (1981).

6.2 Fuel Cells

Fuel cells are unique devices that convert chemical energy of fuels (H_2, methanol, hydrocarbons) directly into electric energy. The fuel is fed continuously to the anode, while the oxidant, usually oxygen from the air, reacts at the cathode. The practical conversion efficiency can be very high because they are not limited by Carnot-cycle efficiency. This makes fuel cells very attractive energy conversion devices.

Five types of fuel cells are under development:

1. *Phosphoric acid* fuel cells with concentrated phosphoric acid as the electrolyte and operating with H_2 and air at a temperature of ~200 °C. The H_2 is usually obtained from reformer operating on a hydrocarbon such as natural gas.
2. *Solid proton-exchange membrane* fuel cell with a solid ionic conducting polymer as the electrolyte and operating on very pure H_2 and air at a temperature of 80–100 °C. The H_2 can be prepared from a hydrocarbon using a reformer, but the residual carbon monoxide must be almost completely removed. Efforts are in progress to develop new ionic-conducting polymer electrolytes that will permit this fuel cell to operate at much higher temperatures (> 150 °C).
3. *Alkaline electrolyte fuel cells* using a concentrated alkali-metal hydroxide as the electrolyte and operating at ~200 °C on H_2 and O_2 all of which must be free of CO_2. The principal application for the cell has been the Apollo space mission and other manned space missions.
4. *Molten carbonate fuel cells* using molten alkali-metal carbonates as the electrolyte at ~650 °C and operating on H_2 and air. The anode can be modified to permit direct operation of the cells on natural gas and other hydrocarbons.
5. *Solid oxide fuel cells* with solid ionic conducting oxides as electrolytes at temperatures of ~1000 °C and operating on hydrocarbons or other fuels and air.

The phosphoric acid cells are in an advanced state of development for electric utility applications but suffer from relatively low overall system conversion efficiency, principally because of the large overpotential of the air-consuming cathodes due to the inadequacy of the electrocatalysts. Phosphoric acid fuel-cell plants of several tens of megawatts have been built.

6.3 Large-Scale Industrial Processes

The electrochemical production of chlorine and sodium hydroxide is the largest tonnage production of any single process in the chemical industry. Most of the technologically important metals, except iron, are either obtained or refined electrochemically. Aqueous solutions are used in many cases, but aluminum, magnesium, titanium, zinc, and alkali and alkaline-earth metals are obtained from molten salts. The electrochemical production of aluminum metal alone involves $\sim 5\%$ of the total electric generating capacity of the United States. The operating cell voltages of most of these processes greatly exceed the thermodynamic cell potentials, and the redesign of many of these cells could save considerable electricity.

6.4 Inorganic and Organic Electrosynthesis

Hydrogen and a whole range of oxo compounds, such as chlorate, perchlorate, hypochlorite, hydrogen peroxide, perborate, etc., are produced electrochemically. Some industrially important organic compounds and pharmaceuticals are produced by organic electrosynthesis. Electrochemical processes have usually been developed in the cases where a standard organic synthesis was unavailable or required several steps, or the electrochemical process was more attractive from the energy or ecology points of view. The dimerization of acrylonitrile to adiponitrile which is used in nylon manufacture is the largest volume electro-organic process. Many electro-organic processes require the use of organic solvents, and this results in relatively poor conductivity of the electrolytic solutions. Furthermore, solubility and mass transport may limit the current densities to relatively low values. New types of electrochemical cells have been designed in order to optimize performance under these rather adverse conditions.

A particularly promising area for the use of electrochemical synthesis or organic molecules is in the pharmaceutical industry when the relatively high cost associated with electrosynthesis may be small compared to other costs, where there is a special premium on selectivity and yield, and where the total amounts of the final products are also relatively small.

6.5 Electroplating

Protective and decorative coatings of metals and alloys are obtained by an electrodeposition process called electroplating. Not only metal objects, but also nonconductors such as plastics, glass, ceramics, etc., can be electroplated. This is accomplished by first depositing a thin metal layer by a chemical reduction (electrodeless) technique and then building up the metal deposit by conventional electroplating. The corrosion resistance of electroplated objects is usually considerably enhanced. Electroplating processes play a major role in the electronics industry in the manufacture of circuit boards, plating of gold contacts, and memory devices.

6.6 Electrochemical Sensors

Electrochemical cells are basic to many sensor devices which can monitor concentrations of various species in the environment and in living organisms. From an electrochemical point of view they can be classified as potentiometric, amperometric, and conductometric. The size of the electrode depends on the sensor application. Miniaturization of various sensors takes advantage of integrated-circuit technology. Such sensors are under development for such applications as the monitoring of blood gases and ionic constituents including pH, O_2, and CO_2. The application of sensors span such diverse fields as industrial chemical processes and electrophysiology.

6.7 Corrosion and Corrosion Protection

Most corrosion processes involve electrochemical reactions. Most of the metals used for construction would be far too unstable in contact with water or moist air if it were not that they are covered by an oxide layer which blocks the corrosion. The formation and structure of this passivation layer have been intensely studied by electrochemists using the *in situ* optical and other surface techniques described earlier in this review. Even so, they are only partially understood.

Electrochemical techniques are used to suppress corrosion. The most common illustration is the cathodic protection of steel structures such as bridges, pipe lines, and ship hulls. This involves maintaining the potential of the steel structure at a negative value where the corrosion no longer occurs, using a second electrode as the anode. Another approach is electrogalvanization, which involves the electrodeposition of a layer of zinc on the steel surface. Zinc is a more active metal than iron or steel and it dissolves, while maintaining a potential at which the steel is cathodically protected. Electrogalvanization has greatly suppressed corrosion in the automobile. Even with these various ways to suppress corrosion, 10% to 15% of the ferrous metals produced annually in the U.S. are destroyed by corrosion.

7. CHALLENGING PROBLEMS FOR THE FUTURE

Electrochemistry today enters into various fields that were heretofore outside the traditional electrochemical science. For example, electrochemical mechanisms are operative in many biological processes from blood clotting to the transfer of nerve impulses, and the field of bioelectrochemistry is developing rapidly. Interfacial electrochemistry is expanding rapidly as a part of surface science as a whole. Much of this rapid growth is the result of the development of *in situ* optical and other techniques for the study of electrochemical interfaces.

Two particularly challenging areas of electrochemistry are the Fleischmann–Pons phenomenon and the electrochemistry of superconductor–electrolyte interfaces. Fleischmann *et al.* (1989) have reported evidence for nuclear fusion of deuterium electrochemically injected into palladium at room temperature. This evidence includes the apparent generation of tritium, excess heat in calorimetric measurements, and the generation of neutrons. The palladium cathode is known to be able to take up to at least one deuterium per Pd atom. Whether a nuclear reaction can occur when deuterium is electrochemically injected in Pd remains a matter of great controversy. Further work with well-characterized systems should provide the answer to this question of paramount importance.

High-temperature superconductors offer promise for great advances in various technologies. Electrochemical characterization of superconductor–liquid-electrolyte-solution and superconductor–solid-electrolyte interfaces and electrochemical synthesis of superconducting compounds will be of great electrochemical interest in the future.

8. CHALLENGING OPPORTUNITIES IN ELECTROCHEMISTRY

Some of the challenging fundamental and technological problems in electrochemistry are the following:

Fundamental Problems

1. More definitive and comprehensive models for electrochemical interfaces, taking into account the discrete structure of the electrode surface and the electronic properties as well as the structure of the compact and diffuse ionic layers.
2. Techniques capable of identifying short-lived intermediates in electrochemical reactions, both in solution and adsorbed on the electrode surface.
3. The development of a quantitative understanding of surface-enhanced Raman scattering, including the selection rules and the relation of the enhancement to the surface properties of the electrode.
4. The refining of scanning tunneling microscopy so as to achieve routinely atomic-level resolution in *in situ* studies (particularly improved methods for preparing scanning tips).
5. Studies of the electrochemical properties of superconductor–electrolytic-solution interfaces and particularly quantum-mechanical phenomena that will result in unusual electrochemical effects (e.g., barrierless electron-exchange processes, unusual double-layer properties, prevention of any penetration of the electric field into the electrode phase).

Technological Problems

1. Fuel cells suitable for terrestrial applications, such as for vehicle propulsion and not only for space missions; problem areas

include
-more active catalysts for O_2 reduction and for the oxidation of practical fuels (e.g., hydrocarbons, alcohols),
-new polymer electrolytes suitable for use in fuel cells at much higher temperatures than presently possible.

2. New and improved rechargeable batteries for vehicle propulsion such as
-lithium–polymer-electrolyte systems,
-metal–air cells (e.g., Zn–air).

3. Photoelectrochemical systems affording high conversion efficiency at reasonable costs and with long lives.

4. Implantable microsensors for biomedical applications:
-blood gases—CO_2, O_2;
-*p*H and the concentrations of other ionic constituents (e.g., KI^+, Na^+, Ca^{2+});
-glucose (diabetes);
-neurotransmitters (dopamine).

5. New surface treatments of steel affording more effective inhibition of corrosion; for example,
-surface alloys,
-amorphous surface structures,
-coatings or deposits.

6. Definitive studies to establish whether any nuclear phenomena are involved during the electrochemical charging of palladium with deuterium, as has been reported by Fleischmann *et al.* (1989); i.e., the production of excess heat, neutrons, γ radiation, and tritium. The claim by these researchers that a nuclear fusion reaction is involved has produced much controversy among electrochemists and also between electrochemists and nuclear physicists. Some of the observations of Fleischmann *et al.* (1989) have also been reported by some other electrochemists including the authors of this article (Adžić *et al.*, 1990) but it is far from clear whether the effects are the result of nuclear fusion or some other nuclear process.

INTRODUCTION

Electromagnetism is ultimately at the heart of almost everything we are and do. Indeed, our world and the worlds of other animate and inanimate objects function almost exclusively on electromagnetic interactions. Atoms, the basic building blocks, are bound in their unique structures by electric forces (with dynamics subject to the laws of quantum mechanics). The admittedly nonelectromagnetic energy source, the Sun, transmits its energy to us by electromagnetic radiation.

Copyright © WILEY-VCH Verlag GmbH & Co KGaA. All rights reserved.

That radiation is converted by photosynthesis into other forms of energy, stored electromagnetic energy inside complex molecules. More immediately, the process of reading this page occurs through the scattering of light to the reader's eye, where it is absorbed and converted to electrical signals sent to the brain. We human beings and the plants and rocks around us are basically electromagnetic devices, interacting and communicating by means (whether chemical or physical) that are fundamentally electric in nature. Our societies are increasingly governed overtly by electricity and electronics.

The history of the development of our understanding of electricity and magnetism and of light and other electromagnetic radiation is a fascinating subject in itself. Here only the briefest account, with many omissions, can be given. The reader wishing to read a full and authoritative history should consult Whittaker (1951).

The properties of amber (ηλεκτρον, Greek) and lodestone were known in ancient times, but the creation of electrodynamics as a quantitative, mathematical subject occurred in about one hundred years (1766–1864). William Gilbert (1544–1603), in his book *De magnete,* published in 1600, clearly differentiated between electrical and magnetic phenomena. By 1733 the distinction had been made between resinous and vitreous electricity (surplus and deficiency of electrons, respectively). Forty years later, electrostatics was developed rapidly and quantitatively in about twenty years. Benjamin Franklin (1706–1790) made a crucial observation that was recognized by Joseph Priestley (1733–1804) as implying the inverse square law for electrical forces (1766). Henry Cavendish (1731–1810) conducted his remarkable experiments in electrostatics from 1771 to 1773. Charles Augustin Coulomb (1736–1806) began publishing his monumental researches in 1785.

These years marked the beginning of quantitative research in electricity and magnetism on a worldwide scale. Technical developments such as the invention of the battery in 1800 by Alessandro Volta (1745–1827) hastened progress in the study of electrical currents and their interactions. By 1820 Hans Christian Oersted (1777–1851) was observing the deflection of a compass needle by the current in a nearby wire, and André Marie Ampère (1775–1836) began publishing his results on the mechanical forces between current-carrying wires. By 1825 he had a mathematical description. In 1831 Michael Faraday (1791–1867) discovered his law of electromagnetic induction; in 1836 he used the famous Faraday cage to establish the law of conservation of electric charge. Faraday's many researches paved the way for the brilliant synthesis by James Clerk Maxwell (1831–1879), a dynamical theory of the electromagnetic field, published in 1864. Along the way, Karl Friedrich Gauss (1777–1855) and Simeon Denis Poisson (1781–1840) contributed importantly to the mathematical development, while practical concepts such as resistance were discovered (1827) by Georg Simon Ohm (1787–1854).

While Maxwell's paper of 1864 provided a complete classical description of electricity, magnetism, and light, its correctness and far-reaching applicability were not understood for some years. Not until 1888, when Heinrich Rudolf Hertz (1857–1894) gave a brilliant demonstration of the generation, transmission, polarization, reflection, and refraction of what we now know as radio waves, were the unity of light, Hertz's waves, and static electricity and magnetism fully appreciated. By the 1890s the basic principles of electromagnetism were thoroughly understood and ripe for the development of the myriad applications in the last hundred years.

This article is concerned with the fundamental principles of classical electrodynamics. Some derivations are sketched, but space limitations prevent lengthy proofs. Many results are just stated. References for details or elaboration are given in the text and also in the Further Reading section at the end. Applications are discussed elsewhere, under Electromagnetic Technology or Optics, for instance, as are more detailed treatments of special aspects, for example, ELECTROSTATICS, MAGNETOSTATICS, and ELECTROMAGNETIC RADIATION. The motion of charged particles under the action of external electric and magnetic fields is an important topic in its own right. The reader interested in these aspects should consult the articles on CHARGED-PARTICLE OPTICS; ACCELERATORS, LINEAR; CYCLOTRONS; SYNCHROTRONS; BETATRONS; PLASMA PHYSICS; INTENSE PARTICLE BEAMS; and FUSION, MAGNETIC CONFINEMENT.

The four laws that comprise the Maxwell equations are described physically and then mathematically in differential and integral form, with brief comments on the limitations imposed by the discreteness of physical charges and of quantum-mechanical modifications. The equations governing macroscopic fields inside material media, constitutive relations, and boundary conditions on fields at media interfaces precede a treatment of the frequency dependence of simple dielectric constants. The concept of causality is used to develop relations between the absorptive and dispersive parts of the dielectric constant (dispersion relations). The energies associated with electric and magnetic fields are exploited to define coefficients of capacitance and inductance, quantities useful in electric circuit analysis, and some examples of both are given. The scalar and vector potentials are introduced and their arbitrariness discussed (gauge transformations). Solutions of the wave equations in terms of the potentials are derived and the appropriateness of advanced and retarded solutions discussed. A general formula for radiation by a harmonically varying source is given. Poynting's theorem on the conservation of energy for fields and sources is derived, as is the conservation of momentum. The lumped-circuit concepts of impedance and admittance are discussed in terms of the fields by means of Poynting's theorem for harmonic fields. Because of its close connection to electrodynamics, the main ideas and results of special relativity are presented, along with a relativistic formulation of electrodynamics and a brief treatment of classical Lagrangian field theory.

1. UNITS, SYMBOLS, AND CONVENTIONS

The dimensions and units of quantities in electricity and magnetism are often viewed as contentious, with much heat and little light generated in polemics on the subject. The truth is that convenience of use is the only sensible criterion. Provided the schema is consistent, the choices of dimensions and units of magnitude of electromagnetic quantities are largely arbitrary, with no set more fundamental than any other. The interrelations among the various physical quantities through the laws of electrodynamics means, of course, that one does not have complete freedom of choice. The interested reader may consult the appendix of Jackson (1975) for a nonpartisan discussion. Traditionally (because mechanics preceded electromagnetism as a coherent subject), mass, length, and time are viewed as distinct in their dimensions. Systems of units differ in the amounts defined as unit magnitudes of each.

In this article the Système International (SI) of units is used, except when explicitly stated otherwise. In electromagnetism, the units of mass (the kilogram, abbreviated as kg), length (the meter, abbreviated as m), and time (the second, abbreviated as s) are augmented by a fourth, the unit of charge (the coulomb, abbreviated as C). The second is defined in terms of the frequency of a specific atomic transition, while the meter is defined as the distance light travels in vacuum in 1/299 792 458 seconds, or equivalently such that the speed of light in vacuum is $c = 299\,792\,458$ m/s. The electromagnetic parameters, the permittivity (ϵ_0) and the permeability (μ_0) of free space, are therefore both without experimental uncertainty. The permeability of free space is defined to be $\mu_0 = 4\pi \times 10^{-7}$ H/m, while the permittivity is $\epsilon_0 = 10^7/(4\pi c^2)$ F/m, where the henry (H) and the farad (F) are units of inductance and capacitance, respectively (see below). With the speed of light as a nine-digit number, $(4\pi\epsilon_0)^{-1} = 10^{-7}c^2$ is an exact 17-digit number (times a power of 10), the first six of which are $8.987\,55 \times 10^9$. To the same accuracy, $\epsilon_0 = 8.854\,19 \times 10^{-12}$ F/m. The quantity $\sqrt{\mu_0/\epsilon_0} = 376.730\ \Omega$ is called the impedance of free space. (See METROLOGY; ELECTROMAGNETIC QUANTITIES, MEASUREMENT OF BASIC.)

Harmonically varying quantities, or superpositions of them, play an important role in electromagnetism. Time-averaged entities such as power and energy are conveniently handled by means of complex numbers. The conventions are as follows.

Complex numbers:

$z = x + iy$, where $i = \sqrt{-1}$

$\mathrm{Re}(z) = x$, $\mathrm{Im}(z) = y$,

$z = \rho e^{i\theta}$, where $\rho = |z| = \sqrt{x^2 + y^2}$ and

$\theta = \tan^{-1} y/x$

$z^* = x - iy = \rho e^{-i\theta}$.

Harmonic quantities:

$$A(t)=A_0\cos(\omega t-\alpha)$$
$$=\mathrm{Re}(A_0e^{i\alpha-i\omega t})$$
$$\to A_0e^{i\alpha-i\omega t}.$$

Time averages:

$$\langle A(t)B(t)\rangle=\tfrac{1}{2}\mathrm{Re}[A(t)B^*(t)],$$

where $A(t)$ and $B(t)$ are understood to be complex amplitudes whose real parts correspond to the real harmonically varying physical quantities. It is often useful to discuss phenomena in either the time (space) or the frequency (wave-number) domain. An important tool is the Fourier integral, written here for time–frequency conversion, but easily adapted to space–wave-number domains in more than one dimension.

Fourier integrals:

$$A(\omega)=\frac{1}{\sqrt{2\pi}}\int_{-\infty}^{\infty}dt\,A(t)e^{i\omega t}, \tag{1}$$

$$A(t)=\frac{1}{\sqrt{2\pi}}\int_{-\infty}^{\infty}d\omega\,A(\omega)e^{-i\omega t}.$$

If $A(t)$ is real, then $A(-\omega)=A^*(\omega)$. Subject to appropriate existence and convergence properties, the following relation holds between $A(t)$ and $A(\omega)$:

$$\int_{-\infty}^{\infty}|A(\omega)|^2d\omega=\int_{-\infty}^{\infty}|A(t)|^2\,dt. \tag{2}$$

If $A(t)$ is real, the frequency integral can be written as an integral over only positive frequencies of $2|A(\omega)|^2$.

2. THE MAXWELL EQUATIONS IN VACUUM IN DIFFERENTIAL AND INTEGRAL FORM

The basic equations governing electromagnetic phenomena are the Maxwell equations, supplemented by constitutive relations describing the responses of material media. We first summarize the Maxwell equations in vacuum in terms of the electric and magnetic fields, $\mathbf{E}(\mathbf{r},t)$ and $\mathbf{B}(\mathbf{r},t)$, and electric charge and current densities, $\rho(\mathbf{r},t)$ and $\mathbf{J}(\mathbf{r},t)$.

2.1 Coulomb's Law

The first of the Maxwell equations stems from the 18th-century observations of Cavendish, Coulomb, Franklin, and others on the forces between electrically charged objects. The conclusion that the force between small charged bodies ("point charges") varies as the product of the charges, inversely as the square of the distance between them, and along the line joining them is expressed mathematically by the divergence equation,

$$\nabla\cdot\mathbf{E}=\rho/\epsilon_0, \tag{3}$$

where $\mathbf{E}(\mathbf{r},t)$ is the electric field strength, defined as the force per unit charge, with units of volts per meter (V/m), while $\rho(\mathbf{r},t)$ is the electric charge density in units of coulombs per cubic meter (C/m^3). By means of the divergence theorem of vector calculus, Eq. (3) can be cast into integral form,

$$\int_S \mathbf{n}\cdot\mathbf{E}\,da=\frac{1}{\epsilon_0}\int_V \rho\,d^3x. \tag{4}$$

The volume V is bounded by the closed surface(s) S, with $\mathbf{n}$ being the outwardly directed normal to its surface. The left-hand integral is thus the total or integral flux of electric field emerging from the volume; the right-hand integral is the total charge inside, divided by ϵ_0. Equation (4) is the integral electric flux theorem, or integral form of Coulomb's law. The simplest application of Eq. (4) is a point charge Q at the center of a sphere of radius r. The electric field points radially outward and has magnitude $|\mathbf{E}(\mathbf{r})|=Q/4\pi\epsilon_0r^2$. (See ELECTROSTATICS.)

2.2 Ampère–Maxwell Law

The second Maxwell equation concerns magnetic fields caused by currents and is known as the Ampère–Maxwell equation. Ampère's researches in the early 19th century were the study of forces between current loops carrying time-independent currents; Maxwell's contribution in mid-19th century was to recognize that Ampère's equation needed modification for time-varying sources and fields. The abstraction of a magnetic flux density **B** from the forces between currents is inherently more complex than that for the electric field **E** because there are no "point magnetic charges" [see the fourth Maxwell equation, Eq. (18)]. The magnetic force at a point (on a moving point electric charge, for example) is caused by a distribution of current; furthermore, the force is not central. The increment of magnetic flux density $d\mathbf{B}$ caused by an infinitesimal line element of current $I\, d\mathbf{l}$ is

$$d\mathbf{B}=\frac{\mu_0}{4\pi}\frac{I\, d\mathbf{l}\times\mathbf{r}}{r^3}, \tag{5}$$

where $\mathbf{r}$ is the coordinate vector from the current element to the observation point and I is the current (units of amperes=coulombs per second, abbreviated as A). The units of the magnetic induction are tesla (abbreviated as T). In reality, one must sum over all the current elements in a closed circuit, but the infinitesimal expression shows the parallels and differences with the electric field of a point charge q, $\mathbf{E}=q\mathbf{r}/4\pi\epsilon_0 r^3$. The magnetic flux density $\mathbf{B}$ of a long straight wire of circular cross section carrying a current I points in the azimuthal direction (circles centered on the wire, with sense given by the right-hand rule) and has a magnitude $|\mathbf{B}|=\mu_0 I/2\pi d$, where d is the perpendicular distance from the wire (Biot–Savart law).

If an infinitesimal current element $I\, d\mathbf{l}$ is in a magnetic flux density $\mathbf{B}$, the infinitesimal force on it is $d\mathbf{F}=I\, d\mathbf{l}\times\mathbf{B}$, a relation that may be viewed as an empirical result, but that has a more fundamental basis in the Lorentz force on a charge q in motion with a velocity $\mathbf{v}$, $\mathbf{F}=q(\mathbf{E}+\mathbf{v}\times\mathbf{B})$. The combination of Eq. (5) with the expression for the force on a current in a magnetic flux density permits the definition of the unit of current (1 A) in terms of the mechanical force per unit length between two very long, straight, and parallel current-carrying wires with separation d, namely,

$$\frac{dF}{dl}=\frac{\mu_0}{2\pi}\frac{I_1 I_2}{d}. \tag{6}$$

The force is attractive if the currents flow in the same direction and repulsive for opposite flow. Since μ_0 is defined to have a definite numerical value, measurements of the mechanical force per unit length and the separation of the wires permit the current to be defined without reference to the magnetic flux density $\mathbf{B}$. Note, however, that electrodynamics is involved, because the meter is defined in terms of the speed of light. It is amusing that one of Ampère's basic observations in the 1820s is the basis for the accepted definition of the SI unit of current.

The general expression for the force on a closed circuit C_1, fixed in position and carrying a steady current I_1, caused by a steady current I_2 flowing in a fixed closed circuit C_2 is

$$\mathbf{F}_{12}=-\frac{\mu_0 I_1 I_2}{4\pi}\oint\oint\frac{(d\mathbf{l}_1\cdot d\mathbf{l}_2)\mathbf{r}_{12}}{r_{12}^3}, \tag{7}$$

where the integration is over both of the closed circuits.

In differential form, the Ampère–Maxwell equation relating the magnetic flux density to the current density is

$$\nabla\times\mathbf{B}=\mu_0\mathbf{J}+\mu_0\epsilon_0\frac{\partial\mathbf{E}}{\partial t}, \tag{8}$$

where the right-hand side is the sum of the conduction current density (A/m^2) times μ_0 and the Maxwell "displacement current" density. The displacement-current term is necessary to make Eq. (8) compatible with Eq. (3), Coulomb's law, and the conservation of charge and current densities,

$$\nabla\cdot\mathbf{J}+\frac{\partial\rho}{\partial t}=0. \tag{9}$$

Use of Stokes's theorem from vector calculus converts Eq. (8) into the integral statement of Ampère's law:

$$\int_C \mathbf{B}\cdot d\mathbf{l}=\int_S \mathbf{n}\cdot\left(\mu_0\mathbf{J}+\mu_0\epsilon_0\frac{\partial\mathbf{E}}{\partial t}\right)da. \tag{10}$$

The left-hand side is the line integral of $\mathbf{B}$ along a closed path C, while the right-hand side is μ_0 times the total conduction and displacement current flowing through the open area bounded by C. (For more on Ampère's law and its use, see MAGNETOSTATICS.)

2.3 Faraday's Law

The third of the Maxwell equations is Faraday's law, codifying the observations of Faraday in the first half of the 19th century that time-varying magnetic fields produce electromotive forces. In differential form, Faraday's law reads

$$\nabla\times\mathbf{E}+\frac{\partial\mathbf{B}}{\partial t}=\mathbf{0}. \tag{11}$$

Its integral form, obtained by application of Stokes's theorem for an open surface S bounded by a closed curve C, is

$$\int_C \mathbf{E}\cdot d\mathbf{l}=-\int_S \frac{\partial\mathbf{B}}{\partial t}\cdot\mathbf{n}\; da. \tag{12a}$$

If the circuit C is stationary, the time derivative can be taken outside the integral sign to give

$$\int_C \mathbf{E}\cdot d\mathbf{l}=-\frac{d}{dt}\int_S \mathbf{B}\cdot\mathbf{n}\; da. \tag{12b}$$

In words, the electromotive force (emf) or line integral of the electric field around the closed circuit C (left-hand side) is equal to the negative of the time rate of change of the magnetic flux through the surface S (right-hand side). The negative sign reflects the empirical observation called Lenz's law, whereby the current induced by the emf tends to counteract the change in magnetic field.

Application of Faraday's law often involves nonstationary circuits. Care must be taken in using Eqs. (12a) or (12b). To understand the exact meaning of Faraday's law, we go back to Faraday's observations of 1831. He discovered that transient current flow occurred in a circuit when conditions were changed in adjacent current-carrying circuits. Specifically, he found a transient current induced when (a) the steady current flowing in a nearby circuit was turned on or off, (b) a nearby circuit with a steady current was moved relative to the first, or (c) a permanent magnet was thrust into or out of the circuit. No transient occurred unless the adjacent circuit's current changed or there was relative motion of the two circuits. Other observations showed that alteration of the shape of the first circuit in the presence of a circuit with a steady current caused a transient current in the first while its shape was being altered. Faraday interpreted the transient current in every situation as being caused by a changing magnetic flux linking the observed circuit. The current in the circuit is driven, according to Ohm's law, by the force acting on the charge carriers in the wire. We are thus led to consider the current to be proportional to the electromotive force $\mathscr{E}$, defined for a stationary circuit as the line integral of the electric field around the path of the circuit, as given by the left-hand sides of Eqs. (12a) and (12b). With the flux through the circuit defined as

$$\Phi_M=\int_S \mathbf{B}\cdot\mathbf{n}\; da, \tag{13}$$

where S is any open surface spanning the circuit C, Faraday's law in integral form is

$$\mathscr{E}=-\frac{d\Phi_M}{dt}. \tag{14}$$

To accommodate the possibility of movement of the circuit in time, we must generalize the definition of the electromotive force $\mathscr{E}$. Motion of the first circuit in the presence of a stationary second circuit or the same relative motion with the first circuit stationary produces the same transient current. But if an element $d\mathbf{l}$ of the first circuit is in motion with velocity $\mathbf{v}$, the charge carriers comoving with that element experience a force per unit charge equal to $\mathbf{E}+\mathbf{v}\times\mathbf{B}$. This means that the total electromotive force $\mathscr{E}$ causing the current flow in a circuit C whose path elements have velocity $\mathbf{v}(\mathbf{l})$ must be

$$\mathscr{E}=\oint_C (\mathbf{E}+\mathbf{v}\times\mathbf{B})\cdot d\mathbf{l}. \tag{15}$$

With Eq. (15) for the electromotive force around a circuit in motion (translating and perhaps changing shape if $\mathbf{v}$ is different for different parts of the path), Eq. (14) generalizes Eq. (12b) and is applicable to any situation. One sometimes considers the electromotive force between two points A and B in space. Then the integral in Eq. (15) is an open line integral between the points. In contrast to the electrostatic situation, the emf is in general path dependent. Care must be exercised in distinguishing between electrostatic potential differences and electromotive forces. With a closed path through which the magnetic flux is changing in time, parts of the path may be in regions where $\partial\mathbf{B}/\partial t=0$. Over such a segment the line integral of $\mathbf{E}$ can be interpreted as a potential difference without ambiguity, since $\nabla\times\mathbf{E}=\mathbf{0}$ there.

To connect Faraday's law, derived rather directly from the transient current flow in resistive circuits and embodied in Eq. (14), with the Maxwell equation, Eq. (11), one can consider how the magnetic flux Φ_M, Eq. (13), changes in time if the circuit C is in motion.

Whether C is in motion or not, the flux changes if $\mathbf{B}$ changes in time. There will therefore be a contribution to $d\Phi_M/dt$ from $\mathbf{n}\cdot\partial\mathbf{B}/\partial t$ at each point of the surface S. If the circuit C is in motion, there is an additional contribution whose nature can be seen from Fig. 1(a). In an infinitesimal time Δt the path $C(t)$ changes into $C(t+\Delta t)$. The surface spanning $C(t+\Delta t)$ can be taken as the surface spanning $C(t)$, minus the infinitesimal area around the sides, defined by the directed element of area, $d\mathbf{l}\times\mathbf{v}\Delta t$. Per unit time, the total change in magnetic flux is therefore

$$\frac{d\Phi_M}{dt}=\int_S \frac{\partial \mathbf{B}}{\partial t}\cdot\mathbf{n}\,da-\oint_C \mathbf{B}\cdot(d\mathbf{l}\times\mathbf{v}). \qquad (16)$$

Rearranging the triple scalar product and substituting Eqs. (15) and (16) into (14), one finds

$$\oint_C (\mathbf{E}+\mathbf{v}\times\mathbf{B})\cdot d\mathbf{l}=-\int_S \frac{\partial \mathbf{B}}{\partial t}\cdot\mathbf{n}\,da + \oint_C (\mathbf{v}\times\mathbf{B})\cdot d\mathbf{l}. \qquad (17)$$

The contribution to the time rate of change of the flux from the motion of the path C cancels the magnetic part of the electromotive force; Eq. (17) becomes Eq. (12a). We have thus returned to the third Maxwell equation, (11). It should be noted that these equations contain no reference to apparatus. Thus the path C and its spanning surface S can be viewed as mathematical abstractions. The integral and differential forms of Faraday's law in terms of $\mathbf{E}$ and $\mathbf{B}$ have a validity and generality far beyond their concrete origins.

A simple illustration of Faraday's law and its relation to other approaches is afforded by the situation sketched in Fig. 1(b). A conducting right circular cylinder of radius a rotates about its axis at angular speed $\omega=2\pi f$. There is a uniform magnetic induction parallel to the axis. Consider the open radial path OA, which is of length r and is rotating with the conductor. From Eq. (15), the emf from the axis at O to the point A is

$$\mathscr{E}_{OA}=\int_O^A (\mathbf{v}\times\mathbf{B})\cdot d\mathbf{r}=\tfrac{1}{2}\,\omega B r^2$$
$$=f(\pi r^2)B$$
$$=f\Phi_M(r).$$

Here $\Phi_M(r)$ is the magnetic flux contained within the radius r. The emf $\mathscr{E}_{OA}$ is equal to the rate at which the flux is cut by the rotating radial line.

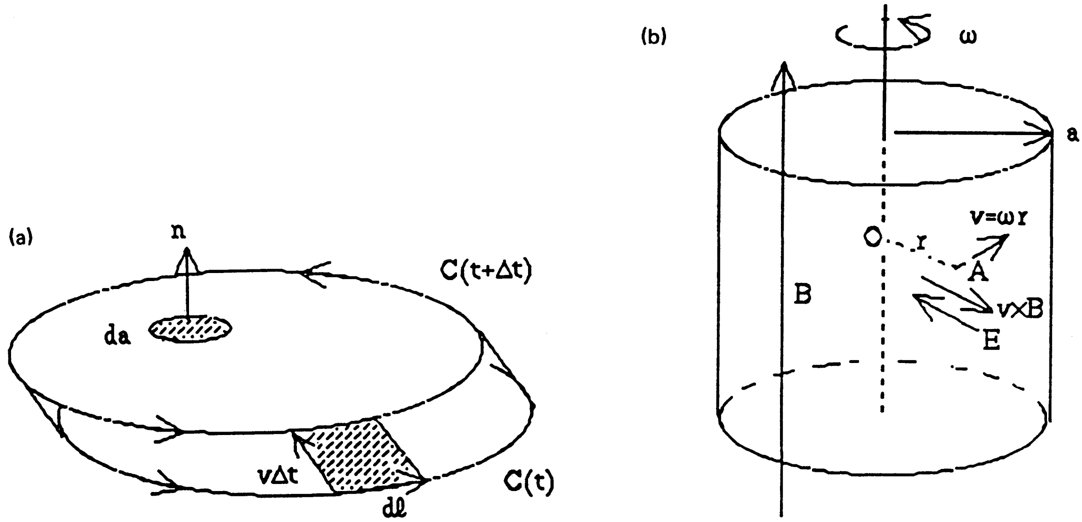

FIG. 1. (a) Closed circuit in Faraday's law. The closed path $C(t)$ changes in time Δt to $C(t+\Delta t)$. The surface spanning $C(t+\Delta t)$, with directed area element $\mathbf{n}da$, can be taken as that spanning $C(t)$, minus the "sides" defined by the directed area elements $d\mathbf{l}\times\mathbf{v}\Delta t$ around the path. (b) A long conducting right circular cylinder of radius a rotates about its axis at constant angular frequency ω in a uniform magnetic field $\mathbf{B}$ parallel to the axis.

An alternative way of approaching the problem is to consider Ohm's law in the rotating conductor. The current density is given by $\mathbf{J}=\sigma(\mathbf{E}+\mathbf{v}\times\mathbf{B})$. In the steady state no current flows. Within the conductor, there is an electrostatic field developed to oppose the magnetic force. At the typical point A (now considered as fixed in space, rather than rotating with the conductor), the electric field is radial and given by $E_r=-\omega Br$. There is a uniform volume charge density, $\rho=\epsilon_0\nabla\cdot\mathbf{E}=\epsilon_0(1/r)\partial(rE_r)/\partial r=-2\omega B\epsilon_0$. If the long cylinder is uncharged, there will be a surface charge density, $\sigma=\omega Ba\epsilon_0$. (There is a small magnetic field generated by the motion of these charge densities, but it is of higher order in smallness for surface speeds small compared to the speed of light.)

If sliding contacts fixed in space are made with the axis of the cylinder and its surface, a potential difference equal to the emf $\mathscr{E}_{OA}(a)$ or to the line integral of the electrostatic field,

$$V_{OA}=-\int_O^a E_r\,dr,$$

will be measured by a voltmeter. This example is qualitatively similar to one of Faraday's original experiments with a rotating copper disk.

2.4 Law of Magnetic Flux

The final Maxwell equation embodies the fact that, as far as is presently known, there are no magnetic charges or magnetic charge density. Its differential and integral forms parallel the first Maxwell equation, namely,

$$\nabla\cdot\mathbf{B}=0, \qquad (18)$$

$$\int_S \mathbf{B}\cdot\mathbf{n}\,da=0. \qquad (19)$$

Equation (19) is the integral magnetic flux theorem, stating that the total magnetic flux emerging from a closed surface S vanishes.

2.5 Limitations

The equations listed above are the Maxwell equations of *classical* electrodynamics in vacuum, an accurate and wonderfully successful description of myriad phenomena at the classical level. At the atomic and subatomic levels, there are quantum modifications. For example, basic to the discussion so far is the assumption that the charge and current densities are continuous, corresponding to infinitely divisible charges. But Nature supplies charges in discrete units, integral multiples of the electronic charge ($e=-1.602\times10^{-19}$ C). In many practical macroscopic applications, this unit is so small that the discreteness of charge densities can be ignored. An important relativistic quantum effect is the modification of the inverse square law of electrostatics at short distances ($r<\hbar/m_ec$, the electronic Compton wavelength). This modification, causing the force to be stronger at short distances and resulting in a tiny shift of atomic energy levels, is the result of "vacuum polarization" (see QUANTUM ELECTRODYNAMICS). A discussion of the idealizations and limitations of classical electrodynamics can be found in the introductory chapter of Jackson (1975).

3. MATERIAL MEDIA, CONSTITUTIVE RELATIONS, BOUNDARY CONDITIONS, AND SIMPLE DIELECTRIC AND MAGNETIC PROPERTIES OF MATTER

3.1 Macroscopic Maxwell Equations

The basic equations of electromagnetism of the previous section can be viewed as a description at the microscopic level, with the charge and current densities representing all the sources, whether free or bound. At length and time scales large compared to the atomic ($L\gg10^{-10}$ m, $T\gg10^{-17}$ s), the rapid fluctuations of the microscopic fields are unobservable. Only suitable averages over microscopically large, but macroscopically small, regions of space and/or time are relevant. Such averaged sources and fields are called macroscopic fields and sources. They satisfy the *macroscopic Maxwell equations* given below, and reflect the response of the material media to applied fields and sources.

In the process of averaging the microscopic equations, a distinction is made between bound charges (and atomic circulating currents) and the free charges (conduction electrons) whose averages define the familiar macroscopic charge and current densities, $\rho(\mathbf{r},t)$ and $\mathbf{J}(r,t)$:

$$\rho(\mathbf{r},t)=\langle\rho_{\text{free}}(\mathbf{r},t)\rangle,\quad \mathbf{J}(\mathbf{r},t)=\langle\mathbf{J}_{\text{free}}(\mathbf{r},t)\rangle, \qquad (20)$$

where the brackets ⟨ ⟩ indicate spatial averaging or its equivalent (Jackson, 1975, Sec. 6.7; Robinson, 1973, Chaps. 6–8). The contributions of the bound charges and currents are systematized in terms of the electric polarization $\mathbf{P}(\mathbf{r},t)$ [dominated by the averaged electric dipole moment density, but including in principle the electric quadrupole density $Q'_{jk}(\mathbf{r},t)$ and higher multipoles], and the magnetization $\mathbf{M}(\mathbf{r},t)$ (averaged magnetic dipole moment density, plus higher magnetic multipoles). These polarizations require the introduction of two new phenomenological fields $\mathbf{D}(\mathbf{r},t)$ and $\mathbf{H}(\mathbf{r},t)$, called the electric displacement and magnetic field strength, respectively, in the equations involving sources [Eqs. (3) and (8)]. The local macroscopic Maxwell equations are

$$\begin{aligned}
&\nabla\cdot\mathbf{D}=\rho,\\
&\nabla\times\mathbf{H}=\mathbf{J}+\frac{\partial\mathbf{D}}{\partial t},\\
&\nabla\times\mathbf{E}+\frac{\partial\mathbf{B}}{\partial t}=\mathbf{0},\\
&\nabla\cdot\mathbf{B}=0.
\end{aligned}\tag{21}$$

Here the electric field $\mathbf{E}$ and the magnetic induction $\mathbf{B}$ of the two homogeneous equations are just the averaged quantities of the corresponding microscopic equations. The new macroscopic fields that include the responses of the bound charges are

$$D_i=\epsilon_0E_i+P_i \tag{22}$$

and

$$H_i=\frac{1}{\mu_0}B_i-M_i. \tag{23}$$

Since $\mathbf{B}$ is the fundamental magnetic field quantity and $\mathbf{H}$ is phenomenological, Eq. (23) is the rational way to express the relationship. The minus sign associated with the magnetization is a natural one. It is conventional, however, to rearrange Eq. (23) and write the connections between the four fields as

$$\begin{aligned}
&\mathbf{D}=\epsilon_0\mathbf{E}+\mathbf{P},\\
&\mathbf{B}=\mu_0(\mathbf{H}+\mathbf{M}),
\end{aligned}\tag{24}$$

even though the basic physics is thereby obscured.

Integral statements of the Maxwell equations can be written down from Eqs. (21) in complete analogy with the development in Sec. 2.

3.2 Constitutive Relations

The Maxwell equations (21) are eight coupled partial-differential equations in space and time for the twelve field quantities **E, B, D**, and **H**. The system cannot be solved without the *constitutive relations* relating **D** and **H** to **E** and **B**:

$$\mathbf{D}=\mathbf{D}[\mathbf{E},\mathbf{B}],\quad \mathbf{H}=\mathbf{H}[\mathbf{E},\mathbf{B}]. \tag{25}$$

For conducting media, there is a generalized Ohm's law,

$$\mathbf{J}=\mathbf{J}[\mathbf{E},\mathbf{B}]. \tag{26}$$

The square brackets in Eqs. (25) and (26) signify that the connection may be nonlinear, nonlocal, and dependent on past history (hysteresis). The connections (24) show that the electric polarization and the magnetization of matter determine the nature of the constitutive relations. In general, these relations are far from simple, especially in crystalline solids, with ferroelectric and ferromagnetic materials having nonzero **P** or **M** even in the absence of applied fields. The study and elucidation of these properties is the province of condensed-matter physics. Only the simplest aspects are discussed here (for more detail, see Kittel, 1986; OPTICAL PROPERTIES OF SOLIDS; DIELECTRIC PROPERTIES OF INSULATORS; MAGNETOSTATICS; MAGNETIC MATERIALS).

In substances other than ferroelectrics or ferromagnets, a weak applied electric or magnetic field induces a polarization proportional to the magnitude of the applied field. The response of the medium is then said to be linear, and the constitutive relations take the form

$$D_i=\sum_{k=1}^{3}\epsilon_{ik}E_k,\quad B_i=\sum_{k=1}^{3}\mu_{ik}H_k. \tag{27}$$

The tensors ϵ_{ik} and μ_{ik} are called the electric permittivity or dielectric tensor and the magnetic permeability tensor, respectively. They are generally dependent on the frequency of the applied field, and on bulk properties of the material, such as density and temperature, as well as on details of molecular and perhaps crystalline structure. For simple materials (gases, liquids, some solids) the linear response is isotropic in space. Then $\epsilon_{ik}=\epsilon\delta_{ik}$ and $\mu_{ik}=\mu\delta_{ik}$; $\mathbf{D}=\epsilon\mathbf{E}$ and $\mathbf{B}=\mu\mathbf{H}$; $\epsilon/\epsilon_0=\epsilon_r$ is called simply the (relative) dielectric "constant," and $\mu/\mu_0=\mu_r$ the (relative) magnetic permeability. Many crystals have anisotropies in their dielectric constant (or magnetic permeability). The elements of the tensor ϵ_{ik} form a nonsingular matrix with eigenvalues ϵ_1, ϵ_2, ϵ_3, and associated principal axes in the crystal (which may or may not be along the axes of symmetry of the crystal). When expressed with respect to these axes, the tensor ϵ_{ik} takes the diagonal form $\epsilon_{ik}=\epsilon_i\delta_{ik}$. Unless the eigenvalues are all equal, such crystals (e.g., calcite or mica) exhibit birefringence and double refraction. See Hecht and Zajac (1974), Sec. 8.2.

For orientation, we mention that at low frequencies ($\nu<10^6$ Hz), where all charges, regardless of their masses, respond to an applied electric field, solids have dielectric constants typically in the range $\epsilon_r=\langle\epsilon_{ii}\rangle/\epsilon_0 \approx 2$–20, with larger values not uncommon. Systems with permanent molecular dipole moments can have much larger and temperature-sensitive dielectric constants. Distilled water, for example, has a static ($\nu=0$) dielectric constant of $\epsilon_r=80$ at 0 °C and $\epsilon_r=56$ at 100 °C. At optical frequencies only the electrons can respond significantly. The dielectric constants are frequency dependent in the range $\epsilon_r\approx 1.7$–10, with $\epsilon_r\approx 2$–3 for most solids. Water has $\epsilon_r\approx 1.77$–1.80 over the visible range, essentially independent of temperature from 0 to 100 °C.

Applied magnetic fields induce different responses, depending upon the properties of the individual atoms and also on their interactions. *Diamagnetic* materials consist of atoms or molecules with no net angular momentum. The response to an applied magnetic field is the creation of circulating atomic currents that produce a very small bulk magnetization opposed to the applied field ($\mu_{ii}<\mu_0$). Bismuth, the most diamagnetic substance known, has $1-\mu_r=1.8\times10^{-4}$. Diamagnetism is clearly a very small effect. If the basic atomic unit of the material has a net angular momentum from an unpaired electron, the substance is *paramagnetic*. The magnetic moment of the odd electron is aligned parallel to the applied field and $\mu>\mu_0$. Typical values are in the range $\mu_r-1\approx10^{-2}$–10^{-4} at room temperature, decreasing at higher temperatures because of the randomizing effect of thermal excitations. (See MAGNETOSTATICS.)

Ferromagnetic materials are paramagnetic (unpaired electrons), but show drastically different behavior because of interactions among the atoms. Below the Curie temperature (1040 K for iron, 630 K for nickel), ferromagnetic substances show spontaneous magnetization; all the atomic magnetic moments within a microscopically large region called a domain are aligned. Neighboring domains have random directions of alignment, but the application of a very modest external magnetic field tends to cause domains to merge or to line up in the same direction, leading to the saturation of the bulk magnetization. Removal of the field leaves a considerable fraction of the moments still aligned. The residual "permanent" magnetization can be as large as $\mu_0|\mathbf{M}|\gtrsim 1$ T. (See MAGNETS; MAGNETIC MATERIALS.)

For data on dielectric and magnetic properties of materials, the reader may consult Weast, *Handbook of Chemistry and Physics*, 69th ed. (1989).

Materials that show a linear response in weak fields eventually show *nonlinear behavior* at high enough field strengths as the electronic or ionic oscillators are driven to large amplitudes. The linear relations (27) are modified to, for example,

$$D_i=\sum_k \epsilon_{ik}^{(1)}E_k+\sum_{k,m}\epsilon_{ikm}^{(2)}E_kE_m+\cdots. \qquad (28)$$

For static fields the consequences are not dramatic, but for time-varying fields it is another matter. A large-amplitude wave of two frequencies ω_1 and ω_2 generates waves in the medium with frequencies 0, $2\omega_1$, $2\omega_2$, $\omega_1+\omega_2$, $\omega_1-\omega_2$, as well as the original ω_1 and ω_2. From cubic and higher nonlinear terms an even richer spectrum of signals can be generated. Lasers can produce peak electric fields $\gtrsim10^{12}$ V/m, comparable to or larger than the internal electric fields in atoms ($e/4\pi\epsilon_0a_0^2\approx5\times10^{11}$ V/m). The regime of nonlinearity is readily accessible for research in the laboratory and provides a vast array of applications. (See LASER PHYSICS; OPTICS, NONLINEAR.) The treatment here is restricted to linear phenomena.

3.3 Boundary Conditions at Interfaces between Different Media

At interfaces between different media, with different constitutive relations between **E** and **D** and **B** and **H**, and perhaps with surface charge and current densities, the various fields obey boundary conditions that can be inferred from the integral forms of the four Maxwell equations. Application of the divergence theorem to the first and last equations in (21) yields the integral statements

$$\int_S \mathbf{D}\cdot\mathbf{n}\, da = \int_V \rho\, d^3x \tag{29a}$$

and

$$\int_S \mathbf{B}\cdot\mathbf{n}\, da = 0. \tag{29b}$$

Here S is the closed surface bounding the volume V. Similarly, use of Stokes's theorem on the second and third equations in (21) yields the integral relations

$$\int_C \mathbf{H}\cdot d\mathbf{l} = \int_{S'} \mathbf{t}\cdot\left(\mathbf{J}+\frac{\partial \mathbf{D}}{\partial t}\right) da \tag{30}$$

and

$$\int_C \mathbf{E}\cdot d\mathbf{l} = -\int_{S'} \mathbf{t}\cdot\frac{\partial \mathbf{B}}{\partial t} da. \tag{31}$$

In (30) and (31) the surface S' is an open surface bounded by the closed curve C, and **t** is a unit normal to the surface S'.

For an interface between different media the appropriate geometrical arrangement of volumes and surfaces is shown in Fig. 2. The Gaussian pillbox of volume V, with top and bottom surfaces just inside each medium, and normal **n** defined as going from medium 1 to medium 2, is suitable for Eqs. (29a) and (29b). In the limit of vanishing height of the pillbox, these equations yield relations between the normal components of **D** and **B** on either side of the boundary surface, namely,

$$(\mathbf{D}_2-\mathbf{D}_1)\cdot\mathbf{n}=\sigma, \quad (\mathbf{B}_2-\mathbf{B}_1)\cdot\mathbf{n}=0. \tag{32}$$

In words, the normal component of **B** is continuous, while the discontinuity of the normal component of **D** is equal to the surface charge density σ at that point.

Applying Eqs. (30) and (31) to the infinitesimal Stokesian loop in Fig. 2, with sides of negligible length perpendicular to the surface, gives relations between the tangential components of **E** and **H** on either side of the interface,

$$\mathbf{n}\times(\mathbf{E}_2-\mathbf{E}_1)=\mathbf{0}, \quad \mathbf{n}\times(\mathbf{H}_2-\mathbf{H}_1)=\mathbf{K}. \tag{33}$$

The surface current **K** (with dimensions of current per unit length and units A/m) is assumed to have only components parallel to the interface. The tangential component of **E** is continuous across the interface, while the tangential component of **H** is discontinuous by an amount whose magnitude is equal to the magnitude of the surface current **K** and whose direction is parallel to $\mathbf{K}\times\mathbf{n}$. The discontinuity equations (32) and (33) for the normal and tangential components of the fields are useful in solving the Maxwell equations in different regions and then splicing them together to provide a solution throughout all space.

For completeness it can be noted that Eq. (9), the differential statement of charge–current-density conservation, leads to a corresponding boundary condition for the volume current density and the surface current and charge densities,

$$(\mathbf{J}_2-\mathbf{J}_1)\cdot\mathbf{n}+\nabla_{\parallel}\cdot\mathbf{K}+\frac{\partial\sigma}{\partial t}=0. \tag{34}$$

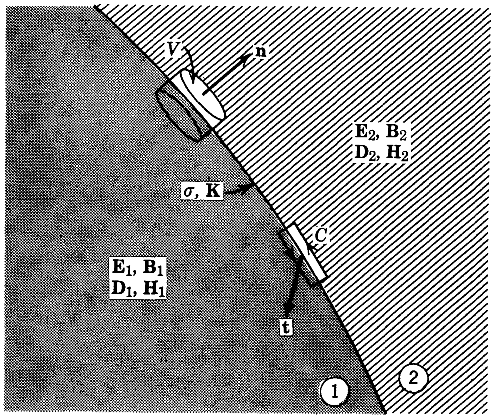

FIG. 2. Schematic diagram of boundary surface (heavy line) between different media. The boundary is assumed to carry idealized surface charge and current densities, σ and **K**. The volume V is a pillbox with its plane surfaces parallel to the interface. The normal **n** to the planes points from medium 1 to medium 2. The rectangular contour C, half in one medium and half in the other, is oriented so that the normal t to its spanning surface is tangent to the interface. [From Jackson (1975), reproduced by permission of John Wiley & Sons, Inc.]

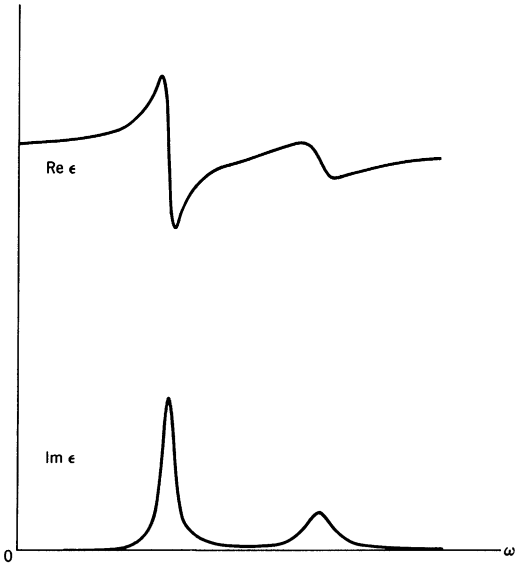

FIG. 3. Real and imaginary parts of the dielectric constant $\epsilon(\omega)$ as functions of frequency ω in the neighborhood of two resonances. [From Jackson (1975), reproduced by permission of John Wiley & Sons, Inc.]

3.4 Frequency Dependence of the Dielectric Constant

A completely correct description of the linear response of a material medium to applied electromagnetic fields requires the use of quantum mechanics, but the behavior of the dielectric constant can be inferred from largely classical considerations. Consider a model of the atom as a collection of Z electrons, each of mass m and charge $-e$, bound harmonically, with f_k of them having circular binding frequency ω_k and damping constant γ_k $(\Sigma_k f_k = Z)$. In the low-density limit in which the applied fields can be assumed to be those acting on the individual atoms, each electron obeys an equation of motion of the form

$$m(\ddot{\mathbf{x}}+\gamma_k\dot{\mathbf{x}}+\omega_k^2\mathbf{x}) = -e\mathbf{E}(0,t),$$

where the amplitude of oscillation is assumed small enough that the applied electric field can be evaluated at the average position of the charge (dipole approximation). For sinusoidal time dependence at frequency ω, the atomic dipole moment can be found as a sum over the contributions of all the electrons. With N atoms per unit volume, the dielectric constant at frequency ω is

$$\epsilon(\omega) = \epsilon_0 + \frac{Ne^2}{m} \sum_k f_k(\omega_k^2 - \omega^2 - i\omega\gamma_k)^{-1}. \quad (35)$$

With suitable quantum-mechanical definitions of f_k (called the oscillator strengths), γ_k, and ω_k, Eq. (35) is an accurate description of the electronic contributions to the dielectric constant. The relation $\Sigma_k f_k = Z$ is called the oscillator strength sum rule. Classically, it merely records the fact that there are Z electrons in the atom; quantum mechanically, it is a statement about the sum of the squares of the transitional dipole moments, weighted by the transitional frequencies, from a given quantum state to all others.

The damping constants γ_k in Eq. (35) are generally very small compared to the resonance frequencies ω_k. This means that $\epsilon(\omega)$ is approximately real for most frequencies, and, despite the fact that the overall trend with increasing frequency is downward, the most common behavior, called *normal dispersion,* is for $\mathrm{Re}[\epsilon(\omega)]$ to increase with frequency. The overall trend is produced by rather violent behavior in narrow regions around $\omega \approx \omega_k$, called regions of *anomalous dispersion,* in which $\mathrm{Re}[\epsilon(\omega)]$ decreases rapidly with frequency. A typical situation is illustrated in Fig. 3, which shows the behavior of the real and imaginary parts of $\epsilon(\omega)$ in the neighborhood of two resonances. In a region of anomalous dispersion, the imaginary part of $\epsilon(\omega)$ shows a typical resonant form. A significant $\mathrm{Im}[\epsilon(\omega)]$ represents dissipation of electromagnetic energy from the wave into the medium—such regions are called regions of resonant absorption. The fractional decrease in intensity $(\Delta I/I)$ of a monochromatic electromagnetic wave, per wavelength divided by 2π $(\Delta z = \lambda/2\pi)$, can be shown to be given by $\mathrm{Im}[\epsilon(\omega)]/\mathrm{Re}[\epsilon(\omega)]$.

Ohm's law is the statement that the electric field strength and the current density are related by $\mathbf{E} = \rho\mathbf{J}$, where the proportionality constant ρ, characteristic of the material, is called the electrical resistivity (units of ohms times meters, abbreviated as Ω m). Ohm's law holds in a wide range of practical situations, although it is clearly an approximation and sometimes a gross oversimplification. If it is inserted in the second Maxwell equation in Eq. (21) and the medium is linear, the right-hand side of the equation is linear in the electric field (and its time derivative). This suggests that electrical conductivity and dielectric response are actually two facets of the same phenomenon. Conduction is caused by the motion of quasifree electrons (and holes). Suppose a fraction f_0 of the "bound" electrons in the model for $\epsilon(\omega)$ are actually free, that is, they have no binding—their resonant frequency is zero. Their contribution to $\epsilon(\omega)$ in Eq. (35) can be separated off to give

$$\epsilon(\omega)=\epsilon_{\text{bound}}+i\frac{Ne^2f_0}{m\omega(\gamma_0-i\omega)}. \tag{36}$$

Because it is $-i\omega\epsilon(\omega)$ that enters the right-hand side of the Ampère–Maxwell equation, the singular behavior of the contribution from the free electrons represents a well-behaved resistivity,

$$\rho=m(\gamma_0-i\omega)/Ne^2f_0. \tag{37}$$

This expression is essentially the Drude (1900) expression for electrical resistivity, with f_0N being the number of free electrons per unit volume. The damping constant γ_0/f_0 can be determined empirically. For copper, $N\approx 8\times 10^{22}$ atoms/cm^3, and at normal temperatures the low-frequency resistivity is $\rho\approx 1.8\times 10^{-8}$ Ω m. This gives $\gamma_0/f_0\approx 3\times 10^{13}$ s^{-1}. With the assumption that $f_0=O(1)$, Eq. (37) shows that up to frequencies well beyond the microwave region ($\omega\leqslant 10^{11}$ s^{-1}) resistivities of metals are essentially real and independent of frequency. At higher frequencies the simple model fails in detail, but still describes the qualitative behavior. The reader may consult Wilson (1953) or Beam (1965) for details on the role of lattice vibrations, lattice imperfections, and impurities in determining the temperature dependences and magnitudes of resistivities.

At frequencies far above the highest atomic resonance, the expression (35) for $\epsilon(\omega)$ simplifies to

$$\epsilon_r(\omega)\approx 1-\omega_p^2/\omega^2,$$

where

$$\omega_p^2=NZe^2/\epsilon_0 m. \tag{38a}$$

The frequency ω_p, which depends only on the total number NZ of electrons per unit volume, is called the *plasma frequency* of the medium. In a metal, if $\omega\gg\gamma_0$, the conduction electrons give a term like the second one in Eq. (38a), so that one has

$$\epsilon_r(\omega)\approx\epsilon_{r,\text{bound}}-\omega_p^2/\omega^2,$$

where

$$\omega_p^2=ne^2/\epsilon_0 m^*. \tag{38b}$$

The plasma frequency is now that of the conduction electrons only, with an effective mass m^* to include effects of the binding (band structure). At frequencies such that $\omega\ll\omega_p$, the last term dominates; ϵ_r is negative; the index of refraction is purely imaginary; waves are reflected by the metal. When ω is sufficiently large that $\epsilon_r(\omega)>0$, waves can penetrate and propagate through the metal. Typically, this transition occurs in the ultraviolet and one speaks of the ultraviolet transparency of metals. Aluminum, for example, shows a sharp drop in reflectance for wavelengths shorter than about 80 nm, corresponding to a conduction-electron plasma energy of $\hbar\omega_p\approx 15$ eV compared to a theoretical value of 15.7 eV from Eq. (38b) with three conduction (valence) electrons per atom and $m^*=m$. For further discussion of this transition and other dielectric properties of metals in the optical and ultraviolet regions, see Pines (1963), Wooten (1972), and OPTICAL PROPERTIES OF SOLIDS.

We mentioned above that the free-electron contribution to the dielectric constant could be viewed alternatively as a representation of Ohm's law, while the bound electrons gave the usual dielectric constant. The dominance of one or the other contribution governs the behavior of fields in matter. Consider for simplicity a uniform isotropic linear medium with resistivity ρ, dielectric constant ϵ, and magnetic permeability μ, all real. For harmonic fields, the second and third Maxwell equations in Eq. (21), combined with the fourth and Ohm's law, lead to a Helmholtz wave equation for **H**,

$$\nabla^2\mathbf{H}+k^2\mathbf{H}=\mathbf{0},$$

where

$$k^2=i\omega\mu(\rho^{-1}-i\omega\epsilon)$$

is the square of the (complex) wave number. If the medium is poorly conducting, the Maxwell displacement current dominates and $k^2\approx\mu\epsilon\omega^2$. The wave vectors are approximately real, and the electric field is in time phase with the magnetic field. If, on the other hand, the resistivity is small enough (i.e., $\rho\omega\epsilon\ll 1$), the conduction current dominates and $k^2\approx i\omega\mu/\rho$. Then the wave numbers are complex,

$$k \approx \pm [(1+i)/\sqrt{2}]\,\sqrt{\omega\mu/\rho},$$

with equal real and imaginary parts. The electric field is 135° out of phase with the magnetic field. For the plane surface of a good conductor, the field components vary with distance x into the conductor as $e^{-x/\delta} \times \cos(x/\delta+\beta)$, where the skin depth δ is

$$\delta = \sqrt{2\rho/\omega\mu}. \qquad (39)$$

The behavior in other geometries is similar—for cylinders, for example, the fields are proportional to Kelvin's ber and bei functions, Bessel functions of complex argument. For copper ($\rho \approx 1.7\times 10^{-8}$ Ω m at 20 °C) the skin depth is numerically $\delta \approx 6.6/\sqrt{\nu(\mathrm{Hz})}$ cm. At 10 GHz, the skin depth in copper is less than 1 μm. The concept of skin or penetration depth in conducting media applies in several domains, from quasistatic induction heating to microwave components.

3.5 Causality and Analytic Properties of $\epsilon(\omega)$

The dielectric constant, Eq. (35), viewed as a function of complex ω, has a pattern of singularities and domain of analyticity that are a consequence of the causal nature of the response of the charged atomic particles to applied fields. If a single-frequency component of the field is considered, **D** and **E** at a given point in space are related by

$$\mathbf{D}(\mathbf{r},\omega) = \epsilon(\omega)\mathbf{E}(\mathbf{r},\omega). \qquad (40)$$

If use is made of the Fourier integrals in time and frequency [Eq. (1)], $\mathbf{D}(\mathbf{r},t)$ can be expressed nonlocally (in time) in terms of $\mathbf{E}(\mathbf{r},t)$ through

$$\mathbf{D}(\mathbf{r},t) = \epsilon_0\left(\mathbf{E}(\mathbf{r},t) + \int_{-\infty}^{\infty} G(\tau)\mathbf{E}(\mathbf{r},t-\tau)\,d\tau\right), \qquad (41)$$

where $G(\tau)$ is the Fourier transform of $\epsilon_r(\omega)-1$,

$$G(\tau) = \frac{1}{2\pi}\int_{-\infty}^{\infty} [\epsilon_r(\omega)-1]e^{-i\omega\tau}\,d\omega. \qquad (42)$$

$G(\tau)$ is called the susceptibility kernel. A simple, single-oscillator model of $\epsilon(\omega)$ is sufficient to illustrate its general features. If $\epsilon_r(\omega)$ is given by

$$\epsilon_r(\omega) = 1 + \omega_p^2(\omega_0^2-\omega^2-i\omega\gamma)^{-1}, \qquad (43)$$

then

$$G(\tau) = \omega_p^2 e^{-\gamma\tau/2}\,\frac{\sin \nu_0\tau}{\nu_0}\,\theta(\tau), \qquad (44)$$

with

$$\nu_0 = \sqrt{\omega_0^2 - \tfrac{1}{4}\gamma^2},$$

where $\theta(\tau)$ is the unit step function [$\theta(x)=1$ for $x>0$; $\theta(x)=0$ if $x<0$]. Evidently the susceptibility kernel for Eq. (35) is just a linear superposition of terms like Eq. (44). There are three major features: (a) $G(\tau)$ is causal, that is, it vanishes for $\tau<0$. This is a general feature, not restricted to the particular model used here. (b) $G(\tau)$ is oscillatory, at a frequency that is closely the resonant frequency ω_0 (since $\gamma \ll \omega_0$). (c) $G(\tau)$ is damped in time for $\tau>0$ with the damping constant of the electronic oscillator. These damping constants, quantum mechanically the widths in frequency of the relevant spectral lines, are typically 10^7–10^9 s^{-1}. The nonlocality in time in Eq. (41) is therefore of the order of 10^{-7}–10^{-9} s. For frequencies above the microwave region many earlier cycles of the electric field oscillations contribute to the value of **D** at a given instant of time. [Actually, the response of the medium is nonlocal in space as well as time, but for insulators the spatial nonlocality is only of the order of atomic sizes. The concept of a dielectric constant $\epsilon(\omega)$ or index of refraction $n(\omega)$ therefore applies far beyond the visible into the soft-x-ray region. For metals, especially at low temperatures, where electrons have very long mean free paths, the nonlocal region can be macroscopic in size. See Pippard (1960).]

Viewed as a function of complex ω, the dielectric constant, Eq. (35), or its special case, Eq. (43), has poles only in the lower half-plane. The absence of singularities above the real axis is directly responsible for the causal behavior of $G(\tau)$. The relation inverse to Eq. (42) expresses $\epsilon(\omega)$ in terms of $G(\tau)$ as

$$\epsilon_r(\omega) = 1 + \int_0^{\infty} G(\tau)e^{i\omega\tau}\,d\tau. \qquad (45)$$

From the reality of $G(\tau)$ it can be inferred from Eq. (45) that (a) for complex ω, $\epsilon(-\omega) = \epsilon^*(\omega^*)$; (b) $\epsilon(\omega)$ is an analytic function of ω in the upper half-plane and on the real axis ($\omega \neq 0$), provided $G(\tau)$ is finite for all τ. At the origin it is necessary to invoke the requirement that $G(\tau)\to 0$ as $\tau\to\infty$ to assure that $\epsilon(\omega)$ is also analytic there. This is true for insulators, but not for conductors. For the latter, $G(\tau)\to$const as $\tau\to\infty$ and $\epsilon(\omega)$ has a pole at $\omega=0$, as already discussed in connection with Eq. (36).

The analyticity of $\epsilon(\omega)$ in the upper half-plane permits us to use Cauchy's theorem to deduce "dispersion relations" or Kramers–Kronig relations (1926–27), as they are called. [See Jackson (1975), p. 310ff, for a derivation.] These relations express the real part of $\epsilon_r(\omega)$ as an integral over the imaginary part, and vice versa. For insulators (without the pole at $\omega=0$), the Kramers–Kronig relations are

$$\mathrm{Re}\ \epsilon_r(\omega)=1+\frac{2}{\pi}\ \mathrm{P}\int_0^\infty \frac{\omega'\ \mathrm{Im}\ \epsilon_r(\omega')}{\omega'^2-\omega^2}\,d\omega',$$

$$\mathrm{Im}\ \epsilon_r(\omega)=-\frac{2}{\pi}\ \mathrm{P}\int_0^\infty \frac{[\mathrm{Re}\ \epsilon_r(\omega')-1]}{\omega'^2-\omega^2}\,d\omega'. \tag{46}$$

Here the symbol P denotes "principal part" of the integral, namely, the integral over ω', omitting the symmetric interval around $\omega'=\omega$ from $\omega'=\omega'-\epsilon$ to $\omega'=\omega+\epsilon$, in the limit $\epsilon\to 0$. The power of these relations lies in their generality. Experimental information on absorption [Im $\epsilon(\omega)$] permits calculation of Re $\epsilon(\omega)$, etc. The asymptotic behavior of $\epsilon(\omega)$ for large ω, Eq. (38a), can be used as a definition of the plasma frequency, i.e., $\omega_p^2=\lim_{\omega\to\infty}\{\omega^2[1-\epsilon_r(\omega)]\}$. Application of this limit to the first equation in Eqs. (46) leads to a "sum rule" for the plasma frequency, equivalent to the sum rule for the oscillator strengths,

$$\omega_p^2=\frac{2}{\pi}\int_0^\infty \omega\ \mathrm{Im}\ \epsilon_r(\omega)d\omega. \tag{47}$$

This optical sum rule is one of many that can be developed (Altarelli *et al.*, 1972; Wooten, 1972).

The analyticity of $\epsilon(\omega)$ translates into analytic properties for its square root, the index of refraction, relevant for the propagation of electromagnetic waves in matter. In two historical papers in 1914, Sommerfeld and his student Brillouin (a) showed that no electromagnetic disturbance in matter can propagate faster than the speed of light in vacuum, despite the fact that the phase velocity of the wave in the material can exceed that speed; and (b) analyzed in detail the rather complex arrival of the signal at a distant point. See Sec. 7.11 of Jackson (1975) for a simplified account, including discussion of an experimental demonstration, and Brillouin (1960) for translations of the original papers and subsequent work.

4. ELECTROSTATIC AND MAGNETOSTATIC ENERGIES, CAPACITANCE, AND INDUCTANCE

(See also ELECTROSTATICS; MAGNETOSTATICS; CIRCUIT ELEMENTS; ELECTROSTATIC CAPACITIVE STORAGE OF ENERGY; INDUCTORS.)

4.1 Electrostatic Energy

For static fields Faraday's law states that the electric field has zero curl. It can therefore be written as the gradient of a scalar potential function $\phi(\mathbf{r})$, called the electric potential. Conventionally, the signs are chosen so that

$$\mathbf{E}=-\nabla\phi. \tag{48}$$

If an infinitesimal point charge δq is moved from infinity to a point at $\mathbf{r}$ through a preexisting electric field $\mathbf{E}$ whose potential vanishes at infinity, the mechanical work done on the charge (the negative of the work done by the field) is $\delta W=\delta q\phi(r)$. This work represents the electrostatic energy of δq. Suppose now that the preexisting field is produced by a charge density $\rho(\mathbf{r})$ and that, instead of an infinitesimal point charge δq being brought in from infinity, there is an infinitesimal change $\delta\rho$ in the charge density throughout space (think of all the little bits of charge making up $\delta\rho$ being brought into their places from infinity). The work done to accomplish the change is

$$\delta W=\int \delta\rho(\mathbf{r})\phi(\mathbf{r})d^3x, \tag{49}$$

where the integration is over all regions where $\delta\rho\neq 0$. Without any assumptions about linearity, uniformity, isotropy, etc., the infinitesimal change in the charge density $\delta\rho$ can be related to a change in the electric displacement $\delta\mathbf{D}$ through the first Maxwell equation in Eq. (21):

$$\delta\rho=\nabla\cdot(\delta\mathbf{D}).$$

An integration by parts then leads to

$$\delta W = \int \mathbf{E}\cdot\delta\mathbf{D}\, d^3x,$$

where it has been assumed that $\rho(\mathbf{r})$ is a localized charge distribution. The total electrostatic energy (total work done in assembling the charge density) can be written formally as

$$W = \int d^3x \int_0^D \mathbf{E}\cdot\delta\mathbf{D}[\mathbf{E}]. \tag{50}$$

The symbolic integration over $\delta\mathbf{D}$ from zero to a final value contains all the information in the constitutive relations. For linear media, $2\mathbf{E}\cdot\delta\mathbf{D}=\delta(\mathbf{E}\cdot\mathbf{D})$. The electrostatic energy for linear media is thus

$$W = \frac{1}{2}\int \mathbf{E}\cdot\mathbf{D}\, d^3x, \tag{51}$$

where the integration is over all space. The integrand in Eq. (51) may be identified as an electrostatic energy density distributed in space. Use of Eq. (48) and the first equation in (21) will transform Eq. (51) into

$$W = \frac{1}{2}\int_V \rho(\mathbf{r})\phi(\mathbf{r})d^3x - \int_S \phi(\mathbf{r})\mathbf{D}\cdot\mathbf{n}\, da. \tag{52}$$

Here a formal device of finite volume V and surrounding surface S has been used to show explicitly the integration by parts. If the charge density is localized, the volume V can be expanded to infinity. The potential decreases inversely or faster with distance and the field $\mathbf{D}$ falls off with one higher power. The surface integral therefore manifestly vanishes as S goes to infinity. [It must vanish as soon as S is large enough to contain all of $\rho(\mathbf{r})$, but that is not immediately obvious.]

The last expression for the energy is what occurs for the microscopic Maxwell equations, where all the charges, both bound and free, are included in the computation of the work. In macroscopic electromagnetism, it is a valid result only for linear media. In general, Eq. (50) must be used.

4.2 Capacitance and Coefficients of Capacitance

A set of n conductors is embedded in a linear (but not necessarily isotropic or uniform) medium, with each conductor having a total charge Q_j and a corresponding potential V_j $(j=1,2,\ldots,n)$. The electrostatic energy of the system can be expressed in terms of the potentials V_j alone and certain geometrical quantities called coefficients of capacitance. The simplest example is an isolated metal sphere of radius R with a total charge Q in an isotropic, uniform medium with dielectric constant ϵ. The electrostatic potential at the surface of the sphere is $V=Q/4\pi\epsilon R$ and the energy is $W=QV/2$. Elimination of Q gives $W=CV^2/2$, where the coefficient $C=4\pi\epsilon R$ is called the capacitance of a sphere. This example illustrates the geometrical aspect of capacitance. Apart from the conventional factor $4\pi\epsilon$, the dimensions of capacitance are those of length. For the isolated sphere, capacitance is defined as the ratio of charge to potential, $C=Q/V$. A closely parallel definition applies for each set of n conductors, as is immediately apparent.

For a given configuration of conductors in a linear medium, the linear connection of the fields and potential with the charge density implies that the potential of the jth conductor is related linearly to the charges on all the conductors, that is,

$$V_j = \sum_{k=1}^{n} p_{jk}Q_k,$$

where the coefficients p_{jk} depend on the geometry of the conductors and the medium (if nonisotropic and/or nonuniform). These n equations can be inverted to yield the charge on the jth conductor in terms of all the potentials, with coefficients that are purely geometrical and independent of field strengths,

$$Q_j = \sum_{k=1}^{n} C_{jk}V_k, \quad j=1,2,\ldots,n. \tag{53}$$

The diagonal coefficients C_{jj} are called *capacitances*, while the C_{jk} $(j\neq k)$ are called coefficients of capacitance. From Eq. (53) it is evident that the capacitance of a conductor is the total charge on the conductor when it is maintained at unit potential, all other conductors being held at zero potential.

From Eqs. (52) and (53) it is seen that the electrostatic energy of the system of n conductors is

$$W = \frac{1}{2}\sum_{j=1}^{n} Q_jV_j = \frac{1}{2}\sum_{j=1}^{n}\sum_{k=1}^{n} V_jC_{jk}V_k. \tag{54}$$

This expression for the energy, equal to Eq. (51), can be used to find capacitances of specific configurations, either exactly or approximately (by variational methods, for example). The coefficients of capacitance are symmetric, i.e., $C_{jk}=C_{kj}$, as can be proven by means of Green's reciprocation theorem (Sec. 4.5).

Some common example of capacitances (with the surrounding medium isotropic, linear, and uniform) are

1. Isolated conducting sphere of radius R:

   $C=4\pi\epsilon R.$

2. Isolated thin flat circular conducting disk of radius R:

   $C=8\epsilon R.$

3. Two equal flat parallel conducting sheets of area A located one above the other with spacing d (with the smallest dimension across any part of the sheets large compared to d), as shown in Fig. 4, upper left:

   $$C=A\epsilon/d \quad +\text{fringe-field corrections } O(\epsilon d).$$

   To the neglect of the fringing field, the same capacitance applies for a flat sheet of area A positioned parallel to and a distance d away from any larger parallel flat sheet of conductor that extends beyond the projection of the smaller one.
4. Two coaxial cylindrical surfaces, the inner one of radius a, the outer of radius $b>a$, and length l ($l\gg b$), as shown in Fig. 4, upper right, with the potential difference between them:

   $$C=\frac{2\pi\epsilon l}{\ln(b/a)} \quad +\text{end-field corrections } O(\epsilon(b-a)).$$

5. Two long straight parallel right circular cylinder wires of radii a_1 and a_2 and common length l, whose central axes are separated by a distance d as shown in Fig. 4, lower left:

   $$C=2\pi\epsilon l\left[\cosh^{-1}\left(\frac{d^2-a_1^2-a_2^2}{2a_1a_2}\right)\right]^{-1} \approx\frac{\pi\epsilon l}{\ln(d/\sqrt{a_1a_2})}.$$

   The approximate result applies when $d\gg a_1,a_2$. End-field corrections are of the relative order d/l or less.

For conducting surfaces of not too severe shapes, capacitances can be estimated by comparison with known results. It can be proved that the capacitance of a closed surface S is bounded between those of the surfaces $S_<$ and $S_>$, where $S_<$ ($S_>$) lies totally inside (outside) S, as sketched in Fig. 4, lower right. For example, the capacitance of a conducting oblate spheroid with axes $a=b=R$ and $c<R$ has a capacitance between those of a sphere and a disk of radii R. The capacitance of a cube with sides of length a lies between those of the inscribed and circumscribed spheres, $C_<=0.5(4\pi\epsilon a)$ and $C_>=(\sqrt{3}/2)(4\pi\epsilon a)$. The arithmetic average of these bounds, $0.683(4\pi\epsilon a)$, is close to the numerically determined result, $0.655(4\pi\epsilon a)$.

Other examples of capacitance can be found in Sec. 5.b of Gray, *American Institute of Physics Handbook* (1972) and in ELECTROSTATIC CAPACITIVE STORAGE OF ENERGY.

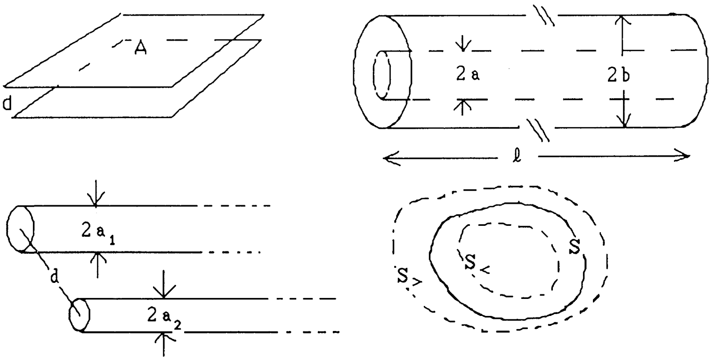

FIG. 4. Some capacitance geometries: parallel plates (upper left), coaxial cylinders (upper right), parallel circular wires (lower left), and closed conducting surface S, with inscribed ($S_<$) and circumscribed ($S_>$) surfaces (lower right).

4.3 Magnetostatic Energy

In deriving the electrostatic energy it is not necessary to consider time variation of the fields explicitly. Charges can be assumed to be moved arbitrarily slowly from infinity to their final locations. For magnetic fields, however, the variation in time of the fields as they are built up to their final magnetostatic configuration (defined by $\nabla\cdot\mathbf{J}=0$, or equivalently, $\partial\rho/\partial t=0$) produces electromotive forces (Faraday's law) that do work on the charges and currents. A treatment paralleling that of Sec. 4.1 [see Jackson (1975), Sec. 6.2] leads to a result for the infinitesimal change in magnetic energy caused by an infinitesimal change in the magnetic flux density of the form

$$\delta W=\int \mathbf{H}\cdot\delta\mathbf{B}\, d^3x. \tag{55}$$

This expression is the magnetic equivalent to the equation above Eq. (50). The constitutive relation between $\mathbf{B}$ and $\mathbf{H}$ is necessary to complete the determination of the total magnetostatic energy. For linear media, the energy is

$$W=\frac{1}{2}\int \mathbf{H}\cdot\mathbf{B}\, d^3x, \tag{56}$$

where the integration is over all space. In analogy with electrostatics, the integrand can be thought of as a magnetic energy density.

An expression for the magnetic energy analogous to Eq. (52) can be written by introduction of the vector potential $\mathbf{A}$, an auxiliary vector field that takes into account the fourth Maxwell equation, $\nabla\cdot\mathbf{B}=0$. Any divergenceless vector field can be written as the curl of another vector field. The magnetic flux density can therefore be defined as

$$\mathbf{B}=\nabla\times\mathbf{A}. \tag{57}$$

Substitution of this definition into Eq. (56), followed by an integration by parts and use of the Ampère–Maxwell equation, leads to the magnetic energy of a linear medium as

$$W=\frac{1}{2}\int \mathbf{J}\cdot\mathbf{A}\, d^3x. \tag{58}$$

The sources $\mathbf{J}$ are assumed to be localized in space; otherwise, there would be an additional surface integral at infinity. [For a localized steady current source, the vector potential decreases asymptotically inversely with distance and the fields decrease as the cube of the distance. The integrand in Eq. (56) therefore vanishes rapidly enough to make (56) equal (58) without a surface term.]

4.4 Inductance

A common situation in magnetostatics is a set of n currents I_j flowing in conductors C_j embedded in a nonconducting, magnetically linear (although not necessarily isotropic or uniform) medium. The conductors, which are also taken to be magnetically linear, are not assumed to be infinitesimally thin wires, although this may be a permissible approximation in some computations. The magnetic energy of the configuration can be expressed as a quadratic form in the currents, with geometrical coefficients of inductance, just as with the electrostatic energy and the coefficient of capacitance. The starting point is Eq. (58), which can be written as

$$W=\frac{1}{2}\sum_{j=1}^{n}\int_{V_j}\mathbf{J}_j\cdot\mathbf{A}_j\, d^3x + \sum_{j=1}^{n}\sum_{k>j}^{n}\int_{V_j}\mathbf{J}_j\cdot\mathbf{A}_k\, d^3x, \tag{59}$$

where $\mathbf{J}_j$ is the current density in the jth conductor (proportional to the total current I_j) and $\mathbf{A}_j$ is the vector potential resulting from that current density. The integrations are over the volumes V_j of the set of conductors. With a linear medium, the magnetic fields $\mathbf{B}_j$ and $\mathbf{H}_j$ and also the vector potential $\mathbf{A}_j$ throughout space are linear in the current I_j. Equation (59) may therefore be expressed in the form

$$W=\frac{1}{2}\sum_{j=1}^{n} L_j I_j^2+\sum_{j=1}^{n}\sum_{k>j}^{n} M_{jk} I_j I_k, \tag{60}$$

where the coefficients L_j and M_{jk} are purely geometrical quantities, dependent upon the configuration of conductors and intervening medium and how the current flows through the conductors, but not dependent on the magnitudes of the currents I_j. The quantities L_j (M_{jk}) are called coefficients of self- (mutual) inductance. Like the coefficients of capacitance, the mutual inductances are symmetric, i.e., $M_{jk}=M_{kj}$.

The approximation of infinitesimally thin wires can sometimes be used in the calculation of mutual inductances (but not for self-inductances, where an infinite value is the result). Consider such a conducting wire of circuit C_1 in the presence of another such circuit C_2. From Eq. (58) the mutual energy is

$$W_{12}=I_1 \oint_{C_1} \mathbf{A}_2\cdot d\mathbf{l}_1. \tag{61}$$

Stokes's theorem, together with Eq. (57) connecting **B** and **A**, can be used to transform W_{12} into

$$W_{12}=I_1 \int_{S_1} \mathbf{B}_2\cdot\mathbf{n}\; da_1.$$

The open surface S_1 spans the circuit C_1. The integral is the magnetic flux Φ_{12} (caused by the second circuit with its current I_2) through the first circuit C_1. The mutual inductance M_{12} is therefore $M_{12}=\mathcal{F}_{12}$, where $\mathcal{F}_{12}$ is the magnetic flux through circuit C_1 caused by unit current flowing in circuit C_2. For wire circuits in a uniform, isotropic medium of permeability μ, it can be shown, from Eq. (61) and the expression for the vector potential in terms of the current, that M_{12} can be written in this approximation in the purely geometric form

$$M_{12}=\frac{\mu}{4\pi} \oint_{C_1} \oint_{C_2} \frac{d\mathbf{l}_1\cdot d\mathbf{l}_2}{r_{12}}. \tag{62}$$

Clearly such an expression is meaningless when applied to self-inductance.

Equation (56) or (58) for the energy can be used together with Eq. (60) to calculate the self-inductances of specific configurations of currents. For mutual inductances, the same approach can be employed, although in some circumstances the linked flux approach or Eq. (62) can be substituted.

Some examples of self-inductances (circuits are in vacuum and at low frequency unless stated otherwise) are the following.

1. A straight right circular wire of radius a, length l ($l \gg a$), and relative permeability μ_r:

   $$L\approx\frac{\mu_0}{2\pi}\, l\left[\ln\left(\frac{2l}{a}\right)-1+\frac{\mu_r}{4}\right].$$

   The contribution $\mu_r/4$ comes from the interior of the wire. At very high frequencies, when the skin depth (39) $\delta \ll a$, this interior contribution is absent. In actuality, the argument of the logarithm is uncertain, or rather, it depends upon the actual way in which the wire of length l and radius a is connected into a complete circuit.
2. Two parallel long straight circular nonpermeable wires of length l with radii a_1 and a_2 and a separation d between their axes, with current flowing down one wire and back the other, as shown in Fig. 5, upper left:

   $$L=\frac{\mu_0 l}{\pi}\left[\ln\left(\frac{d}{\sqrt{a_1 a_2}}\right)+\frac{1}{4}\right].$$

   At very high frequencies the "interior" contribution, $\frac{1}{4}$, is absent.
3. Two coaxial conducting right circular cylinders of length l with current flow in opposite directions, the inner one solid with radius a and relative permeability μ_1, the outer one hollow, with inner radius b, thickness t ($t \ll b$), and relative permeability μ_3, and the space between the cylinders having relative permeability μ_2, as sketched in Fig. 5, upper right:

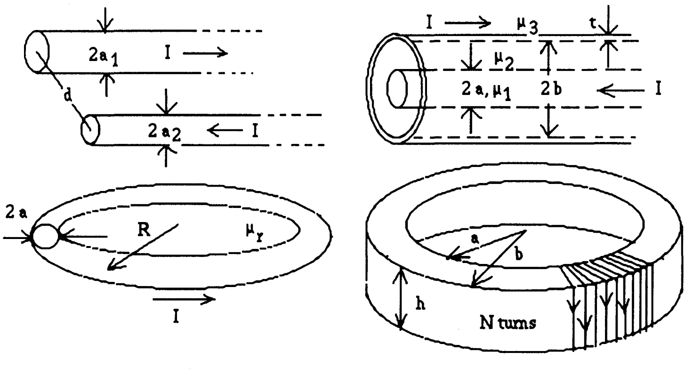

FIG. 5. Some inductance geometries: parallel circular wire transmission line (upper left), coaxial cylinder transmission line (upper right), circular loop of wire (lower left), circular toroid of rectangular cross section (lower right).

$$L\approx\frac{\mu_0}{2\pi}\,l\left[\frac{\mu_1}{4}+\mu_2\ln\left(\frac{b}{a}\right)+\frac{\mu_3 t}{3b}\right].$$

At very high frequencies the terms in μ_1 and μ_3 are absent, as they would be if the inner and outer cylinders were both very thin cylindrical shells.

4. A circular wire of radius a and relative permeability μ_r bent into a circle of mean radius R ($R\gg a$), as shown in Fig. 5, lower left:

$$L\approx\mu_0 R\left[\ln\left(\frac{8R}{a}\right)-2+\frac{\mu_r}{4}\right].$$

There are corrections of order a^2/R^2 and $(a^2/R^2)\ln(R/a)$, and the same comment as above applies about the absence of the interior contribution at high enough frequencies. For a coil of N turns wound closely together such that the bundle has an approximately circular cross section of radius a, the self-inductance is approximately N^2 times that of the single turn, provided the mean radius is used for R.

5. A toroid of rectangular cross section, with inner (outer) radius a (b) and height h, and permeability μ, wound uniformly with N turns, as sketched in Fig. 5, lower right:

$$L\approx\frac{\mu N^2 h}{2\pi}\ln\left(\frac{b}{a}\right).$$

It is assumed that the wire size is very small compared to the dimensions of the toroid and that the number of turns is large enough that there is negligible spacing between turns.

6. A toroid of circular cross section of radius a whose center is a radius R ($R>a$) from the axis of the toroid, with permeability μ, wound uniformly with N turns:

$$L\approx\mu N^2(R-\sqrt{R^2-a^2}).$$

The same assumptions about wire size, etc. apply here as in example **4**.

For examples **4–6**, approximate mutual inductances can be obtained for coils wound closely on top of each other by replacing N^2 by N_1N_2 and using mean dimensions. With the idealized toroids of examples **5** and **6**, the second coil of N_2 turns need not extend around the complete toroid because the magnetic flux is contained entirely within the toroid.

Further examples and more precise expressions for self- and mutual inductances can be found in Sec. 5.b of Gray, *American Institute of Physics Handbook* (1972), and in INDUCTORS.

4.5 Symmetry and Reciprocity Properties

There are useful symmetries and reciprocity relations based on Green's reciprocation theorem of electrostatics and its generalization to magnetostatics. Consider a volume V defined by a set of conducting boundary surfaces collectively labeled S (one of which may be at infinity). Let $\phi(\mathbf{r})$ be the electrostatic potential produced by a volume charge density ρ and a surface charge density σ on the surface(s) S, and let $\phi'(\mathbf{r})$ be the potential produced by another charge distribution, ρ' and σ'. Green's reciprocation theorem states that

$$\int_V \rho\phi'\,d^3x+\int_S \sigma\phi'\,da=\int_V \rho'\,\phi\,d^3x+\int_S \sigma'\phi\,da. \tag{63}$$

Physically, the two sides of Eq. (63) are just different expressions for the mutual electrostatic potential energy of one charge distribution in the presence of the electric potential caused by the other. The equality can be traced back to Newton's third law. For a set of conducting surfaces raised to potentials V_j (V_j') by the placement of charges Q_j (Q_j') on them, Eq. (63) becomes

$$\sum_j Q_j' V_j=\sum_k Q_k V_k'. \tag{64}$$

Suppose that in one situation $Q_1=q$, but all other $Q_j=0$, while in the other, $Q_2'=q$ and all other $Q_j'=0$. Equation (64) shows that the uncharged surface S_2 is raised by the presence of q on S_1 to the same potential as is the uncharged surface S_1 when the same charge q is placed on S_2. In another application, the symmetry of the coefficients of capacitance C_{ij} follows from Eq. (64) if Eq. (53) is used to express the charges in terms of the potentials on both sides of the equation.

The reciprocation theorem can be used to answer questions about induced charges. Consider, for example, a point P_1 a distance r from the center of a conducting sphere of radius a

on which a charge q has been placed. The potential at P_1 is $V_1 = q/4\pi\epsilon r$. If, instead, a point charge q is placed at P_1, the uncharged sphere will be raised to the same potential, $V_2' = V_1$. With the point charge still at P_1, suppose that the sphere is now grounded. Enough charge q' flows in from (out to) infinity to make the sphere's potential zero, i.e., $q'/4\pi\epsilon a + V_2' = q'/4\pi\epsilon a + q/4\pi\epsilon r = 0$, or $q' = -aq/r$, the well-known result for the charge induced on a grounded sphere by a nearby point charge.

In magnetostatics there is a corresponding, although less familiar, reciprocation theorem involving currents in a set of circuits and the resulting magnetic fluxes through them.

5. POTENTIALS, GAUGE TRANSFORMATIONS, AND WAVE EQUATIONS

5.1 Scalar and Vector Potentials and Gauge Transformations

In Sec. 4 the scalar potential ϕ and the vector potential $\mathbf{A}$ were introduced in the context of time-independent fields. For time-dependent phenomena they are equally useful. The definition, Eq. (57), of the magnetic flux density in terms of the vector potential is applicable to the more general situation because it stems from the fourth Maxwell equation, $\nabla \cdot \mathbf{B} = 0$, but the connection of the electric field to the potentials, Eq. (48), must be generalized. Recall that the curl of a gradient vanishes. In contrast, Faraday's law shows that

$$\nabla \times \left(\mathbf{E} + \frac{\partial \mathbf{A}}{\partial t} \right) = \mathbf{0}.$$

With time-dependent fields, it is not $\mathbf{E}$, but $\mathbf{E} + \partial \mathbf{A}/\partial t$ that can be expressed as a gradient of the scalar function. The definitions of the fields $\mathbf{E}$ and $\mathbf{B}$ in terms of the potentials ϕ and $\mathbf{A}$ are thus

$$\mathbf{E} = -\nabla \phi - \frac{\partial \mathbf{A}}{\partial t},$$

$$\mathbf{B} = \nabla \times \mathbf{A}. \tag{65}$$

With these definitions, the two homogeneous Maxwell equations are automatically satisfied.

The electric and magnetic fields are fundamental; the potentials are useful auxiliary fields, but they are not unique. The magnetic flux density is unchanged if the vector potential is modified by adding the gradient of some scalar function $\chi(\mathbf{r},t)$ to it. To keep the electric field unchanged, the scalar potential must also be modified. The simultaneous change of the two potentials,

$$\mathbf{A} \rightarrow \mathbf{A}' = \mathbf{A} + \nabla \chi,$$

$$\phi \rightarrow \phi' = \phi - \frac{\partial \chi}{\partial t} \tag{66}$$

is called a gauge transformation. It preserves the electric and magnetic fields, but can modify the equations satisfied by the potentials.

Consider the Maxwell equations in free space. If $\mathbf{E}$ and $\mathbf{B}$ are eliminated by means of Eq. (65) from the inhomogeneous pair of the Maxwell equations, they become equations for the potentials,

$$\nabla^2 \phi + \frac{\partial}{\partial t}(\nabla \cdot \mathbf{A}) = \frac{1}{\epsilon_0} \rho, \tag{67}$$

$$\nabla^2 \mathbf{A} - \mu_0 \epsilon_0 \frac{\partial^2 \mathbf{A}}{\partial t^2} - \nabla \left(\nabla \cdot \mathbf{A} + \mu_0 \epsilon_0 \frac{\partial \phi}{\partial t} \right) = -\mu_0 \mathbf{J}. \tag{68}$$

The four coupled first-order partial-differential equations of Maxwell have been replaced by two coupled second-order partial-differential equations for the potentials. The freedom to make gauge transformations without affecting the fields means that Eqs. (67) and (68) can be decoupled or otherwise put into forms that are simpler or more convenient. For example, potentials can be chosen such that they satisfy the Lorentz condition,

$$\nabla \cdot \mathbf{A} + \mu_0 \epsilon_0 \frac{\partial \phi}{\partial t} = 0. \tag{69}$$

Then the potentials satisfy the standard second-order wave equation (with $\mu_0 \epsilon_0 = 1/c^2$)

$$\nabla^2 \phi - \frac{1}{c^2} \frac{\partial^2 \phi}{\partial t^2} = -\frac{1}{\epsilon_0} \rho, \tag{70}$$

$$\nabla^2 \mathbf{A} - \frac{1}{c^2} \frac{\partial^2 \mathbf{A}}{\partial t^2} = -\mu_0 \mathbf{J}. \tag{71}$$

Potentials that satisfy Eq. (69) are said to be in the class of Lorentz gauge potentials. If the original set did not satisfy Eq. (69), one can make a gauge transformation, Eq. (66), with χ a solution of

$$\nabla^2\chi-\frac{1}{c^2}\frac{\partial^2\chi}{\partial t^2}=-\left(\nabla\cdot\mathbf{A}+\frac{1}{c^2}\frac{\partial\phi}{\partial t}\right). \tag{72}$$

The new potentials will satisfy the Lorentz condition. Since the solution of Eq. (72) is not unique (any solution of the homogeneous wave equation can be added), it is clear that there is an infinite set of potentials in the Lorentz gauge class. Potentials in the Lorentz gauge are convenient because the equations for ϕ and $\mathbf{A}$ are simple decoupled wave equations with source terms given by the charge density ρ and the current density $\mathbf{J}$, respectively.

Another useful choice of gauge is the gauge in which $\nabla\cdot\mathbf{A}=0$, called the Coulomb, transverse, or radiation gauge. Equation (73) for the scalar potential becomes Poisson's equation, with the solution

$$\phi(\mathbf{r},t)=\frac{1}{4\pi\epsilon_0}\int\frac{\rho(\mathbf{r}',t)}{|\mathbf{r}-\mathbf{r}'|}\,d^3x'. \tag{73}$$

The scalar potential is just the *instantaneous* Coulomb potential caused by the charge density $\rho(\mathbf{r},t)$. The vector potential satisfies an inhomogeneous wave equation,

$$\nabla^2\mathbf{A}-\frac{1}{c^2}\frac{\partial^2\mathbf{A}}{\partial t^2}=-\mu_0\mathbf{J}_t,$$

where

$$\mathbf{J}_t=\mathbf{J}-\epsilon_0\nabla\frac{\partial\phi}{\partial t} \tag{74}$$

is the transverse current density, so named because it is the part of the current that has zero divergence, $\nabla\cdot J_t=0$. The name "transverse gauge" comes from this circumstance.

The Coulomb gauge is often used when no sources are present. The scalar potential can be taken to be zero, while $\mathbf{A}$ satisfies the homogeneous wave equation and $\nabla\cdot\mathbf{A}=0$. Then the fields are given solely in terms of $\mathbf{A}$ by Eq. (65) with $\phi=0$. These fields propagate with the speed of light in vacuum, c. A plane wave, harmonic in time with frequency ω and wave vector $\mathbf{k}$, can be represented by a vector potential, $\mathbf{A}=A_0\boldsymbol{\epsilon}\exp(i\mathbf{k}\cdot\mathbf{r}-i\omega t)$, where $|\mathbf{k}|=\omega/c$ and $\mathbf{k}\cdot\boldsymbol{\epsilon}=0$. From Eq. (65), the fields are $\mathbf{E}=i\omega\mathbf{A}$ and $\mathbf{B}=i\mathbf{k}\times\mathbf{A}$. The transversality of the fields ($\mathbf{k}\cdot\mathbf{E}=\mathbf{k}\cdot\mathbf{B}=0$) is manifest, as well as the orthogonality of $\mathbf{E}$ and $\mathbf{B}$. If $\boldsymbol{\epsilon}$ is a real vector, the plane wave is said to be plane polarized, with the directions of $\mathbf{E}$ and $\mathbf{B}$ fixed in space. If $\boldsymbol{\epsilon}$ is complex, e.g., $\boldsymbol{\epsilon}=(\mathbf{e}_1+i\mathbf{e}_2)/\sqrt{2}$, where $\mathbf{e}_1$ and $\mathbf{e}_2$ are real unit vectors, perpendicular to each other and to $\mathbf{k}$, then the wave is elliptically polarized. (The example is a right circularly polarized or positive helicity wave. See OPTICS, LINEAR.)

Since the electric field strength $\mathbf{E}$ has the dimensions of electric potential per unit length (units of V/m) while the magnetic field strength $\mathbf{H}$ has dimensions of current per unit length (units of A/m), their ratio has the dimensions of impedance (V/A or Ω). For a plane wave in free space this ratio is $Z_0=\mu_0\omega/k=\sqrt{\mu_0/\epsilon_0}$, called the impedance of free space, and is equal to 376.730 Ω. Analogous ratios of electric and magnetic fields in transmission lines and wave guides permit the use of lumped-circuit concepts in systems large compared to the free-space wavelength $\lambda=2\pi c/\omega$. (See ELECTROMAGNETIC WAVE PROPAGATION.)

5.2 Green's Functions for the Wave Equation

The first step in solving the wave equation, Eq. (70) or (71) or (74), is to find a Green's function, that is, a solution of the scalar wave equation with a unit impulse source in space and time. If the source point is at $(\mathbf{r}',t')$, the Green's function $G(\mathbf{r},t;\mathbf{r}',t')$ satisfies

$$\nabla^2G(\mathbf{r},t;\mathbf{r},'t')-\frac{1}{c^2}\frac{\partial^2G(\mathbf{r},t;\mathbf{r}',t')}{\partial t^2}$$
$$=-\delta(\mathbf{r}-\mathbf{r}')\delta(t-t'). \tag{75}$$

If there are no boundary surfaces at finite distances in space and time, the Green's function can only be a function of the relative coordinates, $\mathbf{R}=\mathbf{r}-\mathbf{r}'$ and $\tau=t-t'$. Furthermore, the source is spherically symmetric. The Green's function can be a function only of $R=|\mathbf{r}-\mathbf{r}'|$ and τ. Now introduce a frequency-domain Green's function through the Fourier transforms

$$\delta(\tau)=\frac{1}{2\pi}\int_{-\infty}^{\infty}e^{-i\omega\tau}\,d\omega \tag{76}$$

and

$$G(R,\tau)=\frac{1}{2\pi}\int_{-\infty}^{\infty} G(R,\omega)e^{-i\omega\tau}\,d\omega. \qquad (77)$$

The equation obeyed by $G(R,\omega)$ is the inhomogeneous Helmholtz wave equation,

$$\nabla_{\mathbf{R}}^2 G(R,\omega)+k^2G(R,\omega)=-\delta(\mathbf{R}), \qquad (78)$$

where $k^2=\omega^2/c^2$ is the square of the wave number associated with the frequency ω. Because of the spherical symmetry, only the radial part of the Laplacian gives a nonvanishing contribution. For all points with $R\neq 0$, the right-hand side is zero and the equation reads

$$\frac{d^2}{dR^2}RG(R,\omega)+k^2RG(R,\omega)=0$$

with the solution

$$RG(R,\omega)=Ae^{ikR}+Be^{-ikR}.$$

Furthermore, the δ function in Eq. (78) influences the solution only at the origin, where the second term on the left-hand side is negligible compared with the first. In these circumstances, Eq. (78) becomes Laplace's equation of electrostatics; G must reduce to the potential for a point charge and therefore

$$\lim_{kR\to 0} RG(R,\omega)=1/4\pi.$$

The coefficients A and B above must satisfy $4\pi(A+B)=1$.

It is useful to define the so-called retarded and advanced Green's functions, $G_{\pm}(R,\omega)$, to be

$$G_{\pm}(R,\omega)=\frac{1}{4\pi}\frac{e^{\pm ikR}}{R}. \qquad (79)$$

Given the convention of $e^{-i\omega t}$ for time dependence, G_+ (G_-) represents a spherically diverging (converging) wave propagating outwards from (inwards towards) the origin. To understand the designations, retarded and advanced, it is only necessary to insert $G_{\pm}(R,\omega)$ into Eq. (77) to determine the time-domain Green's function,

$$G_{\pm}(R,\tau)=\frac{1}{4\pi R}\,\delta\!\left(\tau\mp\frac{R}{c}\right)$$
$$=\frac{1}{4\pi|\mathbf{r}-\mathbf{r}'|}\,\delta\!\left(t'-\left[t\mp\frac{|\mathbf{r}-\mathbf{r}'|}{c}\right]\right). \qquad (80)$$

Evidently the retarded Green's function, G_+, represents an effect at $(\mathbf{r},t)$ caused by the action of an impulsive source a distance R away acting at an earlier time $t'=t-R/c$. The time difference R/c is just the time of propagation of the disturbance from one point to the other. Similarly, the advanced Green's function G_- represents sources acting at *later* times.

Because causality is observed in natural phenomena, it is customary to express the action of sources only in terms of the retarded Green's function, but that is not necessarily appropriate. Let $\Psi(\mathbf{r},t)$ and $f(\mathbf{r},t)$ represent ϕ (or a component of $\mathbf{A}$) and ρ/ϵ_0 (or a component of $\mu_0\mathbf{J}$), respectively, in the wave equations, Eqs. (70) and (71). It is assumed that $f(\mathbf{r},t)$ is localized in space and time. At remote times, $t\to\pm\infty$, the wave amplitude Ψ is a solution of the homogeneous wave equation. If Ψ is specified to be equal to a given initial wave, $\Psi_{\text{in}}(\mathbf{r},t)$, at $t\to-\infty$, the solution at all times is given in terms of the retarded Green's function,

$$\Psi(\mathbf{r},t)=\Psi_{\text{in}}(\mathbf{r},t)$$
$$+\int\int G_+(\mathbf{r},t;\mathbf{r}',t')f(\mathbf{r}',t')d^3x'\,dt. \qquad (81)$$

With the sources localized in time, it is clear that at early enough times the integral will be zero; the wave will be given by its initial free-wave form. At late times the sources will have acted; Ψ will consist of the initial wave Ψ_{in} plus waves causally radiated outwards from the sources.

If, on the other hand, the wave is specified to be $\Psi_{\text{out}}(\mathbf{r},t)$ for $t\to+\infty$, the solution is in terms of the advanced Green's function, that is, Eq. (81) with "in" replaced by "out" and G_+ replaced by G_-. The radiation field Ψ_{rad} can be defined formally as the difference, $\Psi_{\text{out}}-\Psi_{\text{in}}$:

$$\Psi_{\text{rad}}(\mathbf{r},t)=\int\int [G_+(\mathbf{r},t;\mathbf{r}',t')$$
$$-G_-(\mathbf{r},t;\mathbf{r}',t')]f(\mathbf{r}',t')d^3x'\,dt. \qquad (82)$$

For the usual situation in which the radiation fields are considered only after the sources have acted, G_+ alone is effective; the familiar retarded solution for the radiation fields emerges.

5.3 Harmonic Fields and Potentials in Uniform, Linear, Isotropic, Dispersive Media

The dispersive nature of dielectric constants and the resulting nonlocality in time for the relation between **D** and **E** has been discussed in Secs. 3.4 and 3.5. It is therefore only approximate to generalize the free-space wave equations such as Eqs. (70) and (71) merely by the replacement of μ_0 and ϵ_0 by μ and ϵ. Only if $\epsilon(\omega)$ and $\mu(\omega)$ are sensibly constant over the range of frequencies of interest can one make such a simple substitution. Instead, one must consider one frequency component of the fields at a time. Assume that all the fields and sources oscillate in time according to $e^{-i\omega t}$ and write $\mathbf{E}(\mathbf{r},t)=\mathbf{E}(\mathbf{r})\,e^{-i\omega t}$, etc., where $\mathbf{E}(\mathbf{r})$ is a complex vector field, and similarly for the other fields and sources. With the generally dispersive connections, $\mathbf{D}=\epsilon(\omega)\mathbf{E}$, $\mathbf{B}=\mu(\omega)\mathbf{H}$, appropriate to a linear, isotropic, uniform medium, the Maxwell equations (21) become

$$\nabla\cdot\mathbf{E}=\rho/\epsilon,$$

$$\nabla\times\mathbf{H}+i\epsilon\omega\mathbf{E}=\mathbf{J},$$

$$\nabla\times\mathbf{E}-i\omega\mu\mathbf{H}=\mathbf{0},$$

$$\nabla\cdot\mathbf{H}=0. \tag{83}$$

The continuity equation for charge and current densities now reads $\nabla\cdot\mathbf{J}-i\omega\rho=0$. If the potentials are similarly decomposed into spatial factors times $e^{-i\omega t}$, the fields are related to them via $\mathbf{E}=-\nabla\phi+i\omega\mathbf{A}$ and $\mu\mathbf{H}=\nabla\times\mathbf{A}$. The Lorentz condition, Eq. (70), is generalized for harmonic time dependence, but dispersive media, to $\nabla\cdot\mathbf{A}=i\mu\epsilon\omega\phi$. In the Lorentz class of gauges, the scalar potential is not an independent quantity. Once **A** is known, ϕ can be computed, but it is not needed—fields can be expressed in terms of **A** alone. The equation satisfied by the vector potential is an inhomogeneous Helmholtz wave equation,

$$\nabla^2\mathbf{A}+\mu\epsilon\omega^2\mathbf{A}=-\mu\mathbf{J}. \tag{84}$$

The solution of Eq. (84) can be written down in terms of the frequency-domain retarded Green's function $G_+(R,\omega)$, Eq. (79):

$$\mathbf{A}(\mathbf{r})=\mathbf{A}_{\text{in}}(\mathbf{r})+\mu\int\frac{e^{ikR}}{4\pi R}\,\mathbf{J}(\mathbf{r}')d^3x', \tag{85}$$

where $k=\omega\sqrt{\mu\epsilon}=\omega\sqrt{\mu_r\epsilon_r}/c$ is the wave number at frequency ω in the dispersive medium. This formula can be used to compute the radiation from harmonically driven sources such as antennas. (See ELECTROMAGNETIC RADIATION.)

If there are no external sources of charge and current, but the medium is conducting, the Ohm's-law contribution ($\mathbf{J}=\mathbf{E}/\rho$) can be written explicitly or included in a complex dielectric constant $\epsilon(\omega)$, as described in Sec. 3.4. With the latter choice, the wave equation (84) becomes a homogeneous equation with a complex wave number.

Auxiliary potentials, called electric and magnetic Hertz vectors, $\mathbf{Z}_e$ and $\mathbf{Z}_m$, are sometimes introduced. For harmonic fields and with any Ohm's-law contribution included in $\epsilon(\omega)$, the electric Hertz vector $\mathbf{Z}_e$ is just proportional to **A**. The connections to ϕ and **A** are

$$\phi=-\nabla\cdot\mathbf{Z}_e,\quad \mathbf{A}=-i\omega\mu\epsilon\mathbf{Z}_e. \tag{86}$$

It may be seen that these definitions yield potentials in the Lorentz class of gauges. In the absence of external sources, $\mathbf{Z}_e$ satisfies the homogeneous wave equation and the fields are given by

$$\nabla^2\mathbf{Z}_e+\mu\epsilon\omega^2\mathbf{Z}_e=0,$$

$$\mathbf{E}=\nabla\times\nabla\times\mathbf{Z}_e,$$

$$\mathbf{H}=-i\omega\epsilon\nabla\times\mathbf{Z}_e. \tag{87}$$

Since the Maxwell equations (83) transform into themselves under the simultaneous substitutions $\mu\leftrightarrow-\epsilon$, $\mathbf{E}\leftrightarrow\mathbf{H}$, in the absence of sources, the same transformation can be made in Eq. (87), leading to the magnetic Hertz vector $\mathbf{Z}_m$, which obeys the same wave equation and has the fields given by

$$\mathbf{E}=i\omega\mu\nabla\times\mathbf{Z}_m,$$

$$\mathbf{H}=\nabla\times\nabla\times\mathbf{Z}_m. \tag{88}$$

Hertz originally introduced these "superpotentials" in a treatment of the macroscopic Maxwell equations that kept explicit the polarization and magnetization densities, **P** and **M**, treating them as given external sources. The two Hertz vectors then satisfied inhomogeneous Helmholtz wave equations with **P** and **M** on the right-hand sides, with solutions like

Eq. (85), but with **J** replaced by **P** or **M**. In all but a few circumstances, it is simpler to deal with the usual scalar and vector potentials.

The plane waves described at the end of Sec. 5.1 have their counterparts in uniform, isotropic, linear media. It is only necessary to replace μ_0 and ϵ_0 everywhere by $\mu(\omega)$ and $\epsilon(\omega)$, respectively. The wave number becomes $k=n(\omega)\omega/c$, where $n(\omega)=\sqrt{\mu_r\epsilon_r}$ is the index of refraction of optics.

6. CONSERVATION LAWS FOR ENERGY AND MOMENTUM

6.1 Poynting's Theorem of Conservation of Electromagnetic Energy

An important theorem of Poynting (1884) concerns the continuity equation for the flux of electromagnetic energy and the energy content in the fields. If an infinitesimal point charge δq is acted on by electric and magnetic fields, **E** and **B**, the rate at which the fields do work on the charge is $\delta W=\delta q\,\mathbf{v}\cdot\mathbf{E}$, where **v** is the velocity of the charge. (The magnetic field does no work because the magnetic force is perpendicular to the velocity.) If there is a continuous distribution of charge and current, the total rate of doing work by the fields in a finite volume V is

$$\int_V \mathbf{J}\cdot\mathbf{E}\,d^3x.$$

This power represents a conversion of electromagnetic energy into mechanical or thermal energy and must result in a decrease in the total electromagnetic energy within V. The necessary conservation law is the content of Poynting's theorem. To find the explicit statement, one substitutes for **J** from the second line in Eq. (21):

$$\int_V \mathbf{J}\cdot\mathbf{E}\,d^3x=\int_V \left(\mathbf{E}\cdot(\nabla\times\mathbf{H})-\mathbf{E}\cdot\frac{\partial\mathbf{D}}{\partial t}\right)d^3x. \tag{89}$$

The vector identity

$$\nabla\cdot(\mathbf{E}\times\mathbf{H})=\mathbf{H}\cdot(\nabla\times\mathbf{E})-\mathbf{E}\cdot(\nabla\times\mathbf{H})$$

may be used, together with Faraday's law [third line in Eq. (21)], to transform the right-hand side of Eq. (89) and obtain

$$\int_V \mathbf{J}\cdot\mathbf{E}\,d^3x=-\int_V \left(\nabla\cdot(\mathbf{E}\times\mathbf{H})+\mathbf{E}\cdot\frac{\partial\mathbf{D}}{\partial t}+\mathbf{H}\cdot\frac{\partial\mathbf{B}}{\partial t}\right)d^3x. \tag{90}$$

Three assumptions are needed to proceed further, namely, that the medium is linear, that it is nondispersive, and that the sum of Eqs. (51) and (56), derived in stationary situations, gives the total electromagnetic energy when the fields are time dependent. With these assumptions, the second and third terms on the right-hand side of Eq. (90) represent the time derivative of the total electromagnetic energy density u, where

$$u=\tfrac{1}{2}(\mathbf{E}\cdot\mathbf{D}+\mathbf{B}\cdot\mathbf{H})=\tfrac{1}{2}(\epsilon E^2+\mu B^2). \tag{91a}$$

If the medium is dispersive then **D** and **B** are nonlocal in time and the conversion of the last two terms in Eq. (90) is more complicated. As first shown by Brillouin in 1921 (Brillouin, 1960; Landau *et al.*, 1984, Sec. 80), if the fields are concentrated in frequency around ω, with slow modulation in time, the last two terms in Eq. (90) correspond to the steady time derivative of

$$\bar{u}=\frac{1}{2}\left(\frac{d(\omega\epsilon)}{d\omega}\overline{E^2}+\frac{d(\omega\mu)}{d\omega}\overline{B^2}\right), \tag{91b}$$

where bars denote time averages over the rapid oscillations. If the medium is nondispersive, Eq. (91a) is recovered.

The first term on the right-hand side of Eq. (90) can be converted to a surface integral by means of the divergence theorem. It evidently represents a flow of energy out through the surface S bounding the volume V. It is therefore natural to define an electromagnetic energy flux density, called the *Poynting vector*,

$$\mathbf{S}=\mathbf{E}\times\mathbf{H} \tag{92}$$

with dimensions of energy per unit area per unit time. Equation (90) can then be written as a differential or integral statement of conservation of electromagnetic energy,

$$\frac{\partial u}{\partial t}+\nabla\cdot\mathbf{S}+\mathbf{J}\cdot\mathbf{E}=0,$$

$$\int_V \frac{\partial u}{\partial t}\,d^3x+\int_S \mathbf{n}\cdot\mathbf{S}\,da+\int_V \mathbf{J}\cdot\mathbf{E}\,d^3x=0. \tag{93}$$

The first two terms correspond to the rate of change of electromagnetic energy, either from doing work on charges and currents or from outward flow, while the third is the energy gained by the charges and currents from the fields. Equation (93) is Poynting's theorem.

6.2 Poynting's Theorem for Harmonic Fields and Field Definitions of Impedance and Admittance

A useful form of Poynting's theorem is that of time-averaged quantities with harmonic fields of a single frequency. For such fields the Maxwell equations take the form

$$\nabla\cdot\mathbf{B}=0,$$

$$\nabla\cdot\mathbf{D}=\rho,$$

$$\nabla\times\mathbf{E}-i\omega\mathbf{B}=\mathbf{0},$$

$$\nabla\times\mathbf{H}+i\omega\mathbf{D}=\mathbf{J}, \tag{94}$$

where all the quantities are complex functions of **r** with time dependence, $e^{-i\omega t}$, understood. In keeping with the conventions of Sec. 1 concerning time averages, the time-average rate of doing work on the charge and current distribution is

$$\frac{1}{2}\mathrm{Re}\left(\int_V \mathbf{J}^*\cdot\mathbf{E}\,d^3x\right).$$

If the steps from Eqs. (89)–(93) are repeated with obvious changes, the result is the pair of complex equations,

$$2i\omega(w_e-w_m)+\nabla\cdot\mathbf{S}+\tfrac{1}{2}\,\mathbf{J}^*\cdot\mathbf{E}=0,$$

$$2i\omega\int_V (w_e-w_m)d^3x+\int_S \mathbf{n}\cdot\mathbf{S}\,da+\frac{1}{2}\int_V \mathbf{J}^*\cdot\mathbf{E}\,d^3x=0, \tag{95}$$

where the complex Poynting vector and harmonic electric and magnetic energy densities are

$$\mathbf{S}=\tfrac{1}{2}\,\mathbf{E}\times\mathbf{H}^*,\quad w_e=\tfrac{1}{4}\,\mathbf{E}\cdot\mathbf{D}^*,\quad w_m=\tfrac{1}{4}\,\mathbf{B}\cdot\mathbf{H}^*. \tag{96}$$

Equations (95) and (96) are the harmonic analog of Eq. (93). The real part of Eq. (95) is the statement of conservation of energy for the time-averaged quantities. Its imaginary part relates the reactive or stored energy to its alternating flow.

The complex form of Poynting's theorem, Eq. (95), can be exploited to define the input (junction) impedance of a general, two-terminal, linear, passive, electromagnetic system. Imagine the isolated system within a volume V with boundary surface S, as shown in Fig. 6. Only the two input–output terminals are protruding. Let the complex harmonic current and voltage at the terminals be I_i and V_i. Then the complex power input is $I_i^* V_i/2$. This power is assumed to flow *into* the volume V through the surface S_i, e.g., the cross section of the coaxial line shown in the bottom half of Fig. 6. In terms of the Poynting vector, one has

$$\frac{1}{2}\,I_i^* V_i=-\oint_{S_i} \mathbf{S}\cdot\mathbf{n}\,da,$$

where **n** is the outwardly directed normal to S, as indicated in Fig. 6. Now applying Eq. (95) to the volume V and total surface S, one obtains

$$2i\omega\int_V (w_e-w_m)d^3x+\int_{S-S_i} \mathbf{n}\cdot\mathbf{S}\,da+\frac{1}{2}\int_V \mathbf{J}^*\cdot\mathbf{E}\,d^3x=\frac{1}{2}\,I_i^* V_i. \tag{97}$$

The surface integral on the left represents the energy flow out of the volume V. If the surface $S-S_i$ is taken to infinity, this integral is real and describes escaping radiation. At low frequencies radiation is generally negligible; no distinction need be made between S and S_i; the upper diagram in Fig. 6 is adequate.

The input impedance $Z=R-iX$ (engineers, please recall that the conventions of Sec. 1 imply $j=-i$) of the system follows from Eq. (97) with its definition, $V_i=ZI_i$. The right-hand side of Eq. (97) is $Z|I_i|^2/2$.

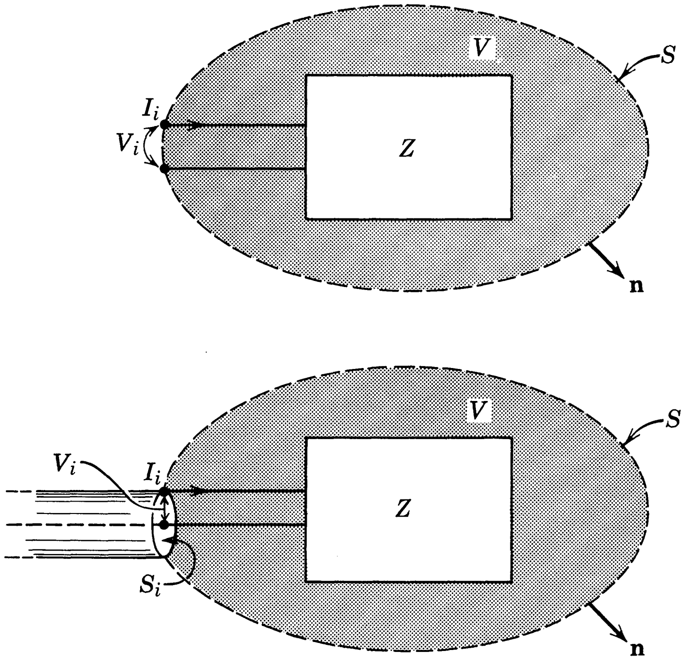

FIG. 6. Schematic diagrams of arbitrary, two-terminal, linear, passive electromagnetic systems. The surface S completely surrounds the system; only the input terminals protrude. At the terminals, the input current and voltage are I_i and V_i, with the input impedance defined through $V_i = ZI_i$. The upper diagram pertains to low frequencies, the lower, with its coaxial feed, to high frequencies where radiation resistance may enter. [From Jackson (1975), reproduced by permission of John Wiley & Sons, Inc.]

The real and imaginary parts of Z are

$$R = \frac{1}{|I_i|^2}\left[\mathrm{Re}\left(\int_V \mathbf{J}^*\cdot\mathbf{E}\,d^3x\right) + 4\omega\,\mathrm{Im}\left(\int_V (w_m - w_e)\,d^3x\right) + 2\int_{S-S_i} \mathbf{n}\cdot\mathbf{S}\,da\right],$$

$$X = \frac{1}{|I_i|^2}\left[4\omega\,\mathrm{Re}\left(\int_V (w_m - w_e)\,d^3x\right) - \mathrm{Im}\left(\int_V \mathbf{J}^*\cdot\mathbf{E}\,d^3x\right)\right]. \tag{98}$$

Here it has been assumed that the power flow out through $S - S_i$ is real. The last term in the expression for R is the *radiation resistance*, important at high frequencies. At low frequencies, the Ohmic losses are generally the only dissipation (**J** in phase with **E**); the electric and magnetic energies densities are real throughout V. Then the expressions simplify to

$$R \approx \frac{1}{|I_i|^2}\int_V \rho|\mathbf{J}|^2\,d^3x,$$

$$X \approx \frac{4\omega}{|I_i|^2}\int_V (w_m - w_e)\,d^3x. \tag{99}$$

Here ρ is the real (low-frequency) resistivity. The expression for the resistance R exhibits the Ohmic heat loss throughout the system. Similarly, the expression for the reactance X shows the expected behavior. If stored magnetic energy dominates, as for a lumped inductance, the reactance is positive, etc. The different dependences on frequency of the reactance for inductances ($X = \omega L$) and capacitances ($X = -1/\omega C$) can be traced to the definition of L in terms of current and voltage ($V = L\,dI/dt$) on the one hand, and of C in terms of charge and voltage ($V = Q/C$) on the other.

The admittance $Y = G - iB$, where G is the conductance and B the susceptance, can be defined via Eq. (97) using $I_i = YV_i$. The low-frequency forms analogous to Eq. (99) are

$$G \approx \frac{1}{|V_i|^2}\int_V \frac{1}{\rho}|\mathbf{E}|^2\,d^3x,$$

$$B \approx -\frac{4\omega}{|V_i|^2}\int_V (w_m - w_e)\,d^3x. \tag{100}$$

It should be noted that the situation depicted in Fig. 6 and the above definitions of impedance or admittance are not immediately applicable to circumstances in which energy input is distributed in space, as, for example, in the exchange of energy between an electron beam and the cavity structure in a magnetron or free-electron laser. Poynting's theorem is applicable and circuit concepts can be used, but care must be taken in the definitions. For example, the voltage V_i in the definition of admittance is replaced by an appropriate line integral of the electric field. For discussions in the microwave domain, see Chap. IX of Slater (1950) or Chap. 2 of Collins (1948).

6.3 Conservation of Momentum, Maxwell Stress Tensor, and Radiation Pressure

The conservation of momentum can be similarly addressed. A particle with infinitesimal charge δq in the presence of fields **E** and **B** experiences a force, called the Lorentz force,

$$\delta\mathbf{F}=\delta q(\mathbf{E}+\mathbf{v}\times\mathbf{B}).$$

If $\mathbf{P}_{\text{mech}}$ is the sum of the mechanical momenta of all the particles within a volume V, Newton's second law can be expressed as

$$\frac{d\mathbf{P}_{\text{mech}}}{dt}=\int_V(\rho\mathbf{E}+\mathbf{J}\times\mathbf{B})d^3x, \qquad (101)$$

where a discrete sum over charged particles is formally replaced by integration over the charge and current densities times the appropriate fields. For simplicity it is assumed that the charges described by ρ and **J** are in otherwise free space, i.e., $\mathbf{D}=\epsilon_0\mathbf{E}$ and $\mathbf{B}=\mu_0\mathbf{H}$, and that the volume V is such that there is no flow of particles into or out of it. If the first two of the Maxwell equations in Eq. (21) are used to eliminate ρ and **J** from Eq. (101), the integrand can be cast in the form

$$\begin{aligned}\rho\mathbf{E}+\mathbf{v}\times\mathbf{B}=&\epsilon_0[\mathbf{E}(\nabla\cdot\mathbf{E})-\mathbf{E}\times(\nabla\times\mathbf{E})]\\&+\mu_0[\mathbf{H}(\nabla\cdot\mathbf{H})-\mathbf{H}\times(\nabla\times\mathbf{H})]\\&-\mu_0\epsilon_0\frac{\partial}{\partial t}(\mathbf{E}\times\mathbf{H}).\end{aligned} \qquad (102)$$

In Cartesian components, the square brackets have the form

$$[\mathbf{E}(\nabla\cdot\mathbf{E})-\mathbf{E}\times(\nabla\times\mathbf{E})]_j=\sum_{k=1}^{3}\frac{\partial}{\partial x_k}(E_jE_k-\tfrac{1}{2}\delta_{jk}\mathbf{E}\cdot\mathbf{E}). \qquad (103)$$

and similarly for the second one. The last term in Eq. (102) has the form of the time derivative of a momentum density ($\mu_0\epsilon_0\,\mathbf{E}\times\mathbf{H}=\mathbf{S}/c^2$). The total electromagnetic momentum within V is thus defined as

$$\mathbf{P}_{\text{em}}=\mu_0\epsilon_0\int_V\mathbf{E}\times\mathbf{H}\,d^3x. \qquad (104)$$

Equation (101) can then be written in component form to express conservation of the sum of mechanical and electromagnetic momentum,

$$\frac{d}{dt}(\mathbf{P}_{\text{mech}}+\mathbf{P}_{\text{em}})_j=\sum_{k=1}^{3}\int_V\frac{\partial}{\partial x_k}T_{jk}\,d^3x, \qquad (105)$$

where the *Maxwell stress tensor* T_{jk} is

$$T_{jk}=\epsilon_0E_jE_k+\mu_0H_jH_k-\tfrac{1}{2}\delta_{jk}(\epsilon_0\mathbf{E}\cdot\mathbf{E}+\mu_0\mathbf{H}\cdot\mathbf{H}). \qquad (106)$$

Application of the divergence theorem to the volume integral in Eq. (105) gives Newton's second law for the combined system of particles and fields within the volume V,

$$\frac{d}{dt}(\mathbf{P}_{\text{mech}}+\mathbf{P}_{\text{em}})_j=-\int_S\sum_k T_{jk}n_k\,da, \qquad (107)$$

where **n** is the *inward*-directed normal to the closed surface S surrounding V. The integrand on the right-hand side of Eq. (107) is evidently the force per unit area transmitted across an element of the surface S and acting on the combined system inside V.

The force per unit area or pressure, $-\Sigma_kT_{jk}n_k$, can be used to calculate forces on material objects such as conductors by integration over an appropriate surface. A simple example of the ponderomotive nature of electromagnetic radiation is *radiation pressure.* A plane wave with wave vector **k** has both **E** and **H** perpendicular to **k**, in the plane of constant phase, with $|\mathbf{E}|=\sqrt{\mu_0/\epsilon_0}|\mathbf{H}|$. The force per unit area in the direction of **k** then comes only from the δ_{jk} terms in Eq. (106). The radiation pressure in the direction of propagation is therefore

$$P_{\text{rad}}=-\sum_{i,j}\hat{k}_iT_{ij}\hat{k}_j=\frac{1}{c}|\mathbf{S}|=u. \qquad (108)$$

Here u is the energy density and **S** the Poynting vector. The pressure (flux of momentum) has the relation to the Poynting vector (flux of energy) expected for relativistically moving (massless) particles (photons). If a plane wave in vacuum is incident and reflected at angle θ to the normal by a perfectly reflecting plane, the radiation pressure on the plane is easily found to be $P_{\text{rad}}=2\cos^2\theta|\mathbf{S}_{\text{inc}}|/c$, where $\mathbf{S}_{\text{inc}}$ is the Poynting vector of the incident wave.

Radiation pressure is the reason why most comets' tails point away from the Sun at perihelion—the dust particles that make up the tail are pushed away from the Sun by the radiation pressure of the solar radiation [a few microjoules per cubic meter or 10^{-11} atmospheres at the radius of the Earth and increasing as $(R_E/R)^2$ at smaller R].

For material media, care must be exercised in defining the purely electromagnetic energy density u, energy flow **S**, momentum flow, and stress tensor T_{jk} because what is considered electromagnetic and what is mechanical is to some extent arbitrary. After all, the mechanical properties of matter are governed by electromagnetic forces, even if the mass is not. It is generally agreed that in matter the energy flow is still given by the **S** of Eq. (92) and that the momentum density is $\mathbf{S}/c^2$. For detailed discussions, see deGroot (1969), and also Landau *et al.* (1984) or Robinson (1973).

7. SPECIAL RELATIVITY AND CLASSICAL FIELD THEORY

7.1 Summary of Results in Special Relativity

The special theory of relativity is based on two postulates:

1. There exists a multiply infinite set of equivalent Euclidean reference frames or coordinate systems moving with constant velocities in rectilinear paths relative to one another in which all physical phenomena occur in an identical matter. For brevity, these frames of reference are called inertial frames. This principle of relativity is very ancient, dating from Copernicus's time or earlier. It conforms with all known observations of ordinary mechanical systems, as well as the Michelson–Morley experiment (failure to detect motion through the putative aether).
2. There is a limiting speed of an object, regardless of the inertial frame from which it is observed. Experimentally, the speed is the speed of light *in vacuo.*

This second postulate, simplicity itself, has radical consequences, changing the concept of time as something absolute and putting it on an equal footing with the spatial coordinates. In high-energy physics, special relativity is verified routinely in very practical ways in the operation of accelerators, in the transport of beams of unstable particles over long distances, etc. See Sec. 11.2 of Jackson (1975) for a discussion of some of the experimental tests.

It is convenient to introduce the time coordinate $x_0=ct$ to give time the same dimensions as the spatial coordinates, $x_1=x$, $x_2=y$, $x_3=z$. Let the unprimed coordinates (x_0,x_1,x_2,x_3) be the coordinates of a point P in space-time with respect to axes fixed in an inertial frame K, and let the primed coordinates (x'_0,x'_1,x'_2,x'_3) be the coordinates of P with respect to axes fixed in the inertial frame K', moving with speed βc parallel to the x_1 axis of K. The axes in the two frames are defined to be parallel to each other and coincident at $x_0=x'_0=0$. The second postulate is equivalent to the invariance of the quantity $x_0^2-x_1^2-x_2^2-x_3^2$. The first postulate implies the isotropy and homogeneity of space-time. Together they lead to the *Lorentz transformation* among the coordinates in K and K',

$$x'_0=\gamma(x_0-\beta x_1),\quad x'_1=\gamma(x_1-\beta x_0),$$
$$x'_2=x_2,\quad x'_3=x_3. \tag{109a}$$

The Lorentz factor γ is

$$\gamma=1/\sqrt{1-\beta^2}. \tag{109b}$$

If the coordinate axes in K and K' remain parallel, but the velocity $\mathbf{v}=\boldsymbol{\beta}c$ of frame K' with respect to frame K is in an arbitrary direction, the Lorentz transformation (109a) has the generalization

$$x'_0=\gamma(x_0-\boldsymbol{\beta}\cdot\mathbf{x}),$$
$$\mathbf{x}'=\mathbf{x}+\frac{\gamma-1}{\beta^2}(\boldsymbol{\beta}\cdot\mathbf{x})\boldsymbol{\beta}-\gamma\boldsymbol{\beta}x_0. \tag{110}$$

Energy and momentum of a particle transform in the same manner as the time and space coordinates. If E is the particle's total energy (including its rest energy, mc^2) and $\mathbf{p}$ its momentum, then $(p_0=E/c, p_1, p_2, p_3)$ transform in the same way as (x_0, x_1, x_2, x_3). One calls the four quantities a four-vector and sometimes writes $x^\mu=(x_0; \mathbf{x})$. Similarly, $p^\mu=(p_0; \mathbf{p})$ is the energy–momentum four-vector. For electromagnetic radiation, $k_0=\omega/c$ and $\mathbf{k}$ form the frequency–wave vector four-vector. The four quantities G^μ $(\mu=0,1,2,3)$ form a four-vector if they transform under the above Lorentz transformation in the same way as the space and time coordinates, namely,

$$G_0'=\gamma(G_0-\beta G_1), \quad G_1'=\gamma(G_1-\beta G_0),$$

$$G_2'=G_2, \quad G_3'=G_3, \tag{111}$$

or the relations equivalent to Eq. (110) for a general velocity $\mathbf{v}$ of K' in K. The inverse transformation is obtained by interchanging primed and unprimed coordinates and changing the sign of β or $\boldsymbol{\beta}$.

Application of Eq. (111) to frequency and wave number yields the *relativistic Doppler formulas*,

$$\omega'=\gamma\omega(1-\beta\cos\theta),$$

$$\tan\theta'=\sin\theta/\gamma(\cos\theta-\beta), \tag{112}$$

where θ and θ' are the angles of $\mathbf{k}$ and $\mathbf{k}'$ relative to the direction of $\mathbf{v}$, the relative velocity of the inertial frame K' with respect to K. The inverse relations can be obtained by interchanging primed and unprimed quantities and reversing the sign of β. The more familiar nonrelativistic Doppler shift has $\gamma\approx 1$ in Eq. (112). The presence of $\gamma\geqslant 1$ shows that there is a frequency shift even for radiation emitted perpendicular to the velocity. This relativistic effect has been detected for rapidly rotating sources (but still $\beta\ll 1$) by means of the Mössbauer effect.

The relativistic law of transformation for velocity is not that of a four-vector. Let $\mathbf{u}'$ be a velocity in the frame K', and let the velocity of K' with respect to K be $\mathbf{v}$. Then the velocity $\mathbf{u}$ in K has components parallel $(u_\parallel)$ and perpendicular $(\mathbf{u}_\perp)$ to $\mathbf{v}$ given by

$$u_\parallel=\frac{u_\parallel'+v}{1+(\mathbf{v}\cdot\mathbf{u}')/c^2}, \quad \mathbf{u}_\perp=\frac{\mathbf{u}_\perp'}{\gamma_v[1+(\mathbf{v}\cdot\mathbf{u}')/c^2]}. \tag{113}$$

Here γ_v is the Lorentz factor associated with the velocity $\mathbf{v}$. The inverse relation is obtained by interchanging primed and unprimed quantities and changing the sign of $\mathbf{v}$. For parallel velocities, the first equation in Eq. (113) shows that, while the intuitive sum of velocities holds for nonrelativistic speeds, the factor in the denominator assures that the second postulate is not violated. In particular, if $u'=c(1-\epsilon)$ and $v=c(1-\epsilon_v)$, then $u\approx c(1-\epsilon\epsilon_v)$, correct to second order in small quantities.

While velocity does not transform in the same way as energy and momentum, a closely related four-vector, U^μ, the four-velocity, can be defined through the ratio of a particle's four-momentum to its mass, i.e., $U^\mu=(\gamma c; \gamma\mathbf{u})$. The four-vector law of transformation, Eq. (111) can be applied to U^μ and then expressions for the parallel and perpendicular components of $\mathbf{u}$ in terms of $\mathbf{u}'$ and $\mathbf{v}$ can be found; Eq. (113) results.

Because of the possibility of interpreting the invariant quantity, $s^2=x_0^2-x_1^2-x_2^2-x_3^2$, as the square of a "length" in a non-Euclidean space, it is useful to introduce the ideas of upper and lower indices, of a metric tensor, and the Einstein summation convention of implicit summation over any repeated index, one lower and one upper. Thus the familiar coordinates (ct,x,y,z) form a contravariant four-vector $x^\mu=(x^0=ct, x^1=x, x^2=y, x^3=z)$. The covariant four-vector $x_\mu=(x_0=ct, x_1=-x, x_2=-y, x^3=-z)$ is obtained from x^μ through multiplication by the metric tensor $g^{\mu\nu}$. Thus $x_\mu=g_{\mu\nu}x^\nu$, where $g^{\mu\nu}=g_{\mu\nu}$ and the only nonvanishing elements are

$$g^{00}=1, \quad g^{11}=g^{22}=g^{33}=-1. \tag{114}$$

The invariant "length" can then be written $s^2=x_\mu x^\mu$. The differential invariant length element in the space described by the metric tensor, Eq. (114) (called Minkowski space), is $(ds)^2=g_{\alpha\beta}\,dx^\alpha\,dx^\beta=dx_\beta\,dx^\beta=dx^\alpha\,dx_\alpha$. The scalar product of two four-vectors is defined as $A\cdot B=A_\mu B^\mu=A^0B^0-\mathbf{A}\cdot\mathbf{B}$, where boldface type means an ordinary vector in three-space. It should be noted that the Jacobian

$$J(x,x')=\frac{\partial(x^0,x^1,x^2,x^3)}{\partial(x'^0,x'^1,x'^2,x'^3)}$$

connecting the four-dimensional volume element $d^4x\equiv dx^0dx^1dx^2dx^3$ and $d^4x'\equiv dx'^0\,dx'^1dx'^2dx'^3$ is equal to unity. The four-volume element is therefore "invariant."

In Minkowski space, differential operators are defined appropriately as

$$\partial^\alpha \equiv \frac{\partial}{\partial x_\alpha} = \left(\frac{\partial}{\partial x^0}, -\nabla\right),$$

$$\partial_\alpha \equiv \frac{\partial}{\partial x^\alpha} = \left(\frac{\partial}{\partial x^0}, \nabla\right),$$

$$\Box \equiv \partial_\alpha \partial^\alpha = \frac{\partial^2}{\partial x^{02}} - \nabla^2. \qquad (115)$$

The four-divergence of a four-vector A^μ is the invariant quantity

$$\partial^\alpha A_\alpha = \partial_\alpha A^\alpha = \frac{\partial A^0}{\partial x^0} + \nabla \cdot \mathbf{A}, \qquad (116)$$

an equation familiar from the continuity of charge and current densities ρ and $\mathbf{J}$, and the Lorentz condition for the potentials ϕ and $\mathbf{A}$. (Here is the first suggestion of specific Lorentz transformation properties of electromagnetic quantities.) The second line in Eq. (115) shows that the wave-equation operator is a Lorentz-invariant four-dimensional Laplacian (denoted by $\Box$).

7.2 Relativistic Formulation of Electrodynamics

If $c\rho$ and $\mathbf{J}$ are interpreted as the time and space components of a four-vector density J^μ, the continuity equation for charge and current, Eq. (9), can be expressed in the invariant divergence form of Eq. (116):

$$\partial_\mu J^\mu = 0. \qquad (117)$$

The validity of such an identification can be inferred from the fact that electric charge is known experimentally to be a Lorentz-invariant quantity. [See Sec. 11.9 of Jackson (1975) for a brief discussion.] Since $\rho\, dx\, dy\, dz = \rho\, dx^1\, dx^2\, dx^3$ is such a quantity of charge and since the four-dimensional volume element d^4x is invariant, one can infer that the charge density ρ transforms as dx^0, that is, as the time component of a four-vector. The requirement that the continuity equation must be true in all inertial frames then forces $\mathbf{J}$ to be the space part of the same four-vector $J^\mu = (c\rho; \mathbf{J})$.

The Lorentz condition, Eq. (69), takes the invariant form of Eq. (116) if the potentials ϕ/c and $\mathbf{A}$ are identified as the components of a four-vector potential $A^\mu = (\phi/c; \mathbf{A})$. The wave equations, Eqs. (70) and (71), are seen to involve the invariant four-dimensional Laplacian operator, with components of the four-vector potential on one side and the four-current density on the other. They therefore provide a properly Lorentz-covariant description summarized in the wave equation

$$\Box A^\mu = \mu_0 J^\mu \qquad (118)$$

with the invariant subsidiary condition,

$$\partial_\nu A^\nu = 0. \qquad (119)$$

The definitions of the electric and magnetic fields in terms of the potentials [Eq. (65)] can be shown to imply that the field strengths $(E_x, E_y, E_z, B_x, B_y, B_z)$ are the elements of a second-rank, antisymmetric, field-strength tensor $F^{\mu\nu} = \partial^\mu A^\nu - \partial^\nu A^\mu$. The explicit form as a matrix array is

$$F^{\mu\nu} = \begin{pmatrix} 0 & -E_x/c & -E_y/c & -E_z/c \\ E_x/c & 0 & -B_z & B_y \\ E_y/c & B_z & 0 & -B_x \\ E_z/c & -B_y & B_x & 0 \end{pmatrix}. \qquad (120)$$

The Maxwell equations can be written in covariant form as

$$\partial_\alpha F^{\alpha\beta} = \mu_0 J^\beta,$$

$$\partial^\alpha F^{\beta\delta} + \partial^\beta F^{\delta\alpha} + \partial^\delta F^{\alpha\beta} = 0. \qquad (121)$$

The first equation embodies Coulomb's law ($\beta=0$) and the three Ampère–Maxwell equations ($\beta = 1,2,3$); the second, in which α, β, and δ are any three of (0,1,2,3), the four source-free equations. Note that current conservation is implicit in the first equation in (121). If the four-divergence is taken of both sides, the antisymmetric nature of $F^{\alpha\beta}$ means that $\partial_\beta \partial_\alpha F^{\alpha\beta} = 0$ and Eq. (117) is recovered. The completely antisymmetric unit tensor $\epsilon_{\alpha\beta\gamma\delta} = -\epsilon^{\alpha\beta\gamma\delta}$ (defined to be zero if two or more indices are the same, and equal to ± 1 depending on the even or odd number of permutations of the indices needed to go from $\epsilon_{0123} = +1$) can be used to define the dual field-strength tensor, $\mathscr{F}^{\alpha\beta} = \frac{1}{2}\epsilon^{\alpha\beta\gamma\delta} F_{\gamma\delta}$, which has the general appearance of Eq. (120), but with the roles of $\mathbf{E}$ and $\mathbf{B}$ interchanged (and some signs different). The contraction of $F^{\alpha\beta}$ with itself and with its dual tensor yield two Lorentz-invariant combinations, quadratic in the field strengths:

$$F_{\alpha\beta}F^{\alpha\beta} = -2(\mu_0\epsilon_0\mathbf{E}\cdot\mathbf{E} - \mathbf{B}\cdot\mathbf{B}),$$

$$F^{\alpha\beta}\mathscr{F}_{\alpha\beta} = -4\sqrt{\mu_0\epsilon_0}\,\mathbf{E}\cdot\mathbf{B}. \qquad (122)$$

The Lorentz transformation properties of the field strengths as a second-rank tensor can be expressed in vectorial form as

$$\mathbf{E}' = \gamma(\mathbf{E} + \mathbf{v}\times\mathbf{B}) - \frac{\gamma^2}{\gamma+1}\,\boldsymbol{\beta}(\boldsymbol{\beta}\cdot\mathbf{E}),$$

$$\mathbf{B}' = \gamma(\mathbf{B} - \boldsymbol{\beta}\times\mathbf{E}/c) - \frac{\gamma^2}{\gamma+1}\,\boldsymbol{\beta}(\boldsymbol{\beta}\cdot\mathbf{B}). \qquad (123)$$

The fields $\mathbf{E}'$ and $\mathbf{B}'$ are those in the inertial frame K', which is moving with velocity $\mathbf{v} = \boldsymbol{\beta}c$ with respect to the frame K. The inverse transformation is obtained, as usual, by interchanging primed and unprimed quantities and changing the sign of $\mathbf{v}$ (and $\boldsymbol{\beta}$).

Consider a point charge q at rest in K', with electric field $\mathbf{E}' = q\mathbf{r}'/4\pi\epsilon_0 r'^3$ and $\mathbf{B}' = \mathbf{0}$ in that frame. In the frame K the charge is moving with velocity $\mathbf{v}$. The inverse of Eq. (123) shows that, to first order in β (i.e., the nonrelativistic approximation), the electric field in K is the same as before, but there is now a magnetic field,

$$\mathbf{B} \approx \frac{\mu_0}{4\pi}\,\frac{q\mathbf{v}\times\mathbf{r}}{r^3}, \qquad (124)$$

which is just the Ampère–Biot–Savart expression for the magnetic field of a moving charge.

The above considerations are restricted to the Maxwell equations in vacuum, apart from the source four-vector, J^{μ}. For a description of the relativistic formulation of moving media, where $(\mathbf{E}/c,\mathbf{B})$, $(c\mathbf{P},\mathbf{M})$, and $(c\mathbf{D},\mathbf{H})$ are separately second-rank tensors (with the electric and magnetic properties of the medium defined in its rest frame), see Pauli (1958) or Penfield and Haus (1967).

7.3 Lagrangian Formulation of Electrodynamics

The powerful methods of Lagrangians, familiar in the classical mechanics of systems with a finite number of degrees of freedom, can be applied to continuous systems (with an infinite number of degrees of freedom). The finite number of coordinates and velocities, $q_i(t)$, $\dot{q}_i(t)$, $i = 1,2,3,\ldots,n$, are replaced by continuous fields and their derivatives. The discrete index i is replaced by the continuous space-time coordinate x^{μ} and perhaps by a finite number of discrete values at each x^{μ}. The correspondences are $q_i(t) \to \phi_k(x)$, $\dot{q}_i(t) \to \partial^{\beta}\phi_k(x)$. Here x stands for the space and time coordinates, and there are N different fields ϕ_k, $k = 1,2,3,\ldots,N$, defined at each point x. The dynamics is defined by a Lagrangian density $\mathscr{L}$ whose integral over all three-space is the Lagrangian L. The Euler–Lagrange equations follow from the stationary property of the action integral (of L over time) with respect to variations $\delta\phi_k$ and $\delta(\partial^{\beta}\phi_k)$ around the physical values. There are thus the following correspondences:

$$i \to x^{\mu},k,$$

$$q_i \to \phi_k(x),$$

$$\dot{q}_i \to \partial^{\beta}\phi_k(x),$$

$$L = \sum_i L_i(q_i,\dot{q}_i) \to \int \mathscr{L}(\phi_k,\partial^{\beta}\phi_k)\,d^3x,$$

$$\frac{d}{dt}\left(\frac{\partial L}{\partial \dot{q}_i}\right) = \frac{\partial L}{\partial q_i} \to \partial^{\beta}\frac{\partial\mathscr{L}}{\partial(\partial^{\beta}\phi_k)} = \frac{\partial\mathscr{L}}{\partial\phi_k}. \qquad (125)$$

The action integral S takes the form

$$S = \int dt \int d^3x\,\mathscr{L} = \int \mathscr{L}\,d^4x. \qquad (126)$$

The necessary Lorentz-invariant nature of the action is preserved provided the Lagrangian density $\mathscr{L}$ is a Lorentz scalar. By analogy with discrete-particle dynamics it is expected that the kinetic energy part of the Lagrangian density is quadratic in the velocities, i.e., in $\partial^{\beta}\phi_k$. The combination, $\partial^{\beta}\phi_k\partial_{\beta}\phi_k$, for each k has the required invariance under Lorentz transformations. Additional terms in $\mathscr{L}$ depend on the physical properties of the fields and their interactions.

For the electromagnetic field, the four-vector potential A^{β} plays the role of the set of ϕ_k. The Lagrangian density is expected to be quadratic in the derivatives $\partial^{\alpha}A^{\beta}$ or equivalently in $F^{\alpha\beta}$. Equation (122) displays the only Lorentz-invariant quadratics in $F^{\alpha\beta}$. Restriction of $\mathscr{L}$ to a scalar under spatial inversions eliminates the second form and leaves a multiple of $F^{\alpha\beta}F_{\alpha\beta}$ as the only possibility. If one recalls that the Hamiltonian (energy) density involves subtraction of $\mathscr{L}$ and compares Eq. (91) with the first term in Eq. (122), it is apparent that the Lagrangian density must be

$$\mathscr{L}=-\frac{1}{4\mu_0}F_{\alpha\beta}F^{\alpha\beta}-J_\alpha A^\alpha. \tag{127}$$

The interaction of the potentials with the external sources J^β has also been included. In order to find the Euler–Lagrange equations of motion [last line in Eq. (125)], the Lagrangian density must be written in terms of the potentials:

$$\mathscr{L}=-\frac{1}{4\mu_0}g_{\lambda\mu}\,g_{\nu\sigma}(\partial^\mu A^\sigma-\partial^\sigma A^\mu)(\partial^\lambda A^\nu-\partial^\nu A^\lambda) \\ -J_\alpha A^\alpha. \tag{128}$$

The ingredients of the Euler–Lagrange equation of motion are

$$\frac{\partial\mathscr{L}}{\partial(\partial^\beta A^\alpha)}=-\frac{1}{\mu_0}F_{\beta\alpha}=\frac{1}{\mu_0}F_{\alpha\beta},\quad \frac{\partial\mathscr{L}}{\partial A^\alpha}=-J_\alpha$$

with the equation of motion taking the form

$$\partial^\beta F_{\beta\alpha}=\mu_0 J_\alpha, \tag{129}$$

equivalent to the first equation in Eq. (121). The homogeneous Maxwell equations do not emerge as Euler–Lagrange equations of motion—they are already implicit in the definition of the fields in terms of the potentials (See Sec. 5.1).

7.4 Further Ramifications

The reader who wishes to explore further ramifications of the relativistic formulation of classical field theory may consult Landau and Lifshitz (1975), Rohrlich (1990), or Soper (1976). Construction of the relativistic generalization of the Hamiltonian density (called the stress–energy–momentum tensor) and its connection to a unified description of the conservation of energy and momentum are discussed briefly in Jackson (1975), Sec. 12.10, and in the just cited references.

GLOSSARY

Admittance: Symbol, $Y=G-iB$ (engineers: read $Y=G+jB$); reciprocal of impedance (Z).

Ampere: The SI unit of electric current, abbreviated A, equal to one coulomb per second.

Capacitance: Amount of charge carried by a conductor raised to a potential difference of one volt.

Capacitance, Coefficients of: Generalization of capacitance; geometrical coefficients for a given configuration of conducting surfaces and linear dielectric media between, which permit the total electrostatic energy to be expressed in terms of the potentials of the conductors—see Eq. (54).

Causality: Loosely, cause precedes effect; the response of a system to an external stimulus always follows in time the application of the stimulus. In relativity, it also involves the concept that signals do not travel faster than the speed of light in vacuum.

Conductivity: Symbol, σ; local property of conducting media, reciprocal of resistivity.

Constitutive Relations: Relations specifying the dielectric and magnetic properties of a medium.

Coulomb: The SI unit of electric charge, abbreviated C. The magnitude of the charge on the electron or the proton in this unit is $e=1.6022\times10^{-19}$ C.

Dielectric Constant: Symbol, $\epsilon(\omega)$ [or $\epsilon_r(\omega)$, for $\epsilon(\omega)/\epsilon_0$]; frequency-dependent proportionality between electric displacement and electric field in simple linear media. More generally a tensor, $\epsilon_{jk}(\omega)$.

Dispersion: Property of dielectrics or magnetic media that the product of the wavelength and the frequency of electromagnetic waves depends on the frequency (in vacuum, $\lambda\nu=c$).

Dispersion Relations: Relations between the real and imaginary parts of the dielectric constant; consequences of causality—see Eq. (46). Have applications in other fields.

Displacement, Electric: Symbol **D**; field variable in dielectrics, related to electric field and electric polarization—see Eq. (24). The SI unit is coulomb per square meter.

Electric Field: Symbol, **E**; a vectorial quantity, defined at a given space-time point as the mechanical force per unit charge experienced by an infinitesimal test charge placed at the point. The SI unit is volts per meter.

Electromotive Force: Line integral of the electric field around a closed path in space; accompanies a magnetic flux density changing in time.

Farad: The SI unit of capacitance, abbreviated F; one coulomb per volt.

Gauge, Gauge Transformation: Particular choice of scalar and vector potentials; modification of choice of potentials, without change in the physically observable quantities.

Henry: The SI unit of inductance, abbreviated H. One henry equals one volt–second per ampere.

Hertz Vectors: Auxiliary potentials used in solution of the wave equation—see Sec. 5.3.

Impedance: Symbol, $Z=R-iX$ (engineers: read $R+jX$). Complex quantity with dimensions of resistance (ohms) that describes the magnitude and phase of the voltage across the terminals of an electrical device with respect to an input current.

Impedance of Free Space: Constant ($\sqrt{\mu_0/\epsilon_0}$) with dimensions of resistance; ratio of electric to magnetic field strengths in a plane electromagnetic wave in vacuum. Numerically, $\sqrt{\mu_0/\epsilon_0}=376.730\ \Omega$.

Inductance: Symbol, L (self-inductance) or M_{12} (mutual inductance); geometrical property of a coil of wire or other circuit describing its ability to develop a voltage difference across it when the current through it (or a neighboring circuit) changes with time—a manifestation of Faraday's law. Symbolically, $V=L\,dI/dt$. The SI unit is the henry.

Inductance, Coefficients of: Totality of self- and mutual inductances of a configuration of circuits, permitting the total energy of the configuration to be expressed in terms of the currents in the circuits—see Eq. (60).

Kramers–Kronig Relations: Another name for dispersion relations.

Linear Media: Substances whose induced electric or magnetic polarizations are linear in externally applied fields.

Lorentz Transformation: Linear transformation in special relativity of space-time coordinates from one coordinate frame to another moving at uniform velocity with respect to the first. More generally, the transformation of four-vectors and higher-rank four-tensors.

Magnetic Field: Symbol, **H**; field variable related to the magnetic flux density and magnetization—see Eq. (24). The SI unit is ampere-turn per meter.

Magnetic Flux Density: Symbol, **B**; analog for currents of electric field. Defined in magnitude as force per unit current, but directions of current flow, **B**, and force are not parallel—see discussion above Eq. (6). The SI unit is the tesla (sometimes, weber per square meter).

Magnetization: Symbol, **M**; macroscopic magnetic property of a substance, the average molecular or atomic magnetic dipole moment density—see Sec. 3.1. The SI unit is ampere per meter.

Maxwell Stress Tensor: Symbol, T_{jk}; tensor bilinear in the electric and magnetic field strengths, used to calculate electromagnetic forces—see Eq. (106).

Minkowski Space: Non-Euclidean space-time—see Eq. (114).

Ohm: The SI unit of resistance, abbreviated Ω; one ohm is equal to one volt per ampere.

Ohm's Law: Law obeyed by many conducting substances: current density locally is proportional to electric field. Generally, there is a tensor of proportionality; often it is a scalar quantity.

Plasma Frequency: Symbol, ω_p; material property governing the high-frequency behavior of dielectric constants—see Eq. (38); depends only on density of electrons (not details of atomic structure).

Polarization, Electric: Symbol, **P**; macroscopic electric property of a substance, the average molecular or atomic electric dipole moment density—see Sec. 3.1. The SI unit is coulomb per square meter.

Pressure, Radiation: Electromagnetic momentum per unit area per unit time.

Resistance: Symbol, R; property of conductor or circuit element to limit the flow of current for a given applied voltage. Symbolically, $V=IR$. The SI unit is the ohm.

Resistance, Radiation: Effective resistance of a radiating element; ratio of radiated power to the square of the driving current.

Resistivity: Symbol, ρ; local property of a conducting substance; enters Ohm's law: $\mathbf{E}=\rho\mathbf{J}$.

Permeability of Free Space: Constant (μ_0) entering the relation between electric current and magnetic flux density [see Eq. (8)]. Defined to be $\mu_0=4\pi\times10^{-7}$ henrys per meter.

Permittivity of Free Space: Constant (ϵ_0) entering the relation between charge and electric field [see Eq. (3)]. Its inverse, divided by 4π, is a 17-digit number related to the speed of light in vacuum. Numerically, $\epsilon_0=8.854\ 19...\times10^{-12}$ farads per meter.

Potential, Four-Vector: Symbol, A^{μ}; set of four potentials, ϕ and the three components of **A**, which transform relativistically in the same way as $x^{\mu}=(x^0,\mathbf{x})$.

Potential, Scalar: Symbol, ϕ; in static situations, the difference $\phi(\mathbf{r}_1)-\phi(\mathbf{r}_2)$ represents the line integral of the electric field from the point $\mathbf{r}_1$ to the point $\mathbf{r}_2$.

Potential, Vector: Symbol, **A**; an auxiliary field related to the magnetic flux density through $\mathbf{B}=\nabla\times\mathbf{A}$.

Skin Depth: Symbol, δ; depth of penetration of fields into a good conductor—see Eq. (39).

Système Internationale (SI): An internationally agreed system of weights and measures; roughly, the metric system.

Tesla: The SI unit of magnetic flux density, abbreviated T; one tesla is equal to one newton per ampere–meter.

Volt: The SI unit of electric potential difference, abbreviated V; one volt equals one joule per coulomb.

INTRODUCTION

Electroluminescence (EL) is a nonthermal generation of light resulting from the application of an electric field to a substance. Although this definition includes light-emitting diodes (LEDs), they are not discussed here; rather they are considered elsewhere in the Encyclopedia (see LIGHT-EMITTING DIODES). EL devices are divided into four types according to the phosphor configuration and the drive-voltage wave forms: ac powder EL, dc powder EL, ac thin-film EL, and dc thin-film EL. Besides these, organic thin-film EL (Tang and VanSlyke, 1987) is of interest, although this belongs to the LED family. Among these,

two types are now commercially available: ac thin-film EL devices (ZnS:Mn) are used as flat screens of laptop personal computers and word processors, and ac powder EL devices are used as backlights for liquid-crystal displays.

High-field electroluminescence was discovered by Destriau in 1936 (Destriau, 1936). Light emission from a ZnS phosphor powder dispersed in an insulator and sandwiched between two electrodes was observed when a high ac voltage was applied. Until 1950, when transparent electrically conductive films made of SnO_2 were developed, no effort was made to develop practical devices. With use of these SnO_2 transparent conductive films, ac powder EL devices were developed, which triggered worldwide research and development of EL devices.

During the period from 1950 to 1960, basic studies on the ac powder EL devices were carried out actively, aiming at flat light sources for wall illumination. However, it was not possible to overcome the weaknesses of these ac powder EL devices: low luminance, low luminous efficiency, and short lifetime. Thus, the first era of EL development gradually drew to a close.

In 1968, the second period of EL development began with dc powder EL devices (Vecht *et al.*, 1968) and ac thin-film EL devices using Lumocen (luminescence from molecular centers) (Kahng, 1968; Chase *et al.*, 1969). The former were made possible by coating powder EL phosphor surfaces with copper ions. These devices were intensively studied because technical advantages of producing large-area multiplexed panels were expected at relatively low production cost. In the latter, rare-earth fluorides as molecular centers were doped into ZnS thin films. These developments were made possible by advances in electronics and materials science, especially in new process technologies and device structures. Thin-film EL devices benefitted, in particular, from development of the double-insulating-layer structure (Russ and Kennedy, 1967), which overcame the problems of short lifetime and low luminance. Inoguchi *et al.* (1974) obtained stable high-luminance thin-film EL panels with this structure, and Mito *et al.* (1974) showed that these EL panels could be used as a TV imaging system. Since then, this type of EL device has been investigated most intensively among the four types because of the highest possibility of practical use.

In regard to the production of thin-film EL panels, Ueda *et al.* (1981) reported on practical EL display units, and Takeda *et al.* (1981) reported on practical application technologies of ZnS:Mn EL display panels. With use of these technologies, mass production of 6-in.-diagonal matrix EL panels started in 1983 (Takeda *et al.*, 1983).

At this point, we consider dc thin-film EL development. Cusano (1962) showed that the luminance of a ZnS:Mn thin film coated with copper gradually increases during operation as a result of an electrical forming process. Although the fabrication process was improved, luminance and reliability improvements were not realized, and interests in dc thin-film EL faded away. It should be noted, however, that low-voltage ($\sim$10 V) driven ZnSe:Mn dc thin-film EL devices were studied using the molecular-beam deposition method (Mishima *et al.*, 1983; Mishima and Takahashi, 1983).

The following treatment concentrates on ac thin-film EL devices, which are all-solid and emissive displays with the following characteristics: fast response, wide viewing angles, high resolution, wide operating temperatures, light weight, and good display quality. Displays with 640×400 dots are now in mass production, and higher-resolution A4-sized display devices with 1024×800 dots (Schmachtenberg *et al.*, 1989) are being developed. These display devices are compatible with high-resolution cathode ray tubes (CRTs). Table 1 lists the specifications of commercially available thin-film EL display devices.

To show more information on the screen, multicoloring of EL displays is necessary. For this purpose, phosphor materials that emit three primary colors, i.e., red, green, and blue, are necessary. Beginning with the pioneering work by Kahng and co-workers (Kahng, 1968; Chase *et al.*, 1969), extensive studies have been conducted on materials and processing technologies. Most efforts were concerned with the ZnS host material doped with various rare-earth luminescent centers. Green-emitting ZnS:Tb,F EL devices were obtained with high luminance and high luminous efficiency, close to those of ZnS:Mn (Ogura *et al.*, 1986; Ohnishi *et al.*, 1987). Despite all these efforts, however, the maximum luminances of blue-emitting ZnS:Tm,F EL devices and red-emit-

ting ZnS:Sm,F EL devices are low compared with those of green-emitting ZnS:Tb,F EL devices (Kobayashi *et al.*, 1985). But recently, bright red EL emission has been obtained by using ZnS:Mn phosphor with a thin-film red filter made of CdSSe (Tuenge and Kane, 1991). And ZnS-based phosphors have been utilized in the fabrication of prototype multicolor thin-film EL devices (Yamauchi *et al.*, 1987; Yamamoto *et al.*, 1989).

In order to obtain efficient color EL phosphors, many studies have been directed to new host materials and luminescent centers. It was found that alkaline-earth sulfides, such as SrS and CaS, doped with rare-earth luminescent centers were promising phosphor materials (Barrow *et al.*, 1984; Tanaka *et al.*, 1985). As these phosphors were good cathodoluminescence phosphors (Lehmann, 1972), they were used for dc power EL phosphors (Higton *et al.*, 1978; Vecht, 1980). The thin-film EL phosphors CaS:Eu and SrS:Ce also seemed promising, and prototype multicolor display panels were fabricated with them (Barrow *et al.*, 1986).

The present review discusses the characteristics of EL devices, with an emphasis on double-insulating-layer type thin-film EL devices, materials requirements, material deposition methods, color EL materials, multicolor EL devices, and reliability. For other topics, readers are referred to the review articles by Howard (1981), Mach and Müller (1982), Kobayashi (1983), Alt (1984), and Ohnishi (1989).

1. EL DEVICE STRUCTURES AND EL EMISSION MECHANISMS

In this section device structures and emission mechanisms of four kinds of EL devices are described. The characteristics of organic thin-film EL diode devices are also discussed.

1.1 ac Powder EL

This type of EL device was first developed by Sylvania in the first era of EL devices. Now they are used as backlights of liquid-crystal displays. The device structure is shown in Fig. 1. The phosphor layer consists of a suitably doped ZnS powder (5–20-μm grains) suspended in a dielectric, which acts as a binder as well. The phosphor layer is sandwiched between two electrodes, one of which is transparent, and is supported by a substrate, consisting of either glass or flexible plastic. As a dielectric, organic material, such as cyanoethylcellulose, or low-melting glass is used. An insulating layer may be placed between the phosphor layer and the rear electrode to avoid catastrophic dielectric breakdown. The important point is that the ZnS grains should be isolated from each other, as shown in the enlarged view of the phosphor layer. In the case of good isolation, an insulating layer is not necessary.

Electric fields of 10^4–10^5 V/cm are necessary to obtain EL emission. Luminance increases proportionally with frequency up to 10 kHz but lifetime is decreased in the same proportion. The luminance level is about 100

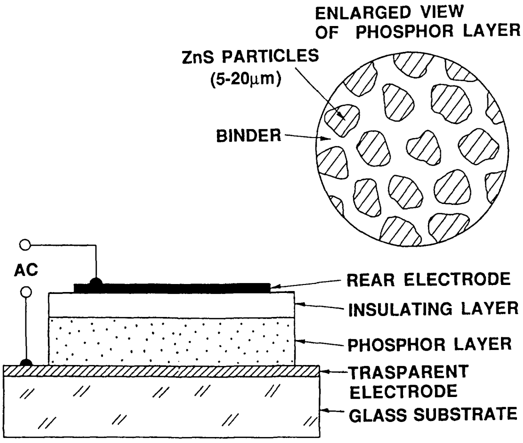

FIG. 1. Cross-sectional device structure of ac powder EL device. Enlarged view of phosphor layer is also shown.

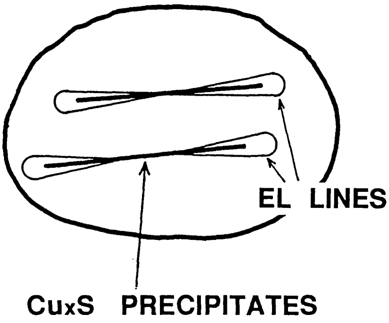

FIG. 2. EL emission mechanism of ac powder EL device (after Fischer, 1963).

cd/m^2 at a voltage of 300 V and frequency of 400 Hz and luminous efficiency is about 1 lm/W.

Emission colors can be controlled by adding different kinds of luminescent centers. A combination of Cu and Cl (ZnS:Cu,Cl) gives either blue (~460 nm) or green (~510 nm) emission, depending on the relative amount of Cl. This EL emission is caused by the recombination transition of *D-A* (donor–acceptor) pairs, where Cu constitutes an acceptor and Cl constitutes a donor. The combination of Cu and Al (ZnS:Cu,Al) gives green and the addition of Mn to Cu and Cl (ZnS: Cu,Cl,Mn) gives yellow (~590 nm). An advantage of this type of EL device is easy control of emission colors by mixing different phosphors with different emission colors.

The EL emission mechanism is considered to be as follows (Fischer, 1962, 1963). EL powders fired at high temperatures have the hexagonal structure but subsequent cooling transforms them into the cubic (zinc blende) structure. Then copper exceeding the solubility limit precipitates on defects. The result is embedded Cu_xS conducting needles, indicated by Cu_xS precipitates in Fig. 2. These precipitates act to concentrate an applied electric field at their tips, and therefore an applied field of 10^4–10^5 V/cm can induce a local field of 10^6 V/cm or more. This electric field is strong enough to induce tunneling of holes from one end of the needle and electrons from the other. The holes are trapped on Cu recombination centers, and upon reversal of the fields the emitted electrons recombine with the trapped holes to produce light. Thus EL emission occurs along the Cu_xS precipitates, as indicated by the EL lines. Larger particle sizes lead to longer needles and greater field enhancement.

Lifetime is a key issue for the application of this EL device. The half-life, defined by the time when the luminance becomes $\frac{1}{2}$ the initial value, now exceeds 10 000 hours through the improvement of phosphor treatment conditions. However, it is very difficult to have both long lifetime and high luminance simultaneously because they are trade-off characteristics.

1.2 dc Powder EL

Since the pioneering work by Vecht *et al.* (1968), dc powder EL devices have been extensively studied in Great Britain. Now commercial panels with the configuration of 640×200 dots are available. In the dc powder EL device, a fine (0.5–1 μm) Mn-doped ZnS powder is deliberately prepared with a Cu_xS coating, and a layer of the powder with a small amount of binder is formed into a device, as shown in Fig. 3. In contrast to the ac powder EL case, there is no insulating layer. To obtain stability and emission uniformity, a forming process is necessary. When a voltage is first applied, a large current flows, the layer heats up, and gradually a narrow region ~1 μm thick adjacent to the SnO_2 anode, begins to luminesce (see Fig. 4).

FIG. 3. Cross-sectional device structure of dc powder EL device. Enlarged view of phosphor layer is also shown.

The emission color of ZnS:Mn,Cu is yellow (~590 nm). In ZnS-based EL devices activated by rare-earth ions, Tm^{3+} gives blue emission, Tb^{3+} and Er^{3+} give green emission, and Nd^{3+} and Sm^{3+} give red emission. In CaS- and SrS-based EL devices, SrS:Ce,Cl gives blue-green emission, CaS:Ce,Cl gives green emission, and CaS:Eu,Cl gives red emission. Luminous efficiency, however, is not high with values of 0.2–0.3 lm/W.

Figure 4 shows the microscopic model of dc powder EL. In the forming process, electromigration drives all copper out of a high-field region near the anode. As the width of this copper-free region grows, the field is progressively reduced. Under a high electric field, electrons, which have tunneled out of the Cu_xS at the edge of the formed region, are accelerated and excite Mn^{2+} luminescent centers by impact. When the excited electrons make transitions radiatively to the ground state, EL emission is realized.

1.3 ac Thin-Film EL

Since Inoguchi *et al.* (1974) reported on high-luminance, long-lifetime EL devices, ac thin-film EL with the double-insulating-layer structure has been the center of research and development. A schematic structure of this type of EL device is shown in Fig. 5, where a thin-film phosphor layer is sandwiched between thin-film insulating layers. These thin films are deposited on the ITO (indium tin oxide)-coated glass substrate, and Al rear electrodes are deposited on the second insulating layer. The thicknesses of the phosphor and the insulating layers are 0.5–1 and 0.3–0.5 μm, respectively. When an ac voltage of about 200 V is applied between the ITO and Al electrodes, EL emission is realized.

The double-insulating-layer type EL devices have the following advantages:

1. Double insulating layers can protect the phosphor layer against impurities and moisture from outside, to ensure higher stability.
2. In this structure, direct electron flows from electrodes to the phosphor layer are prevented, resulting in a high breakdown electric field.
3. Trapped charges at the phosphor layer/insulating layer interfaces cause internal

polarization, which increases the effective electric field under ac drive conditions. As a result, luminous efficiency and luminance are increased.

Emission colors can be controlled by adding different luminescent centers. ZnS:Mn gives orange-yellow emission with the highest luminance. In the ZnS-based EL devices activated by rare-earth ions, ZnS:Tb,F gives green emission, ZnS:Tm,F gives blue emission, and ZnS:Sm,F gives orange-red emission. In the CaS- and SrS-based EL devices, SrS:Ce gives blue-green emission, CaS:Ce gives green emission, and CaS:Eu gives red emission. It should be noted that copper, which is used in powder EL, is not used in ac thin-film EL because copper ions migrate under a high electric field ($\sim 10^6$ V/cm), causing deterioration of the EL device characteristics.

The details of the equivalent-circuit model and the EL emission mechanism are given in Sec. 2.1.

1.4 dc Thin-Film EL

This type of EL device has the simplest structure: a thin film of phosphor layer with electrodes on both sides. Several attempts have been carried out by depositing a thin-film phosphor layer of ZnS:Mn, ZnS:Cu,Cl, and ZnS:Mn,Cu to increase stability and luminance, but good results have not been obtained. Since the basic problem with the device is tendency toward catastrophic failure, employment of a current-limiting layer should be considered. Kobayashi *et al.* (1989) succeeded in fabricating a stable ZnS:Mn EL device by inserting a thick resistive powder layer made of MnO_2 between the phosphor layer and rear electrode. They called this device dc thin-film-powder hybrid EL. The luminous efficiency was 0.8 lm/W and the lifetime was more than 20 000 h.

1.5 Organic Thin-Film EL

Figure 6 shows the structure of an organic thin-film EL diode device (Tang and Van Slyke, 1987; Tang *et al.*, 1989). The substrate is an ITO-coated glass and the first organic layer (about 75 nm) is a hole-transport layer made of amorphous diamine film of molecular structure shown in Fig. 6. The second organic layer (about 60 nm) is the luminescent layer as well as an electron-transport layer, made of 8-hydroxyquinoline aluminum (Alq_3) shown in Fig. 6. The rear electrode is a mixture of Mg and Ag with an atomic ratio of 10:1. The emission color of undoped Alq_3 was green, and a luminance of more than 1000 cd/m^2 and a luminous efficiency of 1.5 lm/W were achieved at a dc pulse driving voltage of 10 V. In the device with an Alq_3 layer doped with fluorescent molecules, the EL quantum efficiency was about 0.025 photon/electron. The EL color was tuned from blue-green to orange-red by a suitable choice of dopants as well as by changing the concentration of the dopant. The electron–hole recombination and emission zones were confined to about 5 nm near the hole-transport interface.

Adachi *et al.* (1988) introduced a three-layer structure made up of a hole-transport layer, a luminescent layer, and an electron-transport layer. By separating the luminescent function from the hole- or electron-transport layers, it became possible to select luminescent-layer materials freely to obtain different emission colors. Figure 7 shows the

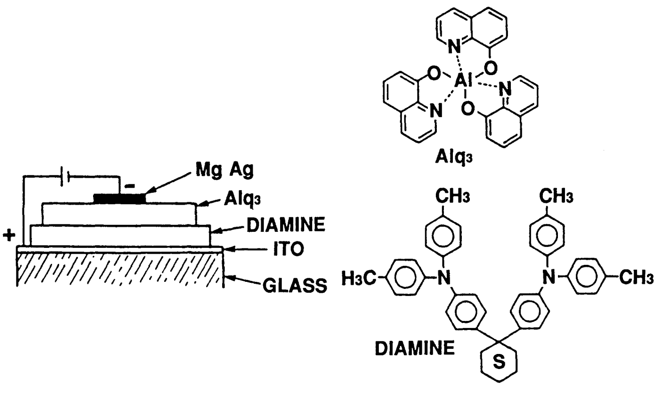

FIG. 6. Configuration of organic EL diode device and molecular structures of Alq_3 and diamine (after Tang and VanSlyke, 1987).

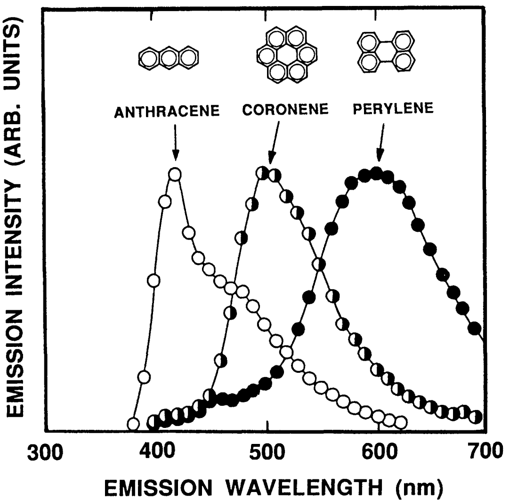

FIG. 7. EL emission intensities of three layered organic EL diode devices with emitter materials; open circles are for anthracene, half-black and half-open circles are for coronene, and black circles are for perylene. Chemical structures of these are shown above (after Adachi *et al.*, 1988).

results: By changing the luminescent-layer material from anthracene to coronene to perylene, the emission color changed from blue to green to red. Here an aromatic diamine and a perylene tetracarboxylic acid derivative were used for the hole- and electron-transport materials, respectively.

Lifetime is a key issue for the application of this EL diode device.

2. PHYSICS OF ac THIN-FILM EL

In this section the physics of ac thin-film EL devices with double-insulating-layer structure is discussed. First, based on the current–voltage (I-V) characteristics, an equivalent-circuit model is introduced and the EL emission mechanism is discussed by use of an energy-band diagram. Then detailed treatments of the electro-optical characteristics are given, and the physical and chemical properties of phosphor materials and luminescent centers of color thin-film EL are described.

2.1 Equivalent-Circuit Model and EL Emission Mechanism

Figure 8 shows the current density vs voltage (I-V) and phase difference vs voltage (ϕ-V) characteristics under 1-kHz sinusoidal-wave drive conditions. The I-V profile is given by two straight lines linked with a kink, the voltage of which corresponds to the threshold voltage. The profile of the phase difference ϕ between current and voltage indicates that below the threshold voltage, only the displacement current flows with 90° phase difference. On the other hand, above the threshold voltage, conduction current in phase with the voltage starts to flow, and with the increase in voltage the phase difference decreases from 90°, indicating that more in-phase conduction current flows. The impedance of the EL device can be estimated from the I-V characteristics. The results are as follows: Below the threshold voltage, the estimated capacitance is equal to the total capacitances of the insulating layer, the phosphor layer, and the insulating layer in series, with the phosphor layer being a capacitor. This indicates that the phosphor layer has high resistivity and acts as an insulator. Above the threshold voltage, the estimated capacitance is equal to the total capacitances of only the insulating layers in series, with the phosphor layer being shunted. This indicates that the phosphor layer loses its insulting characteristics, and electrons at the interface states between the phosphor layer and the insulating layers are injected into the conduction band through a tunneling effect.

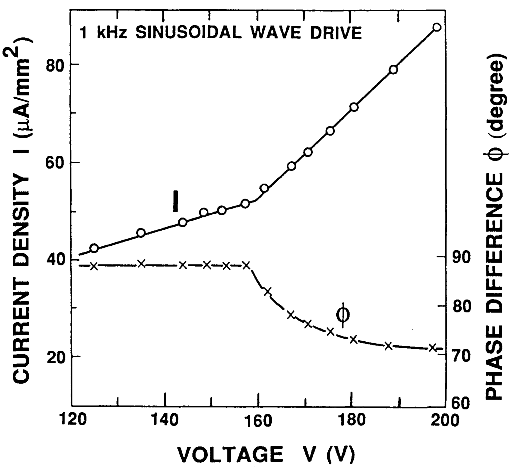

FIG. 8. Current density vs voltage (I-V) and phase difference vs voltage (ϕ-V) characteristics of an ac thin-film EL device with a double-insulating-layer structure.

When the drive voltage becomes larger than the threshold voltage, the average electric field in the phosphor layer becomes (1.3–

1.8) × 10^6 V/cm. Only above this electric field can electrons flow in the phosphor layer. Since EL emission occurs only above the threshold voltage, EL excitation can be considered to be due to this electron flow. It has been verified experimentally (Chen and Krupka, 1972; Smith, 1981; Ono *et al.,* 1989) that the electric field of the phosphor layer is kept at a constant value above the threshold voltage (clamp effect). Therefore, the excess voltage is placed on the insulating layers. This indicates the importance of insulating layers against dielectric breakdown of the EL device.

The above arguments lead to the equivalent-circuit model shown in Fig. 9. Here C_I indicates the effective capacitance of the insulating layers, $C_I = C_{I1}C_{I2}/(C_{I1}+C_{I2})$, with C_{I1} and C_{I2} being the capacitances of the first and second insulating layers, respectively. C_{EL} is the capacitance of the EL phosphor layer, and D_I indicates a bidirectional switching device, which is turned on when the electric field in the phosphor layer becomes larger than the threshold electric field. In an ideal case, this switch can be simulated by back-to-back Zener diodes.

On the basis of the above discussion, the EL emission mechanism is indicated in Fig. 10, which shows an energy-band diagram of the EL device. The EL emission occurs in the following way.

1. Above the threshold voltage, electrons are injected from the interface states between the phosphor layer and insulating layer by high-field–assisted tunneling.
2. The injected electrons are accelerated and gain kinetic energy large enough to excite luminescent centers or the host lattice.
3. High-energy electrons, which are called hot electrons, directly excite luminescent centers through the impact-excitation mechanism. When these electrons in the excited states of the luminescent centers make radiative transitions to the ground state, EL emission is realized.
4. The hot electrons travel through the phosphor layer and are finally trapped at the phosphor–insulator interface states on the anode side, causing polarization.
5. When the polarity of the ac voltage wave forms is reversed, the same process takes place in the opposite direction in the phosphor layer.

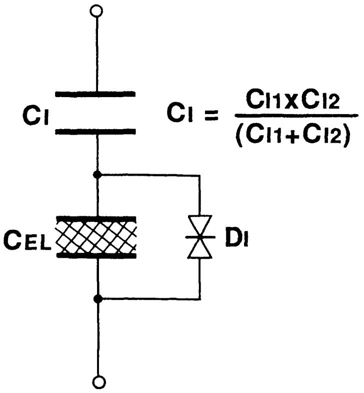

FIG. 9. Equivalent-circuit model of double-insulating-layer type ac thin-film EL device. C_I is the total capacitance of insulating layers in series, with C_{I1} and C_{I2} being capacitances of the first and second insulating layers. C_{EL} is the capacitance of EL phosphor layer, and D_I indicates a bidirectional switch which is on above the threshold electric field.

Since the tunnel injection is temperature insensitive, ac thin-film EL devices can be used over a wide temperature range from −100 to 100 °C.

This mechanism is generally accepted for ZnS-based EL devices (Smith, 1981; Alt, 1984; Okamoto and Miura, 1986; Mikami *et al.,* 1988). In CaS- or SrS-based EL devices, however, an additional mechanism has been proposed (Crandall, 1987a; Tanaka *et al.,* 1988a; Yoshiyama *et al.,* 1989). This additional mechanism is characterized by a field-induced ionization of luminescent centers and subsequent trapping of low-energy electrons, resulting in EL emission.

Since the luminance is approximately proportional to the transferred charge within the phosphor layer (Alt, 1984; Ono *et al.,* 1987), an increase in the transferred charge is necessary to improve luminance. Furthermore, the excitation probability of the luminescent centers by hot electrons should be improved, where the excitation probability is a function of the energy received by hot electrons from the electric field, i.e., a function of the product of the electric field and mean free path. The electric field is limited by the clamp electric field, while the mean free path depends on the crystallinity of the phosphor-layer thin films. From these arguments, an increase in transferred charge density and better crystallinity are necessary to improve luminance.

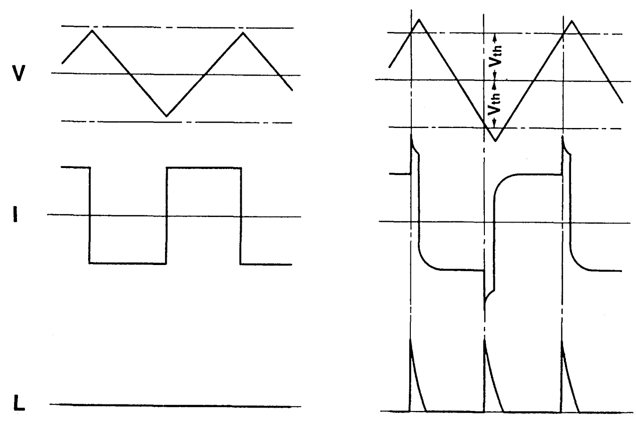
2.2 Electro-Optical Characteristics

Figure 11 shows schematic characteristics of the voltage wave form *V*, the current wave form *I*, and the EL-emission wave form *L* under triangular-wave drive conditions. Below the threshold voltage V_{th}, only a constant displacement current flows and no EL emission results. On the other hand, above V_{th} an additional current flows in the time period when the voltage is larger than V_{th}. This additional current corresponds to an in-phase current that flows through the phosphor layer, causing EL emission, as indicated in the EL-emission wave form *L*. The rise time and decay time of *L* for a ZnS:Mn EL device are of the order of several μs and several ms, respectively. As shown in Fig. 11, there are two EL emissions in one cycle. Therefore, luminance



(a) V < Vth

(b) V > Vth

FIG. 11. Schematic characteristic diagrams of voltage wave form *V*, current wave form *I*, and EL emission waveform *L* under triangular-wave drive condition for double-insulating-layer type ac thin-film EL devices. (a) $V < V_{th}$; (b) $V > V_{th}$.

is proportional to the drive frequency up to several kHz.

Figure 12 shows typical luminance vs voltage (L-V) and luminous efficiency vs voltage (η-V) characteristic curves of ZnS:Mn EL devices with the thickness of the phosphor layer being 0.65 μm. Light emission starts when the voltage becomes larger than the threshold voltage V_{th}, and luminance L increases very sharply with the increase in voltage. The threshold voltage is defined by the voltage corresponding to a luminance of 1 cd/m^2. As indicated in the figure, L_{30} is defined by the luminance at 30 V above V_{th}. This value is very important because under practical drive conditions, the drive voltage is usually set at 30 or 40 V above V_{th}. The sharp increase in luminance is due to tunnel injection of electrons from trap states at the phosphor layer/insulating layer interface. On the other hand, the luminous efficiency η increases just above V_{th} and has a maximum in the voltage region where a steep increase of luminance takes place. Above this voltage region, η decreases slowly. To calculate η [lm/W], luminance L and input power density into the EL devices, P_{in} [W/cm^2], must be measured because η is defined by the following equation (Ono *et al.*, 1987):

$$\eta[\mathrm{ln/W}] = (\pi L[\mathrm{cd/m^2}]/P_{in}[\mathrm{W/cm^2}]) \times 10^{-4}.$$

An estimation method of input power density P_{in} is described by Smith (1981), Tiku and Smith (1984), and Ono *et al.* (1987), based on the Sawyer–Tower circuit shown in Fig. 13. Here a sinusoidal-wave drive condition is employed, and C_t and C_s are the total capacitance of the EL device and the capacitance of sense capacitor, respectively. A schematic charge vs voltage (Q-V) characteristic diagram is shown on an oscilloscope, where charge Q is given by the product of C_s and V_y. In order that the partial voltage of the sense capacitor V_y be much smaller than the total voltage V, the condition $C_t/C_s \ll 1$ must be satisfied. Under this condition accurate Q-V characteristic diagrams can be obtained. In Fig. 14, an enlarged Q-V characteristic diagram is shown together with physical quantities: V_{th} is the threshold voltage of the whole EL device, $V_{th,EL}$ is the threshold voltage of the phosphor layer, ΔQ is the transferred charge,

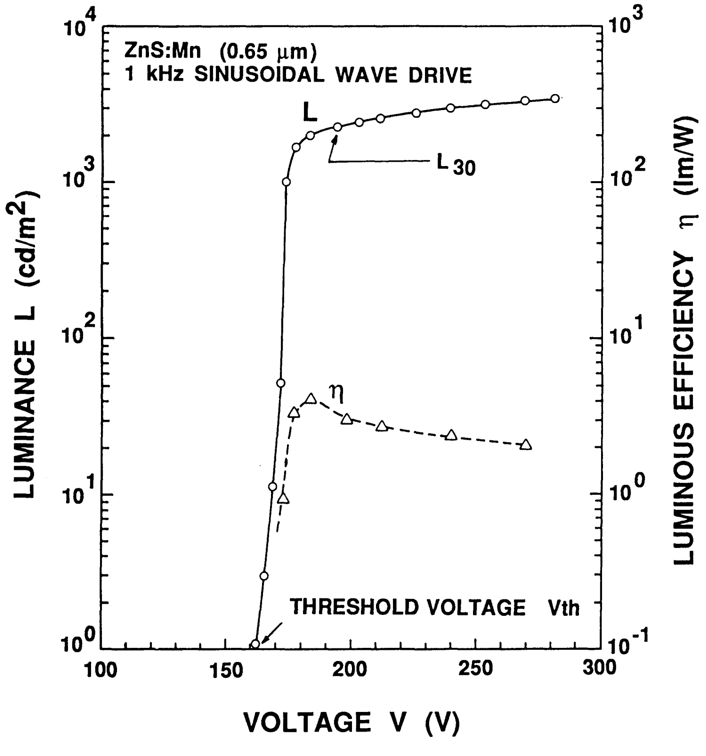


FIG. 12. Typical luminance vs voltage (L-V) and luminous efficiency vs voltage (η-V) characteristic curves of thin-film EL devices and definition of the threshold voltage (after Mikami *et al.*, 1991).

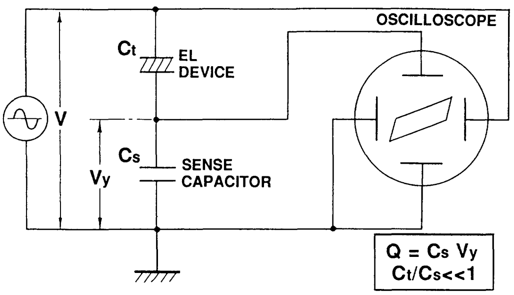

FIG. 13. Charge vs voltage (*Q-V*) characteristic measuring circuit based on Sawyer–Tower circuit (after Ono *et al.*, 1987).

and Q' is the charge remaining in the EL device when V becomes 0 V. Here $V_{th,EL}$ is given by $V_{th}C_I/(C_I+C_{EL})$. The input power density P_{in} is given by the product of drive frequency f and the input energy density per cycle, E_{in}, given by the area encompassed by the Q-V diagram divided by the pixel area A. On the assumption of a parallelogram form for the Q-V diagram, P_{in} is given by

$$P_{in}=fE_{in}=2fV_{th,EL}\Delta Q/A=4fV_{th}Q'/A.$$

As luminance depends on the drive frequency and drive wave forms, it is recommended that the frequency and drive wave form be indicated when luminance values are discussed. Recommended drive wave forms are sinusoidal waves and pulse waves of alternate polarity with frequencies of 50 or 60 Hz or 1 kHz. Furthermore, voltage should be indicated by zero-to-peak values, rather than the rms values, since luminance depends on the peak voltage values.

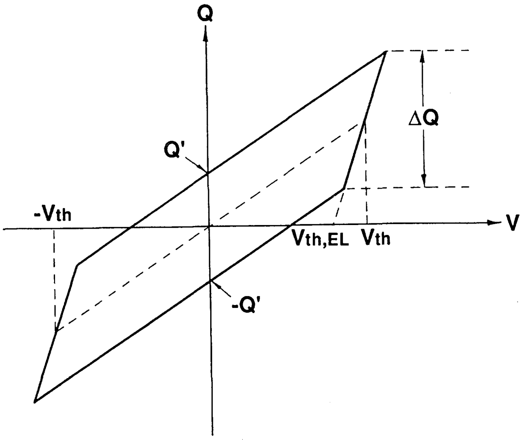

FIG. 14. Charge vs voltage (*Q-V*) characteristic diagram with definitions of physical quantities: V_{th} is the threshold voltage of the EL device, $V_{th,EL}$ is the threshold voltage of the phosphor layer, ΔQ is the transferred charge, and Q' s is the remaining charge in the EL device when V becomes 0.

In regard to increasing the luminance, the light-trapping effect in a ZnS:Mn ac thin-film EL device with a double-insulating-layer structure is discussed. As shown in Fig. 15, a ZnS:Mn phosphor layer with a refractive index n of 2.3 is sandwiched by insulating layers with smaller values of refractive indices, such as Y_2O_3 ($n=1.9$), Al_2O_3 ($n=1.63$), Si_3N_4 ($n=2.0$), or SiO_2 ($n=1.46$). Furthermore, the refractive index of glass is 1.53, larger than the refractive index of air, 1.0. Therefore, a large part of the EL emissions from the phosphor layer do not go through the glass substrate into air; rather they are trapped within the EL device. Various estimates indicate that only 10% of the generated light exits through the front glass surface. Scattering in thin films also affects light output. Increased light output via scattering can be bought at the expense of contrast.

On the other hand, when viewed from the edge of the EL devices, a very bright EL emission can be observed. An application of this edge emission has been proposed (Kun *et al.*, 1986) in the field of electrophotographic printers, i.e., thin-film edge-emitter arrays for the optical image bar in place of a scanning laser with a rotating mirror or LED arrays.

2.3 Physical and Chemical Properties of Phosphor Materials and Luminescent Centers

Phosphor materials of thin-film EL devices are required to have EL emission from the doped luminescent centers and to hold a high

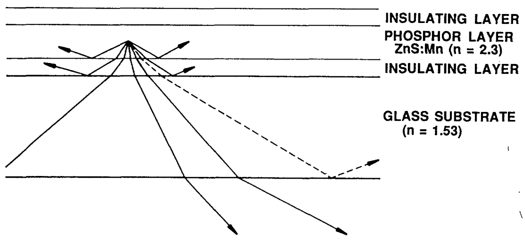

FIG. 15. Schematic representation of light-trap effect in ZnS:Mn ac thin-film EL devices with double-insulating-layer structure. Refractive indices of typical insulating-layer materials are as follows: Y_2O_3, $n=1.9$; Al_2O_3, $n=1.63$; Si_3N_4, $n=2.0$; and SiO_2 $n=1.46$.

electric field of about 10^6 V/cm. For these purposes, wide-gap semiconductors of II-VI compounds are used—IIb-VIb compounds such as ZnS and IIa-VIb compounds such as CaS and SrS. The IIb-VIb compounds have the cubic zinc-blende or hexagonal wurtzite crystal structure. On the other hand, the more ionic IIa-VIb compounds have the rocksalt or sodium chloride structure. Thus alkaline-earth sulfides, such as CaS and SrS, have different properties from ZnS. Table 2 summarizes the material parameters of typical phosphor host materials. The ionic radii of Ca^{2+} and Sr^{2+} are very close to those of rare-earth ions (Table 3). Furthermore, their chemical properties are very similar. Therefore, CaS and SrS are expected to be good candidates for accepting rare-earth ions as luminescent centers. However, since these phosphor materials have hygroscopic characteristics, encapsulation is necessary.

For the luminescent centers, luminescence of the donor–acceptor type is not plausible because a very high electric field is necessary to obtain EL emission. Therefore only isolated luminescent centers are suitable. As indicated in Sec. 2.1, EL emission results from impact excitation of luminescent centers by high-energy electrons accelerated by a high electric field. Because of this, luminescent centers weakly coupled to host materials, i.e., isolated luminescent centers, are expected to have high luminous efficiency. From these discussions, transition-metal ions, such as Mn, and rare-earth ions, such as Tb, Sm, Tm, Eu, and Ce, are found to be suitable luminescent centers.

The rare-earth ions have an open $4f$ shell, which is screened by the outer electrons in the $5s^2 5p^6$ closed shells. Therefore the $4f$ electrons of rare-earth ions in the host materials are not greatly influenced by crystal fields. Two different types of luminescent transitions can be observed: a parity-forbidden f-f intrashell transition, and the parity-allowed f-d transition. Examples of EL emission due to the f-f transition are the green emission from Tb^{3+}, red emission from Sm^{3+}, blue emission from Tm^{3+}, and white emission from Pr^{3+}. Eu^{2+} and Ce^{3+} produce EL emission due to f-d transitions. The $5d$ electrons are easily affected by the crystal field. Therefore the excited energy levels depend on the host material, and the EL emission color can be varied by changing it.

To dope with transition metals or rare-earth elements effectively, matching of chemical properties and ionic radii between the cations of the host phosphor materials and the dopant luminescent centers is very important. Table 3 lists the ionic radii of Zn^{2+}, Ca^{2+}, Sr^{2+}, and rare-earth luminescent-center ions. Since rare-earth ions have different valencies and ionic radii from those of Zn^{2+}, it is difficult to dope them uniformly into ZnS hosts at high concentration. To overcome this difficulty, doping methods featuring addition of charge compensators (Tanaka *et al.*, 1987a) or molecular luminescent centers (Chase *et al.*, 1969) have been proposed, and fluorides or sulfides of these luminescent centers have been used.

3. MATERIALS REQUIREMENTS

In this section, the requirements of materials used in thin-film EL devices with double-insulating-layer structure are discussed in terms of optical, electrical, and physical characteristics.

Table 2. Material parameters of phosphor host materials.

Items	ZnS	CaS	SrS
Melting point (°C)	1000–1900	2400	>2000
Band gap (eV)	3.6	4.4	4.3
Type of transition	Direct	Indirect	Indirect
Refractive index	2.3	—	2.1
Relative dielectric constant	8.3	9.3	9.4
Crystal structure	Zinc blende	NaCl type	NaCl type
Lattice constant (Å)	5.409	5.697	6.019
Ionic radius of cation (Å)	0.74	0.99	1.13
Ionicity	0.623	>0.785	>0.785

Table 3. Ionic radii of Zn^{2+}, Ca^{2+}, Sr^{2+}, and rare-earth luminescent-center ions.

Ion	Ionic radius (Å)
Zn^{2+}	0.74
Ca^{2+}	0.99
Sr^{2+}	1.13
Ce^{3+}	1.034
Pr^{3+}	1.013
Sm^{3+}	0.964
Eu^{2+}	1.09
Eu^{3+}	0.950
Tb^{3+}	0.923
Tm^{3+}	0.869
Mn^{2+}	0.80

3.1 Glass Substrates

The characteristics and surface conditions of the glass substrates control the properties and reliability of EL devices. During EL fabrication, severe processing conditions are used, such as high-temperature (~550 °C) annealing and immersion in acid or alkaline fluids, and so the glass substrates must be heat resistant and acid and alkali resistant. Furthermore, diffusion of alkali-metal ions from the glass into the phosphor layer must be prevented, because they deteriorate the EL characteristics. This has led to nonalkaline phosphosilicate glasses being used for EL devices. A final requirement is that the glass surface be as smooth as that for photomasking.

Physical properties required of the glass substrates are as follows:

1. a high softening temperature, i.e., above 650 °C;
2. low or no alkali-metal content;
3. a high electrical resistivity; and
4. an expansion coefficient that matches that of the deposited films.

Much of the thin-film EL work done to date has used Corning 7059 glass; it is a nonalkaline phosphosilicate glass with high thermal resistivity (Faulkner *et al.,* 1983). The softening temperature of this glass is, however, 598 °C, and glass substrates with higher softening temperature are desired.

3.2 Transparent Conducting Films

Large conductivity values and high transmittance are necessary for transparent conducting films for EL devices, and indium tin oxide (ITO: In_2O_3–10 wt % SnO_2) is best suited. Because of the good characteristics of the thin films obtained and the high production yield, electron-beam deposition (EBD) and sputtering methods are employed to deposit ITO films (Shimizu and Matsudaira, 1985).

A small electrical resistance is required for EL devices. Presently the sheet resistance of typical ITO thin films is about 10–20 Ω/□. The sheet resistance can be decreased by increasing the film thickness, which in turn increases the slope of the etching edge of the ITO stripe electrodes, causing a decrease in the breakdown electric field of the first insulating layer deposited just above the ITO electrode. From experiments it has been found that the film thickness should be less than 150 nm. Then the resistivity must be smaller than 10^{-4} Ω cm, which is the smallest value obtainable at present.

3.3 Insulating Layers

The most important role of the insulating layers is to protect the phosphor layers from electric breakdown. Additionally they must prevent metal-ion diffusion into the phosphor layer and provide interface states at the boundary of the phosphor layer and the insulating layer. From these interface states, electrons are injected into the conduction band of the phosphor layer through tunneling when the applied electric field is larger than the threshold electric field.

For these purposes, the following properties are required (Howard, 1977; Alt, 1984; Tiku and Smith, 1984):

1. high breakdown electric field (E_{BD});
2. high dielectric constant ($\epsilon_0\ \epsilon_r$);
3. small number of pinholes;
4. small tan δ; and
5. good adhesiveness.

Here ϵ_0 and ϵ_r are the dielectric constant of a vacuum and relative dielectric constant, respectively; tan δ is a measure of dissipative characteristics defined by $1/2\pi fCR$, where f is the drive frequency, C is the capacitance, and R is the resistance.

There are two groups of dielectric materials used in EL devices: (a) amorphous oxides and nitrides, such as Al_2O_3, SiO_2, Y_2O_3, TiO_2, Si_3N_4, and Ta_2O_5; and (b) ferroelectric materials, such as $BaTiO_3$ and $PbTiO_3$. Group-(a) dielectric materials have a small dielectric constant and high breakdown electric field. On the other hand, group-(b) dielectric materials have a large dielectric constant and low breakdown electric field. To characterize dielectric materials for insulating layers, a figure of merit is introduced, which is the product of dielectric constant and breakdown electric field, $\epsilon_0\epsilon_r E_{BD}$. This figure of merit is equal to the maximum trapped charge density Q_{max} at the phosphor layer/insulating layer interface. Table 4 lists figures of merit for typical insulating-layer materials and also relative dielectric constants ϵ_r and breakdown electric fields E_{BD} (Fujita *et al.*, 1984). The numbers should be taken as typical values because there are variations, depending on the deposition conditions and methods. Figure 16 relates ϵ_r and E_{BD} (Fujita *et al.*, 1984).

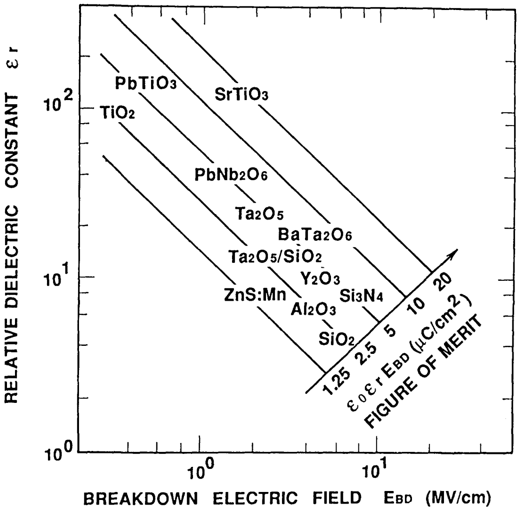

FIG. 16. Relative dielectric constant vs breakdown electric field (ϵ_r–E_{BD}) characteristics of typical dielectric-layer materials for thin-film electroluminescent devices. Straight lines are figures of merit defined by $\epsilon_0\epsilon_r E_{BD}$ in units of $\mu C/cm^2$ (after Fujita *et al.*, 1984).

One more important characteristic for EL devices is the electric breakdown mode, which may be a propagating breakdown mode (PB) or a self-healing breakdown mode (SB). In the former mode, electric breakdown, once occurring somewhere within an insulating layer, propagates to neighboring places, resulting in a large-area electric breakdown. On the other hand, in the latter mode, electric breakdown does not propagate and stays at the initial place, resulting in a small-area electric breakdown. These modes are also indicated in Table 4. Insulating thin films for EL devices must have a self-healing breakdown mode. Generally, dielectric thin films with large dielectric constants or not fully oxidized or not fully nitrified dielectric thin films tend to have a propagating breakdown mode. Coupled with other dielectric thin films, insulating layers with the propagating break-

Table 4. Relative dielectric constant ϵ_r, breakdown electric field E_{BD}, figure of merit defined by the product $\epsilon_0\epsilon_r E_{BD}$ (equal to the maximum trapped charge density), and breakdown mode of typical insulating-layer materials (after Fujita *et al.*, 1984).

Material	Deposition method	ϵ_r	E_{BD} (MV/cm)	$\epsilon_0\epsilon_r E_{BD}$ ($\mu C/cm^2$)	Breakdown mode[a]

---

[a] SB: self-healing breakdown mode; PB: propagating breakdown mode.

down mode can be converted into the self-healing type.

Originally, oxide thin films such as Y_2O_3, Al_2O_3, Ta_2O_5, and SiO_2 were used as EL insulating layers (Okamoto *et al.*, 1981; Kozawaguchi *et al.*, 1982; Tiku and Smith, 1984), but they tended to have deficiencies such as too much porosity and a low breakdown electric field. Furthermore, some of these oxide thin films tended to crystallize and cause nonuniformity in the phosphor thin films deposited on top of them, resulting in nonuniform luminance. To overcome these difficulties, amorphous nitride thin films, such as Si_3N_4, were introduced (Takeda *et al.*, 1981).

Recently, insulating-layer materials with a large figure of merit, such as $SrTiO_3$ and $Ba_2Ta_2O_6$, have been introduced to reduce the drive voltage to approximately 100 V (Fujita *et al.*, 1984). Using $Ba_2Ta_2O_6$ thin films ($\epsilon_r = 22$) for the first insulating layer and $SrTiO_3$ thin films ($\epsilon_r = 140$) for the second one, highly reliable EL devices have been obtained.

3.4 Phosphor Layers

The requirements for the phosphor layers are as follows:

1. Their host materials can be excited by a high electric field, on the order of 10^6 V/cm, to cause electron avalanche.
2. They can maintain a high electric field without electric breakdown and they must have insulating characteristics below the threshold voltage.
3. They can accept suitable luminescent centers that emit light in visible colors.

Phosphor materials satisfying the above requirements are limited to II-VI compounds: IIb-VIb compounds such as ZnS and ZnSe, and IIa-VIb compounds such as CaS, SrS, and SrSe. Detailed discussions of them have already been given in Sec. 2.3.

3.5 Rear Electrodes

The requirements for the rear-electrode materials are as follows:

1. good adhesiveness to the second insulating layer;
2. no metal-ion migration at high electric field;
3. an ability to prevent breakdown spread when dielectric breakdown of the phosphor layer or insulating layers occurs; and
4. low resistivity.

Among the materials satisfying these conditions, Al is considered to be the best. Deposition of Al thin films can be done by thermal heating, electron-beam deposition (EBD), and sputtering methods. One disadvantage in their use is their high reflectivity of light, so that mirror-type reflection occurs. This reflection can be suppressed by a smoke filter of 50%–70% or by circularly polarizing filters. Since Al films have specular reflection, the latter works very well. Then no incident light going into the EL cell can come out from the glass plate and only the EL emissions are effectively taken out from the EL devices.

4. MATERIAL DEPOSITION METHODS

In this section deposition methods used in fabricating phosphor layers of ZnS-based thin-film EL devices (see THIN-FILM DEPOSITION), especially ZnS:Mn EL devices, are discussed, with emphasis on the deposition conditions, crystal structures, and their relations to electro-optical characteristics (Vecht, 1989; Ono, 1990).

To increase the luminance of EL displays, better crystallinity of the phosphor layers is necessary, and a large number of deposition methods have been studied. These deposition methods are divided into two groups: physical vapor deposition (PVD) methods and chemical vapor deposition (CVD) methods [see CVD (CHEMICAL VAPOR DEPOSITION)]. The former include electron-beam deposition (EBD) (Sasakura *et al.*, 1981), multisource deposition (MSD) (Nire *et al.*, 1989), and sputtering (Miura *et al.*, 1983; Ohnishi *et al.*, 1987) methods. The latter include atomic-layer epitaxy (ALE) (Suntola *et al.*, 1980; Törnqvist *et al.*, 1983; Leskelä, 1989), metal-organic chemical vapor deposition (MOCVD) (Cattel *et al.*, 1983; Hirabayashi and Kozawaguchi, 1986; Migita *et al.*, 1988), and low-pressure hydride-transport chemical vapor deposition (HT-CVD) with halogen transport of Mn (Mikami *et al.*, 1991). Among these, the

EBD and ALE methods are now used to fabricate commercially available EL displays.

4.1 PVD Methods

4.1.1 EBD Method. The EBD method is one of the flash evaporation methods suitable for obtaining stoichiometry and reproducibility of the film, since both ZnS and Mn are sublimate materials. The substrate temperature is set at approximately 200 °C. Thermal annealing is performed in vacuum at approximately 550 °C after deposition of the ZnS:Mn thin film. Thermal annealing improves the phosphor layers because it removes strains in the films, enhances crystallinity of the grains, and accelerates Mn diffusion.

For CaS- and SrS-based EL devices, the EBD method is mainly used (Tanaka *et al.*, 1987a).

4.1.2 MSD Method. In this method, evaporation sources for Zn, S, and Mn are placed in a vacuum chamber having a pressure of 10^{-5} to 10^{-6} Torr. By independently controlling the temperatures of these sources, highly crystalline and stoichiometric ZnS:Mn films can be obtained (Nire *et al.*, 1989).

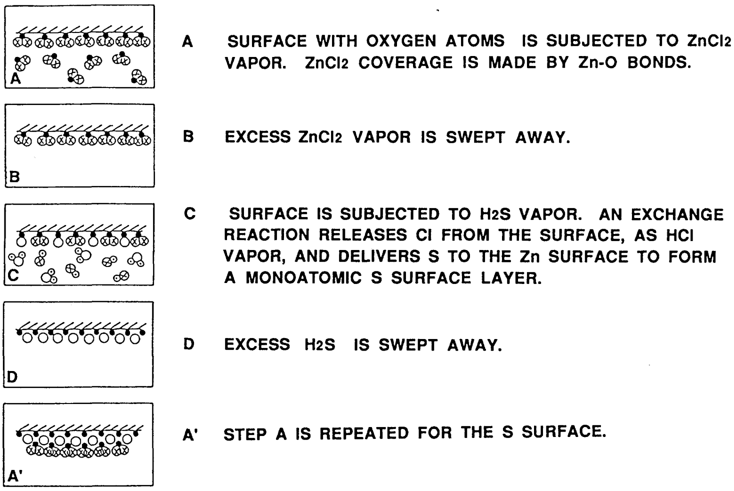
From a cross-sectional transmission electron microscopic (TEM) picture of deposited ZnS:Mn film on a glass substrate, it was found that columnar polycrystals of ZnS extended from the bottom to the top surface. The grain size of these columns was approximately 100 to 200 nm. X-ray diffraction patterns and transmission electron diffraction measurements showed that the crystal structure was hexagonal (wurtzite) with a (002) preferred orientation. The luminance L_{80} was 5300 cd/m^2 and the luminous efficiency η was 3.18 lm/W under a 5-kHz sinusoidal excitation.

SrS:Ce thin-film fabrication has been carried out with MSD, and good crystallinity was obtained (Tanda *et al.*, 1988).

4.1.3 Sputtering Method. The sputtering method (see SPUTTERING) has high deposition rates and is suitable for in-line processes, because both the insulating layers and the phosphor layer can be grown by the same deposition method (Miura *et al.*, 1983). In the case of ZnS:Mn, however, the crystallite diameter of the deposited films is not large, and stoichiometric ZnS films are difficult to obtain (Matsuoka *et al.*, 1988). As a result, a bright ZnS:Mn EL device has not been realized yet. On the other hand, for ZnS:Tb,F, the brightest green-emitting EL devices come from the sputtering method (Ohnishi *et al.*, 1987).

4.2 CVD Methods

4.2.1 ALE Method. The ALE method is an epitaxial deposition method in which the reactants are alternately supplied to the substrate (Suntola *et al.*, 1980; Leskelä, 1989). As shown in Fig. 17, the ALE growth process for ZnS is based on the exchange reaction $ZnCl_2(ads) + H_2S(g) \rightarrow ZnS(s) + 2HCl(g)$. On introduction of $ZnCl_2$ vapor, a single layer of $ZnCl_2$ is formed on a surface covered by oxygen or sulfur, by controlling the substrate temperature. Excess $ZnCl_2$ vapor is flushed away and then H_2S is introduced. Through



A SURFACE WITH OXYGEN ATOMS IS SUBJECTED TO ZnCl2 VAPOR. ZnCl2 COVERAGE IS MADE BY Zn-O BONDS.

B EXCESS ZnCl2 VAPOR IS SWEPT AWAY.

C SURFACE IS SUBJECTED TO H2S VAPOR. AN EXCHANGE REACTION RELEASES Cl FROM THE SURFACE, AS HCl VAPOR, AND DELIVERS S TO THE Zn SURFACE TO FORM A MONOATOMIC S SURFACE LAYER.

D EXCESS H2S IS SWEPT AWAY.

A' STEP A IS REPEATED FOR THE S SURFACE.

FIG. 17. Growth mechanism of the atomic-layer epitaxy (ALE) process for ZnS using $ZnCl_2$ and H_2S as reactants. The substrate temperature must be high enough to prevent condensation of the reactants (after Suntola *et al.*, 1980).

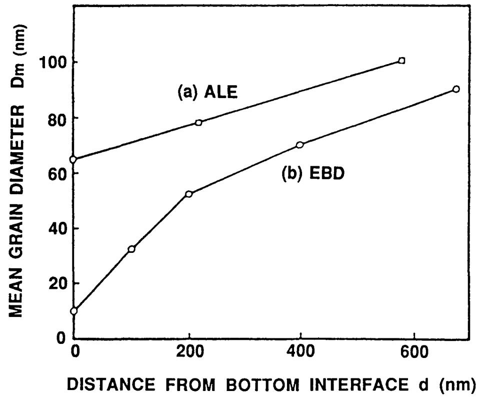


FIG. 18. Mean grain diameter of polycrystalline ZnS:Mn phosphor layer vs the distance from the bottom interface. (a) ALE and (b) EBD processes (after Theis *et al.*, 1983).

reaction of H_2S with the adsorbed $ZnCl_2$, ZnS is formed and HCl is liberated. After flushing away excess HCl, the cycle is repeated. The growth is insensitive to pressure and substrate materials, but the substrate temperature is important.

From x-ray measurements of ZnS films (Tanninen *et al.*, 1983) it was found that thin films grown at 350 °C have the cubic (zinc-blende) crystal structure, and films grown at 500 °C have the hexagonal (wurtzite) structure. Figure 18 shows the mean grain diameter parallel to the film surface vs the distance from the bottom interface (Theis *et al.*, 1983). In the EBD films small grains are present in the so-called dead layer at the beginning of deposition, while in the ALE films, large grains are formed from the beginning. The average luminous efficiency is 3 lm/W, with the maximum being 8 lm/W.

This method has been successfully used to deposit SrS- and CaS-based EL devices (Leskelä, 1989).

4.2.2 MOCVD Method.

The MOCVD method offers several advantages, such as lower growth temperature and easy control of impurity concentration. For Zn, dimethylzinc (DMZ) is used, and for sulfur, H_2S with 5% hydrogen or diethylsulfide (DES) is used. Hydrogen serves as a carrier gas for the reactants. For Mn, tricarbonylmethylcyclopentadienyl-Mn (TCM) is used. X-ray diffraction analysis revealed that EBD films have the zinc-blende crystal structure, while the MOCVD films are wurtzite crystal.

Recently, new Mn sources, di-π-cyclopentadienyl-Mn(CPM) and bis-methylcyclopentadienyl-Mn (BCPM), were studied and both were efficiently decomposed at the optimum growth temperature of ZnS, 280–350 °C (Migita *et al.*, 1988). Figure 19 shows crystallite size vs film thickness of undoped ZnS films prepared by the MOCVD and EBD methods. The former leads to large grains and good crystallinity from the start of growth. The EL devices with CPM have the largest luminance. The saturation luminance L_{sat} is 4300 cd/m^2, and the maximum luminous efficiency is 4.8 lm/W under 1-kHz sinusoidal drive conditions.

Color EL devices based on a ZnS phosphor layer have been fabricated by the MOCVD method; use of $SmCl_3$ as a source material of luminescent centers gave a much brighter red EL emission than SmF_3 (Hirabayashi *et al.*, 1987).

4.2.3 HT-CVD Method.

Good-quality ZnS:Mn phosphor layers can be prepared by using a low-pressure hydride-transport CVD system with halogen transport of Mn and hydrogen transport of ZnS. This system with a horizontal reactor is schematically shown in Fig. 20 (Mikami *et al.*, 1991). The component elements, Zn and S, are transported as vapor and/or gaseous hydride by passing H_2 over the ZnS powder source. The Mn is transported as a gaseous halide by passing HCl over the Mn source. These gases are brought together

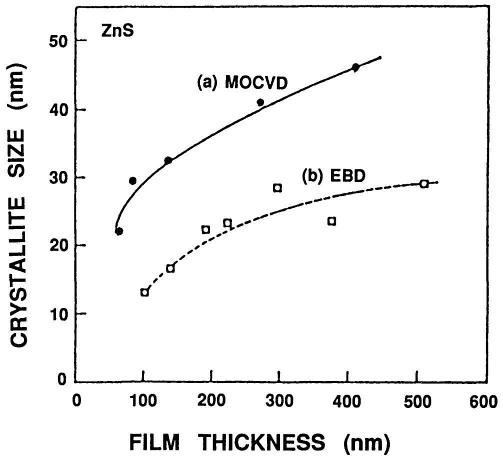

FIG. 19. Crystallite size vs film thickness of undoped ZnS thin films. (a) MOCVD and (b) EBD processes (after Migita *et al.*, 1988).

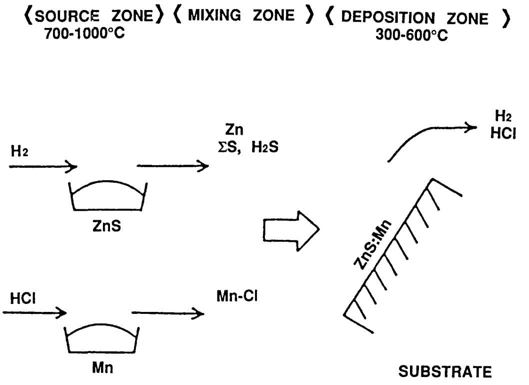

FIG. 20. Growth process of low-pressure hydride-transport CVD (HT-CVD) system with halogen transport of Mn (after Mikami *et al.*, 1991).

in the deposition zone, where the substrates have been placed on a quartz holder.

From the results of x-ray diffraction and reflection high-energy electron diffraction (RHEED) analysis, the following results have been obtained. The undoped ZnS films have the cubic (zinc-blende) crystal structure with a strong (111) orientation. The Mn-doped ZnS films have hexagonal (wurtzite) crystals with a (001) preferred orientation.

Figure 21 shows luminance vs voltage (*L-V*) characteristic curves under a 1-kHz sinusoidal excitation. In the inset, film-thickness dependences of luminance L_{50} and luminous efficiency η are shown. EL devices with film thickness as small as 0.26 μm show steep *L-V* characteristics, and the maximum luminous efficiency is 4.4 lm/W in an EL device with film thickness of 0.5 μm.

4.3 Summary of Deposition Methods

Table 5 summarizes deposition conditions of phosphor layers and luminescent characteristics of ZnS:Mn EL devices. The EL-emitted color differs slightly depending on the crystal structure, and luminous efficiency is larger in the CVD-prepared EL devices.

5. COLOR THIN-FILM ELECTROLUMINESCENT DEVICES

As described in Sec. 2.3, II-VI compounds are used mostly as EL phosphor materials. In the following, recent developments of color EL devices based on ZnS and alkaline-earth sulfides, such as CaS and SrS, are discussed in detail.

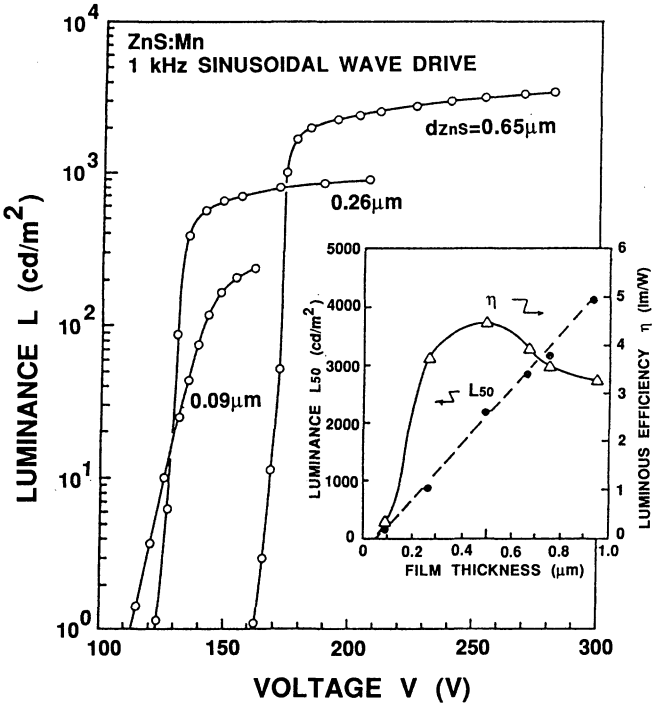

FIG. 21. Luminance vs voltage (*L-V*) characteristics and film-thickness dependence of luminance L_{50} and the luminous efficiency of an EL device fabricated by the HT-CVD method (after Mikami *et al.*, 1991).

Table 5. Comparison of deposition methods used for ZnS:Mn EL devices.

Conditions and characteristics	Physical vapor deposition			Chemical vapor deposition

5.1 Color Thin-Film EL Devices Based on ZnS Phosphors

5.1.1 Orange-Yellow (Amber) Emitting ZnS:Mn. The ZnS:Mn EL device shows the highest luminance and luminous efficiency (Table 6). This can be explained by the following discussion. In this device, Mn^{2+} occupies the lattice site of Zn, having the same valence as the dopant. This valence matching leads to high solid solubility without using charge compensators. Furthermore, as shown in Table 3, the ionic radius of Mn^{2+} is very close to that of Zn^{2+} (only 8% difference), so that it is not difficult for Mn^{2+} to replace Zn^{2+}. These conditions lead to high luminance and high luminous efficiency. The $3d^5$ energy-level configurations of Mn^{2+} are the ^6S ground state and the ^4G first excited state. As shown in Fig. 22(a), a broad orange-yellow (amber) emission with a peak around 585 nm for cubic ZnS:Mn is realized when the transition from ^4G to ^6S occurs. This *d-d* electron transition is partially allowed under perturbation of the crystal field around Mn^{2+}. The CIE (Commission Internationale de l'Eclairage) color coordinates of this emission are $x=0.50$ and $y=0.50$.

Since the emission spectrum of ZnS:Mn is very wide, ranging from green to red, a bright red emission can be obtained by using a red filter. Recently, Tuenge and Kane (1991) reported a bright red EL emission by using an inorganic thin-film, long-wavelength pass filter made of cadmium sulfoselenide. They obtained a luminance of 68.5 cd/m^2 [20 foot-lamberts (ft. L)] under a 60-Hz pulse-wave drive. The color gamut is close to that of the Y_2O_2S:Eu color-TV red phosphor, and the CIE coordinates are $x=0.65$ and $y=0.35$.

5.1.2 Multicolor-Emitting ZnS:RE,F (RE: Rare-Earth Elements). Rare-earth ions have been the most important luminescent centers for multicolor electroluminescent devices since Lumocen devices were reported (Kahng, 1968; Chase *et al.*, 1969). Most rare-earth–doped ZnS EL devices show EL emissions in the visible-light region (Yoshida *et al.*, 1980; Kobayashi *et al.*, 1985; Hamakawa *et al.*, 1988). The valences of rare-earth ions are usually +3, so that charge compensation is necessary. As shown in Fig. 22(b), the EL emission spectra consist of line spectra due to (4*f*) inner-shell transitions. For the three primary-color rep-

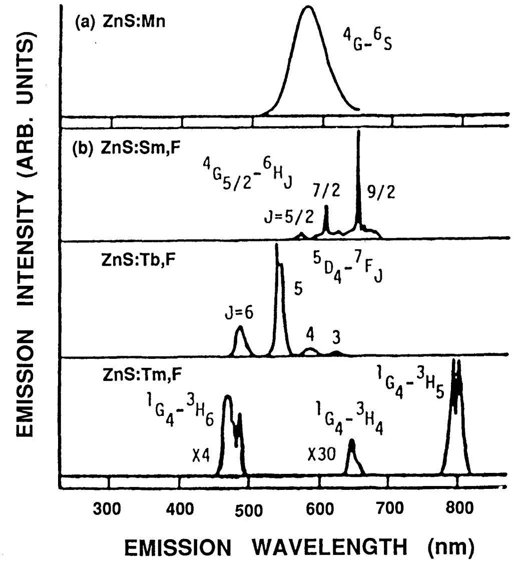

FIG. 22. Emission spectra of ZnS EL devices. (a) ZnS:Mn; (b) ZnS:RE,F (RE: rare-earth elements).

Table 6. Luminance and luminous efficiency of color thin-film EL devices.

Phosphor layer material	Emission color	CIE color coordinates		Luminance L (cd/m^2)		Luminous efficiency
		x	y	1 kHz	60 Hz	η (lm/W)(1 kHz)
ZnS:Mn	Orange-yellow	0.50	0.50	5000	200	2–8
ZnS:Sm,F	Orange red	0.60	0.38	120	8	0.05
ZnS:Sm,Cl	Red	0.64	0.35	200	12	0.08
CaS:Eu	Red	0.68	0.31	200	12	0.05
ZnS:Mn/filter	Red	0.65	0.35	1100	65	0.8
ZnS:Tb,F	Green	0.28	0.62	1500	100	0.5–1
CaS:Ce	Green	0.27	0.52	150	10	0.1
ZnS:Tm,F	Blue	0.11	0.09	2	0.15	<0.01
SrS:Ce	Blue-green	0.19	0.38	1150	70	0.4
SrS:Ce/filter	Blue	0.10	0.19	200	12	0.07

resentations, ZnS:Sm,F is used for red, ZnS:Tb,F is used for green, and ZnS:Tm,F is used for blue. Table 6 lists the maximum luminances and luminous efficiencies of these EL devices.

The ZnS:Tb,F green-emitting EL devices are second in luminance after ZnS:Mn (Ohnishi *et al.*, 1987). Sputtering is usually used to obtain high luminance because of uniform doping of luminescent centers into the ZnS host is possible (Miura *et al.*, 1983). The Tb^{3+} ion has an ionic radius of 0.923 Å, which is larger than that of Zn^{2+} ion by 31% (Table 3). This size mismatch makes thermal diffusion of Tb ions into the ZnS lattice difficult. In this respect, the sputtering method is more effective than the EBD method with subsequent annealing (Mita *et al.*, 1986).

The charge-compensation problem has been studied extensively in order to increase luminance, and the role of F in ZnS:Tb,F has received particular attention (Ogura *et al.*, 1986; Okamoto and Watanabe, 1986; Mikami *et al.*, 1987). In these experiments, the luminance of sputtered ZnS:Tb,F was studied as a function of the luminescent-center concentration in the sputtering targets and the sputtered phosphor films. It was found that not only the Tb concentration but also the F concentration is important to obtain high luminance. As shown in Fig. 23, the highest luminance is obtained when the [F]/[Tb] ratio is close to unity. This is reasonable considering that a Tb^{3+} ion replaces a Zn^{2+} ion and an F^- ion acts as a charge compensator for the excess of +1 charge. Furthermore, recent studies showed that TbOF-complex luminescent centers are more effective in increasing luminance (Okamoto *et al.*, 1989a). Prototypes of green-emitting EL devices have been fabricated (Okamoto *et al.*, 1989b).

In order to increase the luminance of red-emitting ZnS:Sm,F EL devices, the ionic radius difference and valence difference must also be taken into account. Since the emission color is orange-red and the luminance is low,

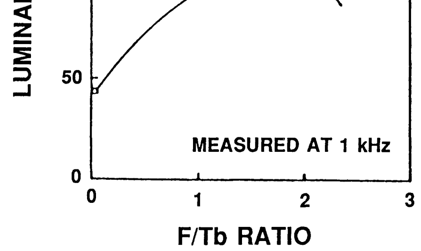

FIG. 23. [F]/[Tb] dependence of luminance in ZnS:Tb,F devices with T_a being the annealing temperature (1ft L=3.43 cd/m^2) (after Ogura *et al.*, 1986).

ZnS:Sm,F is not a good candidate for a red EL phosphor (Kobayashi *et al.*, 1985). Color purity and luminance improvements have been reported from replacing SmF_3 by $SmCl_3$ (Hirabayashi *et al.*, 1987).

For a blue EL phosphor, only ZnS:Tm,F has been reported (Kobayashi *et al.*, 1985). However, the luminance level is very low, because the ionic radius and valence matching between Zn^{2+} and Tm^{3+} is not very good. Furthermore, there is a very strong infrared emission at 800 nm [Fig. 22(b)]. Therefore ZnS:Tm,F is not a satisfactory blue phosphor, although the emission color is pure blue.

5.2 Color Thin-Film EL Devices Based on CaS and SrS Phosphors

Alkaline-earth sulfides, such as CaS and SrS, are known as dc powder multicolor EL phosphors (Higton *et al.*, 1978; Vecht, 1980). The application to thin-film EL devices, however, has not been easy because of the difficulty in obtaining good-quality thin films. With recent development in thin-film fabrication technologies, it is now possible to obtain red and blue EL devices with high luminance (Barrow *et al.*, 1984; Tanaka *et al.*, 1985, 1987a).

By doping rare-earth elements as luminescent centers into CaS and SrS, primary-color EL emissions can be obtained. The EL emission spectra are shown in Fig. 24, and the maximum luminances and luminous efficiencies are given in Table 6. Since EL emissions from Eu^{2+} and Ce^{3+} luminescent centers are due to *f-d* allowed transitions, the emission spectra strongly depend on host phosphor materials.

5.2.1 Red-Emitting CaS:Eu. As shown in Fig. 24(a), EL emission from CaS:Eu is deep red with an emission peak around 650 nm. The CIE coordinates are $x=0.68$ and $y=0.31$. The red purity of CaS:Eu is better than that of ZnS:Sm,F. Since Eu^{2+} is a stable ion and the ionic radius difference from Ca^{2+} is only 10.1%, Eu can easily be doped into a CaS host. These facts make CaS:Eu a promising candidate for a red EL phosphor.

Improvements of luminance and emission response characteristics have been extensively studied. An increase in luminance was achieved by increasing the substrate temperature to 400–500 °C (Tanaka *et al.*, 1987a; Ono *et al.*, 1989). This improvement was found to be related to crystalline improvement; e.g., in CaS:Eu EL, an increase in temperature changed the crystalline alignment plane from (200) to (220) to (111). This change was attributed to the density of dangling bonds on the alignment plane and a reevaporation effect of the deposited atoms (Yoshiyama *et al.*, 1988).

In electron-beam (EB) deposited CaS:Eu devices, emission and charge density responses were found to be slow (Crandall, 1987b), which must be remedied before CaS:Eu can be used commercially as a red phosphor. Recently, it was found that this slow response could be overcome without changing the color gamut by coactivating CaS:Eu with a small amount (0.05 mol %) of Ce (Ando and Ono, 1989).

5.2.2 Green-Emitting CaS:Ce and Blue-Green–Emitting SrS:Ce. As shown in Fig. 24(b), the EL emission from CaS:Ce is green, and the spectrum is broad and has peaks at 505 and 570 nm. The luminance of CaS:Ce is only 10% that of ZnS:Tb,F and therefore, insufficient.

As shown in Fig. 24(c), the EL emission from SrS:Ce is blue-green and the spectrum is broad and has peaks at 475 nm (blue) and 530 nm (green). This spectrum makes it possible to obtain only blue EL emission with good color purity by using a blue filter. In this case

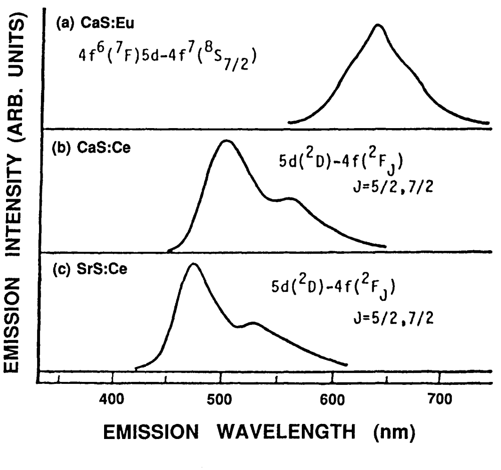

FIG. 24. Emission spectra of CaS and SrS EL devices. (a) CaS:Eu; (b) CaS:Ce; (c) SrS:Ce.

the luminance is reduced to approximately $\frac{1}{5}$ the original luminance with blue-green emission (Ono *et al.,* 1989). This luminance level is about 100 times higher than that of ZnS:Tm,F (Table 6), since the maximum luminance to date is 1150 cd/m^2 under the 1-kHz drive condition (Mita *et al.,* 1991). Therefore SrS:Ce is promising as a blue EL phosphor.

The SrS thin films tend to be sulfur deficient and easily oxidized (Onisawa *et al.,* 1988; Okamoto and Hanaoka, 1988) as well as being hygroscopic. To cope with these problems, sulfur coevaporation and reduction of oxygen in the target materials have been tried, and an increase in luminance has been realized. To prevent moisture from coming into the phosphor layer, device structure optimization, including different insulating-layer material combinations and process conditions, must be studied.

5.3 Summary of Color Thin-Film EL Devices

The above results indicate that the following phosphors are suitable for multicolor EL devices based on considerations of luminance and color gamut: ZnS:Mn with red color filter or CaS:Eu or ZnS:Sm,Cl for red emission; ZnS:Tb,F for green emission; and SrS:Ce for blue emission. The color coordinates of these EL devices are shown in Fig. 25. In the figure, R, G, and B (denoted by black squares) represent the color gamut positions of red, green, and blue of color CRTs, respectively, i.e., R for Y_2O_3:Eu, G for ZnS:Cu,Al, and B for ZnS:Ag. The CaS:Eu red EL emission and ZnS:Tb,F green EL emission are close to the respective CRT emissions. On the other hand, the SrS:Ce blue-green EL emission is far from the blue CRT emission. By using a blue filter, higher-purity blue emission (indicated by the triangle) can be realized. Luminance, however, then falls below the standards required for commercial application.

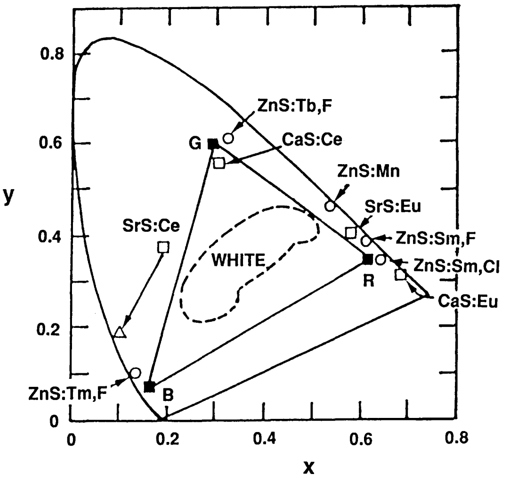

FIG. 25. CIE color coordinates of color EL devices (after Ono *et al.,* 1989).

6. MULTICOLOR THIN-FILM EL PANELS

Three types of multicolor thin-film EL panel structures have been investigated (Hamakawa *et al.,* 1988; King, 1989):

1. stacked-phosphor structure,
2. patterned-phosphor structure, and
3. white or broadband-spectrum phosphor with color filters.

Among these, the patterned-phosphor structure is most easily realizable, considering deposition conditions and drive circuitry.

6.1 Stacked-Phosphor Structure

Figure 26 shows a typical stacked-phosphor device structure, where two EL devices of different colors are stacked to produce

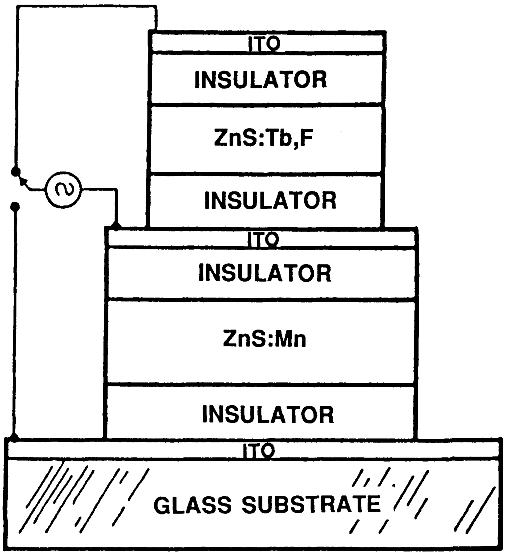

FIG. 26. Structure of a stacked-phosphor type multicolor EL device (after Coovert *et al.,* 1982).

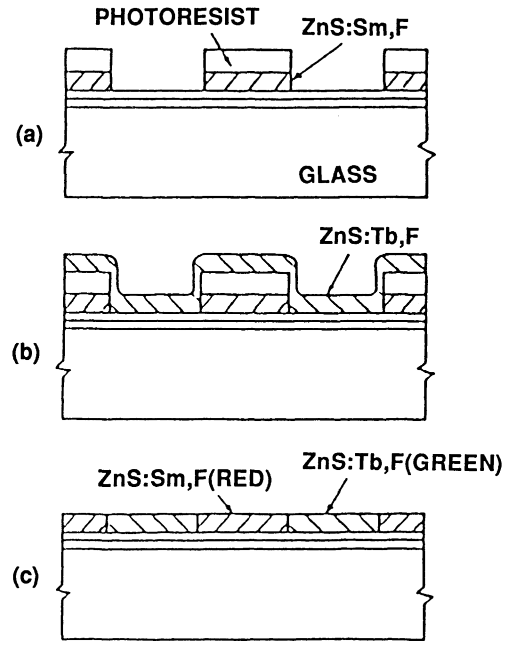

FIG. 27. Process procedure of a patterned-phosphor type multicolor EL device (after Yamauchi *et al.*, 1987).

multicolor emission (Coovert *et al.*, 1982). Advantages of this structure are that the resolution of each EL device can be retained, and there is no need for patterning of phosphor layers. On the other hand, disadvantages are that thin-film deposition becomes harder at the upper layers and the drive circuitry becomes complicated. Barrow *et al.* (1986) fabricated a prototype three-color (green, yellow, and red) EL device by stacking green and red EL devices.

6.2 Patterned-Phosphor Structure

In this structure, photolithographically patterned phosphor layers corresponding to three primary colors are placed on the same plane. Its advantages are a drive circuitry that is essentially the same as the monochromatic EL devices, and simpler deposition processes compared with those of the stacked pattern. Disadvantages are a reduction of resolution and difficulty in phosphor-layer patterning. Examples are shown in Figs. 27 and 28. Figure 27 depicts the process for obtaining a three-color EL device consisting of self-aligned phosphors of red (ZnS:Sm,F) and green (ZnS:Tb,F) (Yamauchi *et al.*, 1987). Barrow *et al.* (1988) fabricated a prototype full-color EL display panel by patterning-phosphor layers of red (ZnS:Sm,F), green (ZnS:Tb,F), and blue (SrS:Ce).

Yamamoto *et al.* (1989) fabricated a prototype 10-in.-diagonal three-color (orange-yellow, yellow, and green) EL display panel. Its structure is shown in Fig. 28. In order to protect the first phosphor layer of ZnS:Mn from being etched, an intermediate layer was placed between the first phosphor layer and the second phosphor layer of ZnS:Tb,F.

6.3 White or Broadband-Spectrum Phosphor with Color Filters

By combining a white-light–emitting EL phosphor having red, green, and blue spectral components, or a broadband-spectrum phosphor, with color filters, it becomes possible to obtain multicolor EL devices. For this purpose, white-light–emitting EL devices using SrS and CaS have been investigated (Tanaka *et al.*, 1987b, 1988b; Ono *et al.*, 1989). Figure 29 shows color coordinates of several white-light–emitting EL devices. In particular, SrS:Ce/SrS:Eu and SrS:Ce,Eu devices (Tanaka *et al.*, 1988b) produced white emissions because blue-green from Ce^{3+} and orange-red from Eu^{2+} are complementary colors. As expected from Fig. 24, the emission spectrum of SrS-based white-emitting EL devices is broad

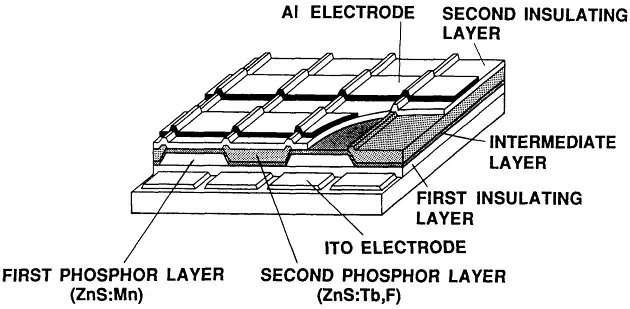

FIG. 28. Structure of a patterned-phosphor type multicolor EL device (after Yamamoto *et al.*, 1989).

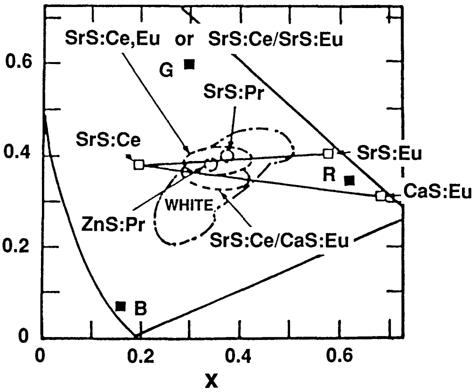

FIG. 29. CIE color coordinates of white EL devices.

so that they are suitable for multicolor EL phosphors. Luminance, however, is still low, at most 1150 cd/m^2 under 1-kHz drive conditions (Mita *et al.,* 1991). For the present purpose, at least 3000 cd/m^2 under 1-kHz drive conditions is necessary. On the other hand, from an ergonomics viewpoint, a paper-white emission is more desirable than the eggshell-white emission from SrS:Ce,Eu or SrS:Ce/SrS:Eu. Therefore, stacked-phosphor layers of SrS:Ce/CaS:Eu were studied (Ono *et al.,* 1989), and good color balance of R:G:B =3:6:1 was obtained by using color filters.

A prototype full-color EL device using CaS- and SrS-based phosphors and interference color filters has been fabricated (Tanaka *et al.,* 1987b). Its cross-sectional structure is shown in Fig. 30. The emission colors were very close to those of a CRT. However, luminance was very low and at least one order of magnitude increase in luminance is necessary.

A candidate for a broadband-spectrum phosphor with high luminance is ZnS:Mn, as shown in Fig. 22(a). Okibayashi *et al.* (1991) fabricated a prototype multicolor (green–red) EL device using ZnS:Mn with organic color filters. The luminances and color coordinates of filtered EL emission under the frame frequency of 60-Hz drive conditions were as follows: $L(\text{green})=80$ cd/m^2 with $x=0.45$ and $y=0.55$, and $L(\text{red})=30$ cd/m^2 with $x=0.66$ and $y=0.34$. Here the original orange-yellow luminance under the same drive conditions was 200 cd/m^2.

7. RELIABILITY

In considering the reliability of EL devices, two important factors must be taken into account:

1. electrical reliability with respect to electrical breakdown, and
2. long-time reliability.

Electrical breakdown properties depend strongly on the electrical properties of the dielectric-layer materials and the thin-film fabrication processes. For long-time reliability, the hygroscopic, adhesive, and photolithographic resistant properties of phosphor and dielectric-layer materials must be taken into account, and proper choices of passivation and sealing materials are essential.

7.1 Electrical Reliability

As discussed in Sec. 3.3, the requirements of the insulating layers are high dielectric constant $\epsilon_0\epsilon_r$ and high breakdown electric field E_{BD}, i.e., a large figure of merit defined by $\epsilon_0\epsilon_r E_{\text{BD}}$, which is equal to the maximum storage charge density, $Q_{\max}$. When insulators with high $Q_{\max}$ are used, a low-voltage drive becomes possible. However, insulators with

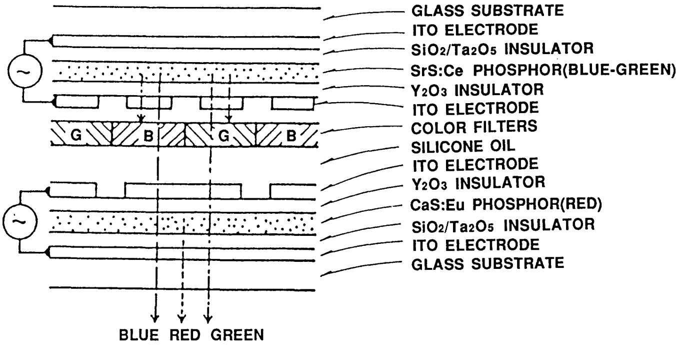

FIG. 30. Cross-sectional view of full-color EL device with stacked EL cells and color filters (after Tanaka *et al.,* 1987b).

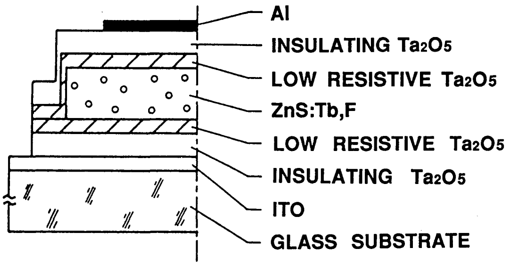

FIG. 31. EL device structure employing insulating and conducting Ta_2O_5 thin films (after Mikami and Ando, 1985).

high Q_{max} tend to have a low reliability, and propagating-type breakdown often occurs. Several multilayered structures of insulating layers have been proposed to overcome this difficulty (Mikami and Ando, 1985; Mita *et al.*, 1987). In Fig. 31, insulating and low-resistive Ta_2O_5 insulators are stacked in the order Al/insulating Ta_2O_5/low-resistive Ta_2O_5/ phosphor layer/low-resistive Ta_2O_5/insulating Ta_2O_5/ITO/glass substrate (Mikami and Ando, 1985). Low-resistive and insulating Ta_2O_5 films can be fabricated by changing deposition conditions. In this structure, insulating Ta_2O_5 films provide electrical insulation and low-resistive Ta_2O_5 films give increased charge generation and better adhesiveness between the phosphor layer and insulating layers. Another combination of the insulating layers is a SiO_2/Ta_2O_5 stacked structure in the order Al/SiO_2/Ta_2O_5/phosphor layer/Ta_2O_5/SiO_2/ ITO/glass substrate (Mita *et al.*, 1987). Here the SiO_2 layers act as electrically insulating layers and the Ta_2O_5 layers serve as partly conductive layers. In addition to these examples, SiO_2, TiO_2, and CaS are used as buffer thin films between electrodes and insulating layers or between insulating layers and the phosphor layer to stabilize EL operation (Nishikawa *et al.*, 1988; Khormaei *et al.*, 1989).

In commercial EL devices, stacked insulating layers are employed to increase the breakdown electric field. This is shown in Fig. 32 (Takeda *et al.*, 1983), where the first insulating layer consists of silicon oxinitride/SiO_2 stacked layers and the second insulating layer, of Al_2O_3/silicon oxinitride. There are two advantages for this stacked layer structure. The first is better adhesiveness; Al_2O_3 is introduced between the rear Al electrode and the second insulating layer of silicon oxinitride. The second advantage is an increase in the breakdown electric field by a decrease of the number of pinholes.

7.2 Long-Time Reliability

The lifetime-determining factors of EL devices are the peeling of thin films and the formation of very small dielectric breakdown holes. These small breakdown holes result from local defects in the thin films during the first stage of the drive annealing process. These holes are approximately 30 μm in diameter and their number does not increase with annealing time. Therefore, they do not cause any practical trouble. Proper control of process conditions is important to decrease the defects.

On the other hand, peeling of the thin films is caused by moisture (water) leaking into the phosphor layer/insulating layer interface through pinholes (Okamoto *et al.*, 1983). During EL drive operation, ionization of the water occurs from hot-electron impact in the phosphor layer, generating H^+ and OH^- ions. The H^+ ions will combine at the interface to form hydrogen gas. The gas pressure lifts the second insulating layer from the phosphor layer, leading to peeling of the thin films. With longer drive periods, peeling proceeds rapidly, and it affects the lifetime of EL devices. To avoid this, proper control of atmospheric

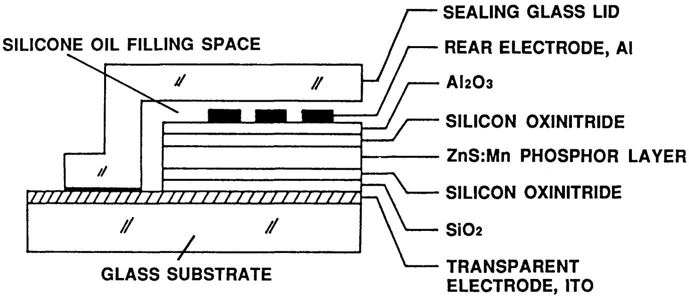

FIG. 32. Cross-sectional structure of commercially available EL devices with double insulating layers (after Takeda *et al.*, 1983).

conditions, especially humidity control, during and after the deposition process is necessary. In particular, encapsulation of EL devices by sealing is very effective to prevent moisture from entering into them. Sealing methods include oil sealing, gas sealing, vacuum sealing, and resin sealing. Among these, the oil sealing method is the best. In commercial EL display devices, silicone oil and silica gel powders are placed in the glass-sealed EL devices as shown in Fig. 32. Furthermore, since in the double-insulating-layer structure the phosphor layer is sandwiched by insulating layers, it is possible to prevent moisture from entering the phosphor layer. By employing the structures discussed above, a long lifetime, more than 20 000 hours, has been realized.

The drive method is also important to obtain long-time reliability (Watanabe *et al.*, 1987; Flegal and King, 1986). In the beginning, a field-refresh drive method was employed (Takeda *et al.*, 1981). Schematic pulse drive wave forms for scan lines are shown in Fig. 33. After all the write-in procedures for the scan lines in the line-at-a-time drive scheme are finished, field-refresh pulses with opposite polarity to the write-in pulse are applied to all the scan lines at the same time, ending a cycle of an ac drive. Therefore there are two EL emissions in one cycle. This drive method utilizes the polarization characteristics described in Sec. 1.3 to obtain high luminance. However, unsymmetrical drive voltage wave forms are created at different parts of the EL devices so that the luminance versus voltage characteristics deteriorate and latent images are created. The deterioration is characterized by decreases in both threshold voltage and luminance within the high-luminance region (Watanabe *et al.*, 1987; Flegal and King, 1986; Müller *et al.*, 1988).

To overcome this difficulty, the *p-n* symmetric drive method and the *p-p* symmetric drive method have been introduced (Harada *et al.*, 1986; Shoji *et al.*, 1989). Schematic pulse drive wave forms for scan lines in the *p-n* symmetric drive method are shown in Fig. 34. This method is also called a field-reversal method, because the polarity of the write-in pulses is reversed in every other field. Therefore, one cycle is composed of two fields and only one EL emission in one field. However, the symmetric drive method allows a higher voltage to be applied to EL devices than that in the field-refresh method, so that saturation regions of the luminance–voltage characteristic curves can be utilized. This makes it possible to realize a uniform luminance over the whole area of the EL device, and the luminance change with time is substantially reduced.

8. FUTURE PROSPECTS

Monochromatic EL display devices are now commercially available from three companies; Sharp Corporation, Planar Systems, and Lohja Corporation (now Planar Systems, International). These EL display devices are used as flat screens of laptop personal computers, workstations, and word processors (see Plates 1 and 2). However, volume production is small compared with that of liquid-crystal displays (LCDs) because of the high cost, and so price reduction is necessary. Lower cost can only be realized if cheaper high-voltage driver integrated circuits (ICs) become available. Thanks to innovations in semiconductor technology, this will be possible in the near future.

A second reason why EL display devices are not so popular is a lack of awareness about

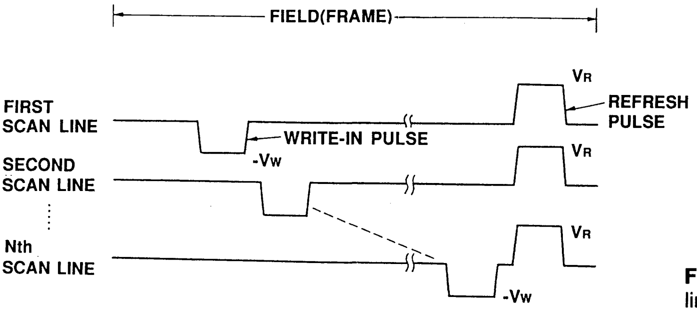

FIG. 33. Pulse drive wave forms for scan lines in the field-refresh drive method.

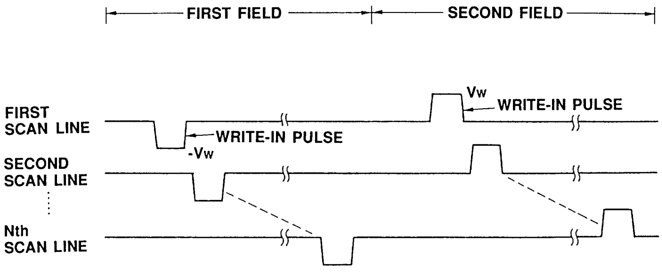

FIG. 34. Pulse drive wave forms for scan lines in the *p-n* symmetric drive method.

their good characteristics. In comparison with other flat-panel displays (See DISPLAY TECHNOLOGY), such as LCDs, plasma display panels (PDPs), and vacuum fluorescent displays (VFDs), EL display devices have the following superior characteristics, and their applications should be encouraged:

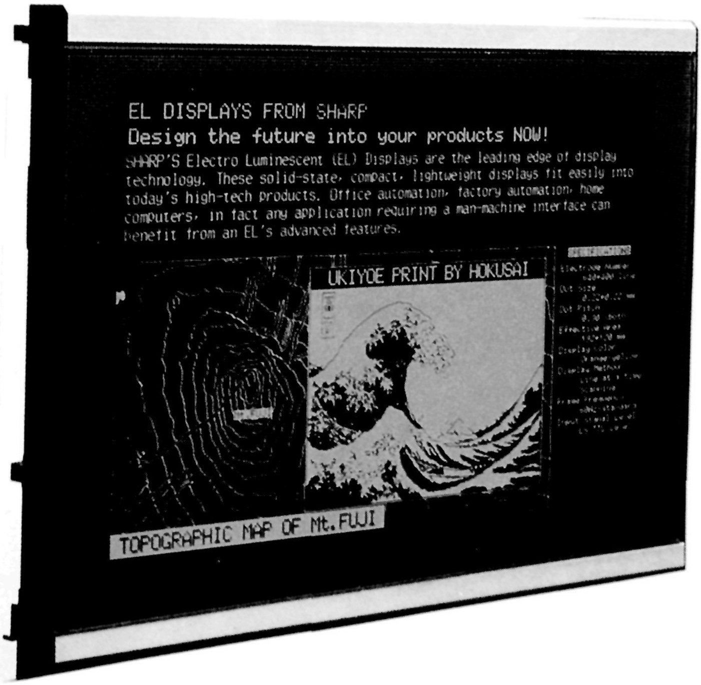
1. good display qualities from an ergonomics viewpoint
   - an emissive display with large viewing angle
   - a possibility of resolution higher than 8 lines/mm
2. temperature-independent emission
   - suitable for automotive equipment used under very severe temperature requirements
3. all-solid devices
   - rugged and vibration resistant
   - suitable for personal computers used under very severe vibrational conditions, such as in military equipment or spacecraft
4. low-power, thin, lightweight devices
   - lowest power consumption among emissive flat-panel displays
   - thickness of less than 24 mm and weight of less than 1 kg in practical panels

This review has discussed the present status of EL with an emphasis on the double-insulating-layer type thin-film EL, because of its high possibility to be commercialized as flat-panel displays. The most important research and development target is realization of multicolor and full-color EL display devices. As discussed in Sec. 6, several prototype multicolor EL display devices have been fabricated (see Plates 3 and 4). However, for full-color EL display devices, bright red, green, and blue EL emissions with good purities and balanced luminance levels are necessary. To realize this, considerations of color phosphor materials and color EL drive methods have to be taken into account.

First, consider phosphor materials. For a green phosphor, ZnS:Tb,F is suitable with respect to luminance and purity. For a red phosphor, ZnS:Mn with a red color filter or ZnS:Sm,Cl or CaS:Eu is a good candidate, but luminance improvement is still necessary. For a blue phosphor, SrS:Ce is a possible candidate, but the emission color is blue-green because of the broad spectrum as shown in Fig. 24(c). Therefore, color filtering is necessary to obtain pure blue, the luminance of which is still low (one order of magnitude increase is desired). However, at this point of writing, no good improvement method for blue emission has been proposed.

The task now should be to find suitable combinations of phosphor materials and luminescent centers suitable for full-color representation. After finding suitable combinations, luminance improvement of each color should be pursued.

Next, consider drive methods. It is possible to obtain memory EL devices by incorporating thin-film transistors (TFTs) at each pixel, which has already been done in color LCD panels. This method was first applied to EL devices, but no practical display panels were fabricated because of difficulties in obtaining large-area, high-voltage TFTs without defects. However, recent success in large-area TFTs for LCDs together with substantial improvements in fabrication technologies should give a strong impetus to the EL community in trying to fabricate TFT-driven EL display devices. One of the advantages of three-terminal TFTs over the present two-terminal devices is that the circuit system with TFTs is easier to handle. Once high-voltage TFT arrays attain a practical level of production, TFT-driven EL display devices should become the mainstream of memory devices.



EL DISPLAYS FROM SHARP

Design the future into your products NOW!

SHARP'S Electro Luminescent (EL) Displays are the leading edge of display technology. These solid-state, compact, lightweight displays fit easily into today's high-tech products. Office automation, factory automation, home computers, in fact any application requiring a man-machine interface can benefit from an EL's advanced features.

GLOSSARY

Contrast Ratio: The ratio of the "on" luminance with respect to the background luminance or "off" luminance. Pixel visibility depends on this quantity.

Impact Excitation: Excitation of ions in a crystal field via a strong interaction with high-energy electrons or hot electrons.

Luminance: Photometric term indicating the radiated power in terms of human eye sensitivity, i.e., a physical measure of luminous intensity per unit area, in units of cd/m^2. Other units, ft L (foot-lambert), are also used: $1\ ft\ L = 3.43\ cd/m^2$.

Luminescence: Physical phenomenon indicating emission of light.

Luminous Efficiency: Number of lumens emitted per watt electrical power.

Pixel (Picture Element): Basic building blocks for displays. One monochromatic pixel is composed of a single dot and one color pixel is composed of three primary color dots, i.e., in red, green, and blue triads.

Powder EL Device: ZnS phosphor powder dispersed in an insulator with a binder, sandwiched between two electrodes.

Primary Colors: Mathematical abstraction of spatial energy distributions which correspond to human sensation of red, green, and blue. The primary colors can be combined to give any desired color. [see the chromaticity diagram of the CIE (Commission Internationale de l'Eclairage), 1931.]

Threshold Voltage: The voltage at which luminance becomes $1\ cd/m^2$.

LIST OF ABBREVIATIONS

ALE: Atomic layer epitaxy
BCPM: bis-methylcyclopentadienyl-Mn
CIE: Commission International de l'Eclairage
CPM: di-π-cyclopentadienyl-Mn
CRT: Cathode ray tube
CVD: Chemical vapor deposition
DES: Diethylsulfide
DEZ: Diethylzinc
EBD: Electron-beam deposition
EL: Electroluminescence, electroluminescent
HT-CVD: Hydride-transport chemical vapor deposition
ITO: Indium tin oxide
LCD: Liquid-crystal display
LED: Light-emitting diode
Lumocen: Luminescence from molecular centers
MOCVD: Metal-organic chemical vapor deposition
MSD: Multisource deposition
PB: Propagating mode breakdown mode
PDP: Plasma display panel
PVD: Physical vapor deposition
RHEED: Reflection high-energy electron diffraction
SB: Self-healing breakdown mode
TCM: Tricarbonylmethylcyclopentadienyl-Mn
TEM: Transmission electron microscopy
TFT: Thin-film transistor

8.1
Introduction

Electromagnetism deals with the relationships between two fields, electric and magnetic. Therefore, two independent electromagnetic units must be defined in terms of the meter, kilogram, and second to ensure that the electrical units are part of the International System of Units (SI) that are now used universally for practically all scientific and engineering measurements. The two necessary connections between the electrical and the mechanical units are made at present by

1. implicitly defining mechanical and electrical power to be equal by using the same unit (watt) for both; and
2. explicitly defining the ampere as "the constant current which, if maintained in two straight parallel conductors of infinite length and negligible circular section placed 1 m apart in vacuum, will produce a force equal to 2×10^{-7} N m^{-1} between these conductors." (This definition of the ampere is equivalent to defining the magnetic permeability of free space μ_0 as $4\pi \times 10^{-7}$ H m^{-1} exactly.)

These abstract definitions have to be put into practice (or realized, in the jargon of metrology). Realizations are carried out by more than one method and in more than one national measurement laboratory to secure confidence in their correctness. To realize an electrical unit, it is necessary to assume the complete accuracy of Maxwell's electromagnetic theory and to use an apparatus in a way that is, according to this theory, consistent with the definitions of the watt and the ampere. Up to about 40 years ago, the two apparatuses that realized the two independent electrical units were

1. some form of current balance in which the force between circular current-carrying coils was weighed as a direct extension of the ampere definition; and
2. a mutual inductor whose carefully measured dimensions established a link between the meter and the ohm.

Neither the current balance nor the mutual inductor is accurate enough for the present-day routine needs of science and commerce at the highest level of accuracy of a part per million (ppm) or better. They have been replaced by electrometers or watt balances that realize the volt or watt and the Thompson–Lampard calculable capacitor that realizes the ohm via the farad (Thompson and Lampard, 1956; see also Section 8.2.1). An alternative route for the ohm is via a measurement of the fine-structure constant and the quantum Hall effect (see Section 8.2.1.2).

The correctness of these realizations has been confirmed by examining the relationships between those fundamental physical constants whose measured values involve mass, length, and time as well as electrical quantities.

Once they have been realized by these difficult and time-consuming measurements (each of which may take many years), the electrical units are preserved for everyday use in national standardizing laboratories by ascribing values to the constants that govern the Josephson (1962) and quantum Hall effects (von Klitzing, Dorda, and Pepper, 1980). These precise effects of quantum physics, which occur at cryogenic temperatures, reproduce voltages and resistances very exactly (to 0.005 ppm at present).

Values of standards to represent other derived, electrical units must then be determined in terms of the ohm and volt. There is usually only one preferred method of establishing each derived unit. This method yields the most accurate measurement in volts and ohms of an artifact standard representing the derived unit.

At present, the stability and reproducibility of volt and ohm units preserved by means of the Josephson and quantum Hall effects greatly exceed the accuracy with which these units can be realized in terms of the meter, kilogram, and second. This situation suggests a possible future scenario: The present link to the meter, kilogram, and second could be replaced by a pair of basic electrical units (voltage defined in terms of the Josephson effect and impedance in terms of the quantum Hall effect) and then the kilogram could be derived from these. μ_0 would become an experimentally measurable physical constant, rather than a defined quantity, and the present prototype kilogram, which is the last unit based on a material artifact, would become a maintained standard whose value would have to be realized either from these new definitions of the volt and ohm via a watt balance or via a measurement of Avogadro's constant (see Section 8.2.2.3).

At the time of writing, the General Conference on Weights and Measures, which recommends changes to the SI for worldwide acceptance, is actively seeking to change the basis of the SI along these lines with a target date of 2011 (Mills *et al.*, 2006).

8.2
Realizing the Base Units

8.2.1
The Farad, Realized by a Calculable Capacitor

The Thompson–Lampard theorem (Thompson and Lampard, 1956) applied to a system of four electrodes of constant cross section in vacuum (Figure 8.1) states that the cross capacitances C_1 and C_2 per meter length are related by the expression

$$\exp(-\pi C_1/\varepsilon_0) + \exp(-\pi C_2/\varepsilon_0) = 1 \tag{8.1}$$

If C_1 is nearly equal to C_2(i.e., $C_1 - C_2 = \Delta C$), this simplifies to give the mean cross capacitance $C = (C_1 + C_2)/2$ as

$$\begin{aligned} C &= \left[\epsilon_0 (ln2)/\pi\right]\left[1 + 0.086(\delta C/C)^2\right] F/m, \\ &= \left[(ln2)/\pi\mu_0 c^2\right]\left[1 + 0.086(\delta C/C)^2\right] \\ &= 1.953\ 549\ 043\{1 + 0.086(\delta C/C)^2\} pF/m \end{aligned} \tag{8.2}$$

The farad can therefore be realized from a single length measurement and the defined values of μ_0 and the speed of light in vacuum c.

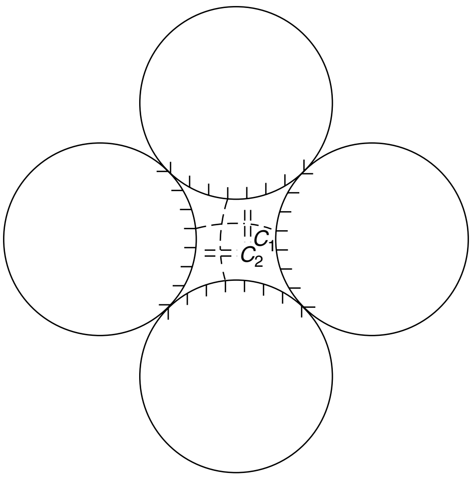

Fig. 8.1 Illustration of the Thompson–Lampard theorem, showing a cross section through four electrodes.

Usually, the cross capacitances are between the inward-facing surfaces of four cylindrical electrodes placed with their axes on the corners of a square (Figure 8.2). The small gaps between the electrodes cause negligible error. The whole structure is surrounded by a guard electrode. To avoid having to calculate the fringing fields at either end of the electrodes, guarding cylinders are inserted along the axis of the structure. The effect of the fringing fields between the ends of these guards and the cylinders is eliminated by observing the differences in the cross capacitances as the guards are moved a measured distance *L* toward each other. They must not approach each other enough to cause the fringing fields to overlap appreciably.

The accuracy of this realization of the farad is limited by the departure of real machined cylindrical electrodes from the constant cross section assumed by the Thompson–Lampard theorem. The fringing fields can be shaped by attaching extensions of lesser diameter to the ends of the inserted guards to reduce this limitation, but it is impossible to eliminate entirely the effect of changes in cross section over a length comparable with these extensions. The accuracy with which the cylinders can be made, therefore, sets a limit of the order of 0.01 ppm to the achievable accuracy in realizing the farad. A similar uncertainty arises from the small inductance of the electrodes, which causes the surfaces of the electrodes to be not quite equipotentials, because there are currents flowing along them.

8.2.1.1 The Ohm, Derived from the Farad

The ohm is obtained from the farad by scaling up the fraction of a picofarad of capacitance of a calculable capacitor to, usually, 1000 pF and then equating its impedance at a frequency of 10^4 rad s^{-1} to a resistance of 10^5 Ω, using ac bridges. This resistance is further scaled to yield the ac resistance of a 1000-Ω resistor so constructed (see Figure 8.3) that the difference in its resistance between ac and dc conditions is small and calculable.

Finally, the 1000-Ω dc SI resistance derived from a calculable capacitor by this long chain of measurements is scaled up, either by the reconfigurable resistor networks known as *Hamon resistors* (Hamon, 1954) or by a superconducting (cryogenic) current comparator (Harvey,

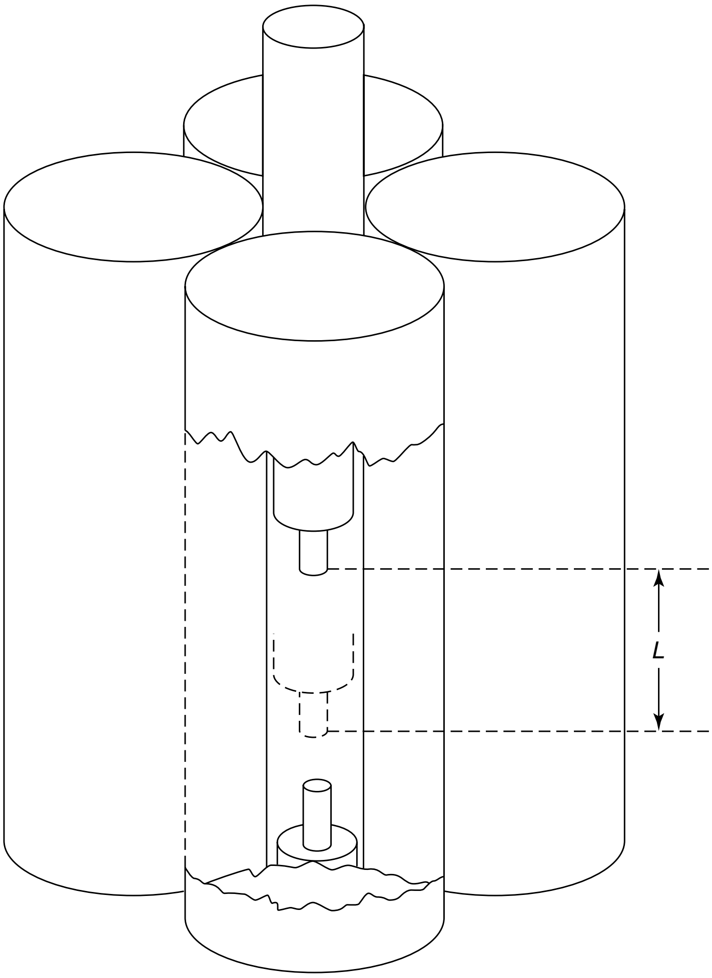

Fig. 8.2 A practical calculable capacitor.

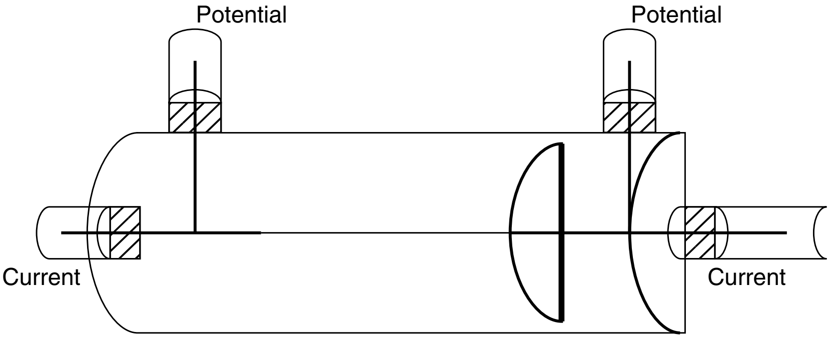

Potential
Potential
Current
Current

Fig. 8.3 A section through a coaxial resistor whose ac value is calculable from its geometry and dc value.

1972), to a value suitable for comparison with the quantum Hall effect.

A superconducting current comparator is also used to scale dc resistance ratios in major standardizing laboratories possessing liquid-helium cryogenic facilities to derive their maintained representation of the ohm from the quantum Hall effect. The construction and use of a superconducting current comparator is described in Section 8.3.2.

The parts-per-billion accuracy achieved in the AC measurements is only possible because the measuring conditions applying at the terminations of an ac standard are carefully defined. An example of these conditions is the four-terminal pair definition illustrated in Figure 8.4, where the *impedance of the standard* is defined as the ratio of the voltage appearing across the P_H coaxial connector when zero current flows through either inner or outer contact to the current flowing from the inner contact of the C_L coaxial connector. The measurement circuit must be so arranged that an equal and opposite current flows into the outer contact of the C_L coaxial connector, and that there is zero voltage between the inner and outer contacts of the associated P_L connector together with zero current flowing through either. The remaining C_H connector has a source connected between its inner and outer contacts, which is adjusted, together with details of the measurement circuitry, to set up these defining conditions. This complete and precise definition, while being somewhat strange at first sight, naturally leads to measuring networks ("bridges") of components joined by coaxial conductors. The definition can be readily understood by recognizing that the impedance Z in the inner circuit is a familiar four-terminal impedance having separate current and potential terminals and that the outer circuit is also a small four-terminal impedance z. The effect of the defining conditions is to make the total impedance of the device as the series combination, $Z + z$. Standard impedances defined in this way are compared in networks in which the current in the coaxial interconnecting conductor of each cable is arranged to be as nearly as possible equal and opposite to that in the outer conductor. Circuitry of this kind has the two important and related properties that the measurements are affected neither by the disposition of cables and components nor by externally generated electric and magnetic fields, including those at the measurement frequency. Further details and an introduction to the literature of this subject have been given by Kibble and Rayner (1984).

8.2.1.2 Realizing the Ohm via Measurements of the Fine-Structure Constant

If certain assumptions are made, the ohm may be derived directly from the quantum Hall effect. Under proper experimental

conditions, the current-to-voltage ratio of a device exhibiting this effect is believed to be a multiple of e^2/h, where e is the elementary charge and h is the Planck constant. A measurement of the fine-structure constant, α, in SI units, [$\alpha = (\mu_0 c/2)(e^2/h)$], would therefore constitute a realization of the SI ohm, because the values of μ_0 and c are defined. A very accurate value for α can be obtained from the measurements of the departure of the value of the magnetic moment of the electron from 2 exactly. This departure can be measured as the ratio of two frequencies and calculated (by a very long and involved calculation that requires many hundreds of hours on a powerful computer) (Kinoshita, 2006). The accuracy of the value of e^2/h, and therefore the ohm, obtained in this way is approaching 0.001 ppm, which is more accurate than that obtainable from calculable capacitors and associated bridges. However, this realization does assume that the theories of the quantum Hall effect and the "anomalous" magnetic moment of the electron are accurate to the uncertainty claimed.

8.2.2
The Volt or Watt

Realizing either of these units involves deriving a force from a mass M subject to gravitational acceleration g to balance against an electromagnetic force. g can be measured with a "free-fall" gravimeter (Niebauer *et al.*, 1995) to approximately 0.005 ppm. Mass was involved in realizations of the ampere using a current balance, and indeed this instrument inspired the definition of the ampere. However, because of experimental difficulties primarily associated with measuring the dimensions of the coils, the accuracy of a current balance was limited to about 5 ppm. The instruments described below have replaced it.

8.2.2.1 **The Watt Balance**

In Figure 8.5a, the force produced when a current I flows through a coil suspended from a balance so that the coil lies partly in the field of a large permanent magnet is made equal to Mg. In a separate measurement, the coil is moved vertically with velocity u and an electromotive force V is induced, as illustrated in Figure 8.5b. Making the measurements separately ensures that virtual, rather than real, power is involved and therefore that errors associated with real energy expenditure such as Joule heating in the coil are eliminated. Equality of mechanical and electrical power ensures that

$$IV = Mgu \tag{8.3}$$

If I is related to V via the voltage drop that it produces across a resistor R, then

$$V = \sqrt{MguR} \tag{8.4}$$

If the voltage is measured in terms of the Josephson effect voltage $\nu = hf/2e$ and the current I in terms of v and the quantum Hall resistance $R = h/\,ne^2$ so that $I = f'\,ne/2$, where n is a small integer and f, f' are frequencies, the Planck constant

h can be measured (see Sections 8.3.1 and 8.3.2 below).

Neither the dimensions of the coil nor the density and distribution of the magnetic flux need to be measured. In principle, instantaneous values are required for u and V as the coil passes through the weighing position, but in practice the magnetic flux and coil can be so shaped that Vu^{-1} is almost constant and a value interpolated from measurements made over a finite distance is adequate. If the mean velocity is measured between two instants by counting optical fringes with a gated timer/counter and the mean voltage between the same two instants with a gated integrator, the correlated fluctuations in the actual velocity and voltage caused by vibration are removed from the data.

In the National Physical Laboratory (NPL) realization (Robinson and Kibble, 2007), a current of about 10 mA is controlled to keep the balance in equilibrium. The current is then reversed and a mass M of about 1 kg is placed on the same side of the balance as the coil. The knives and planes are not disturbed, so that the force caused by the current reversal is measured by substitution. Under good conditions, 0.003-ppm repeatability of the mean is obtained.

Then the coil is moved successively upward and downward some 15 times and the average value of uV^{-1} is measured with an accuracy of 0.015 ppm or better as the coil passes through the weighing position. Taking the mean for the two directions of travel eliminates extraneous voltages. The velocity and weighing parts of the realization each contribute to the total uncertainty, and the reproducibility of the result for the watt or for h is about 0.02 ppm.

Another version of this principle of watt realization is in progress at the National Institute of Standards (NIST) (Steiner *et al.*, 2007) and results accurate to 0.036 ppm have been obtained so far.

8.2.2.2 **Electrometers**

Another direct method of relating the mechanical and electrical SI units is to measure the force exerted on the electrode surface of a capacitor when a voltage V is applied to it. Clothier *et al.* (1989) measured the change in force per unit area as a hydrostatic pressure ρgh on a pool of mercury of density ρ when an electric field applied by a plate a distance d above the surface of the mercury was changed from V_1/d_1 to V_2/d_2 (see Figure 8.6a). The mercury pool is surrounded by a moat connected electrically to a guard electrode above it, to establish the unperturbed mercury level corresponding to $V = 0$ from which the height h of the surface of the mercury is raised and is measured. The density of mercury, ρ, was known from the measurements of Cook (1961) at NPL. No capacitance measurements were necessary, because the change in voltage may be calculated from the equation

$$V_2/\sqrt{h_2} - V_1/\sqrt{h_1} = \left(2\rho g/\varepsilon\right)\left(d_2 - d_1\right) \tag{8.5}$$

where $V_{1,2}$ and $d_{1,2}$ are so chosen that $h_1 \approx h_2$; ε is the relative permittivity of the residual vapor above the mercury surface. h was only about 0.6 mm (equivalent to 2000 optical fringes), but nevertheless this realization reached an accuracy of ±0.32 ppm.

Other realizations of similar accuracy have involved an electrode suspended from a balance, as shown in Figure 8.6b. The force F_x and capacitance changes resulting from the displacement of a second electrode by a measured distance yield V in SI volts, because

$$V^2 = \frac{2F_x}{\partial C/\partial x} \tag{8.6}$$

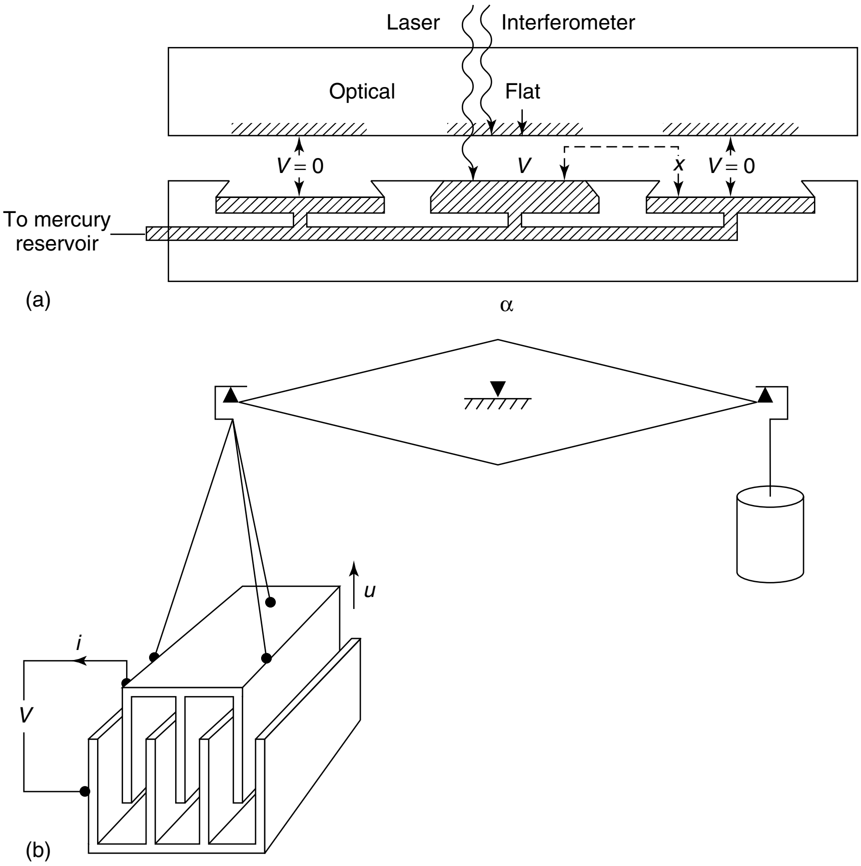

Fig. 8.6 (a) A mercury-pool electrometer. (b) An interleaved plate electrometer.

$\partial C/\partial x$ is obtained either from the dimensions of the apparatus by calculation (Elnekave, Fau, and Delahaye, 1976) or by measurement of capacitance (Bego, 1988; Funck and Sienknecht, 1988), in terms of a calculable capacitor. Because a watt balance seems to offer better accuracy, work on electrostatic balances has ceased for the present but it is also possible to proceed via the virtual work principle that lies behind the watt balance realization. The magnitudes of the quantities involved are less favorable than in a watt balance apparatus, and a measurement having useful accuracy has yet to be made by this technique.

8.2.2.3 **Defining the Kilogram via Avogadro's Constant**

A seemingly straightforward way to define the kilogram in terms of a fundamental constant would be to specify it as the mass of a (very large) number of atoms. Counting such a large number can be accomplished if the atoms are arranged in a crystal whose structure is as nearly perfect as possible (Becker, 2003). The refining techniques that have been developed for silicon make it the best candidate at present. The number of atoms in an almost perfectly spherical artifact of silicon can be calculated from the distance between atoms and the mean diameter of the sphere. The distance between atoms is measured by a device in which a laminar plate is moved a measured distance between two fixed plates while the passage of planes of atoms is counted by observing Moiré fringes in the passage of a collimated X-ray beam that passes perpendicularly through the plates. Obtaining and maintaining subatomic alignment of the planes while translating the middle plate through a few millimeters demands the ultimate precision from strip-hinge technology.

This atom-counting procedure constitutes a measurement of Avogadro's constant, N_A which is connected to Planck's constant, and therefore to the watt balance approach to the kilogram, by the expression

$$N_A = c_0\alpha^2 A_r(\mathrm{e})M_u/(2R_\infty h) \tag{8.7}$$

where the other constants, c_0, the velocity of light in free space, α, the fine-structure constant, $A_r(e)$, the relative atomic mass of the electron, M_u, the molar mass constant and R_∞, the Rydberg constant, have either defined or more accurately known values.

There are two major problems in this approach. First, the mass of a silicon atom is not unique because naturally occurring silicon consists of three isotopes in ratios of approximately 92 : 5 : 3. Determining the ratio of these amounts accurately enough is very difficult, but work is in progress to create artifacts from crystals consisting almost entirely of a single isotope. Second, the surface of a silicon sphere is covered with a layer a few atoms thick of silicon oxides and the thickness of this layer has to be accurately measured by ellipsometry to account for the mass discrepancy it produces.

At the time of writing (2007), there is up to one part-per-million discrepancy between the silicon crystal and watt balance approaches to redefining the kilogram, but it is hoped that this discrepancy will be resolved in the next few years.

8.2.2.4 **Self-Consistency of the SI**

The continuing progress toward basing the SI on the (presumed) unchanging values of fundamental physical constants has raised the question as to whether the von Klitzing constant is exactly h/e^2, the Josephson constant is exactly $2e/h$ and whether electron-counting experiments transport charge in elements of e exactly. Strong evidence for the validity of these assumptions would be obtained from experiments, which examine the closure of the so-called ''metrological triangle'' in which a current measured in counted electrons is passed through a resistance measured by the quantum Hall effect in terms of the von Klitzing constant and the resulting voltage drop measured against a Josephson effect voltage standard. That is, whether

$$(e) \times (2e/h) \times (h/e^2) = 2 \tag{8.8}$$

within experimental error. In principle, a single experimental arrangement in which electrons are counted, pass through a quantum Hall device and the resulting voltage is opposed to a Josephson junction voltage, will examine this. No other units are required provided that the radio frequencies needed to count out the electrons and generate the Josephson voltage are scaled from the same frequency source. At present, the 1-ppm accuracy with which electrons can be counted is a limitation, but this is likely to improve substantially in the future.

8.3 Working Standards of Voltage and Resistance

8.3.1 A Standard for the Volt

We can establish a representation of the SI volt from the ac Josephson effect in which microwaves of frequency f are shone on a junction formed from an insulating barrier a few nanometers thick between two superconductors (see Figure 8.7). A current of electron pairs tunneling through the barrier gives rise to a voltage $V = nf(h/2e) = nf/K_J$ across this insulated junction of superconductors, where n is a small integer, h is the Planck's constant, e is the electronic charge, and $K_J(= 2e/h)$ is the Josephson constant. A measurement of f and knowledge of n gained from the approximate value of the voltage enables V to be derived in terms of a conventional value assumed for $2e/h$. This value is so chosen that V is then expressed in terms of the SI volt as given by the best realizations available. If a single junction is used, V is only a few millivolts and has to be scaled up to 10 V for practical dissemination either by a potentiometric ratio method often involving Hamon resistors or by using a superconducting current comparator (described below in connection with the quantum Hall effect). The technology of connecting many Josephson junctions in a series array so that each is subjected to nearly the same incident microwave power has been developed (Niemeyer, Hinken, and Kautz, 1984; Hamilton *et al.*, 1985), and any multiple of 150 μV up to a few volts can be established. Hundred and fifty microvolts corresponds to the 72.5-GHz microwave radiation for which the array is designed. An array provides a greatly simplified and more accurate voltage standard than the use of a single junction. Modern arrays employ a superconductor fabrication technology, which leads to a nonhysteretic $I - V$ characteristic. The integer n, equal to the number of junctions, is stable and only

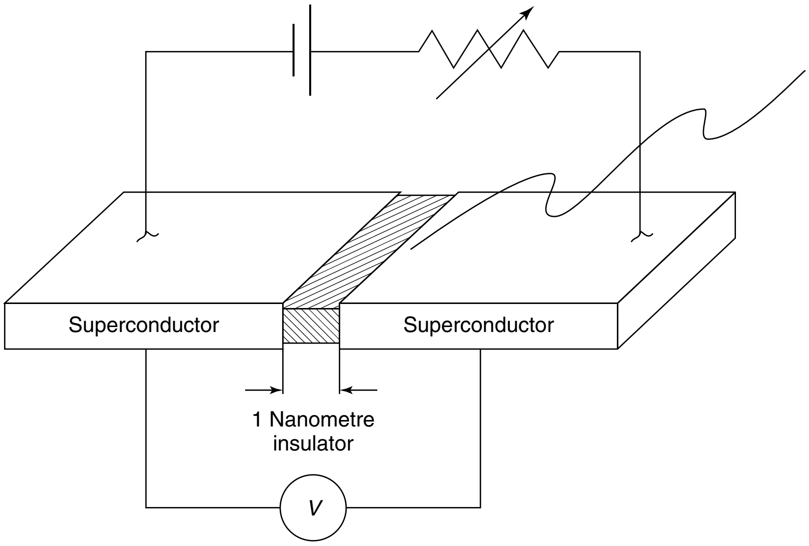

Fig. 8.7 A single Josephson junction.

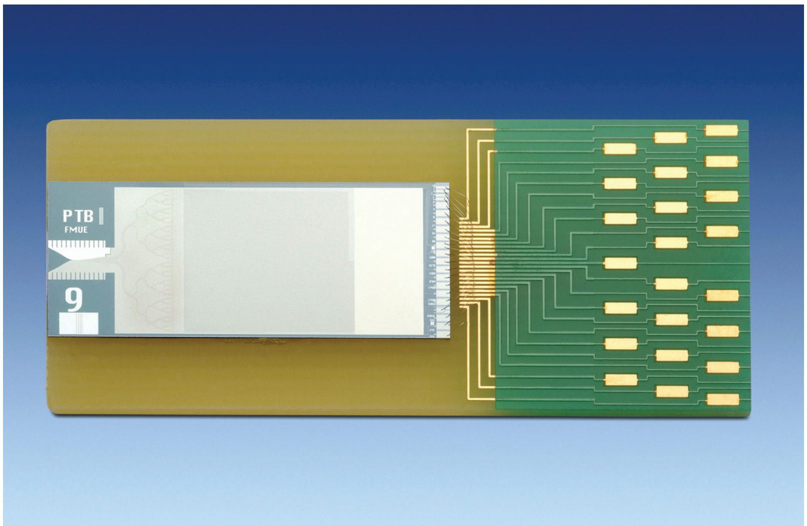

Fig. 8.8 A Josephson multijunction array.

needs to be determined once. Arrays consisting of subarrays with junction numbers forming a binary sequence can be used as programmable quantum digital-to-analog converters and provide a quantum standard for low-frequency ac voltages. (Hamilton *et al.*, 1989; Pöpel *et al.*, 1990) Figure 8.8 shows a modern 10-V array manufactured at the Physikalisch-Technische Bundesanstalt (PTB), Germany.

Using an array of Josephson junctions, calibrations reproducible to 0.01 ppm are readily achieved, the principle limitation being the variability of the thermal emfs arising from the thermal gradients along the conductors connecting the array, which is at a cryogenic temperature, to the room-temperature terminals. To eliminate thermal and other spurious emfs, both voltage sources being compared must be capable of reversal. Taking the mean of the comparison before and after reversal then eliminates all unwanted emfs, provided they do not vary significantly during this short time. A Josephson array can be made to give a voltage of either polarity by presenting its terminals with a voltage of the required magnitude and polarity while increasing the microwave power from zero.

The resolution with which voltage sources can be compared has recently been greatly increased by the availability of electronic null detectors. The noise these contribute to the measurement does not add significantly to the irreducible Johnson noise arising from source resistance. The semiconducting transistor and diode junctions in these electronic detectors are, however, prone to rectify any interference voltage appearing at their input terminals, leading to systematic errors.

8.3.2
A Standard for the Ohm

The quantum Hall effect affords precisely reproducible voltage-to-current ratios, and these constitute the best representation of the SI ohm now available. Both silicon MOSFETs and heterostructures of gallium arsenide-gallium aluminum arsenide at liquid helium temperatures provide the necessary conditions to establish a two-dimensional electron gas in a boundary layer of a few nanometers thick. When a strong $(1 - 14T)$ magnetic field is applied in a direction perpendicular to this layer, the ratio of the voltage between the sides of the layer to the current flowing across the layer (i.e., the Hall "resistance" R_H) is found to take one of a number of discrete values depending on the strength of the applied magnetic field (see Figure 8.9). The peculiar quantum-mechanical nature of the device is such that any two-terminal measurement of the voltage-to-current ratio between any two points on the boundary of the layer reveals a true resistance equal to the step resistance plus that any contact resistances involved. By contrast, in a four-terminal measurement when the current and potential terminals alternate around the boundary, the voltage-to-current ratio equal to R_H is observed. The theory of the effect indicates that $R_H = h/ie^2$, where i is an integer, as the temperature approaches absolute zero for certain ranges of magnetic field values. Measurements made so far support this theory, at least to an accuracy of 0.01 ppm. Moreover, the values of R_H have been measured to be independent of the particular device used to generate them to within 0.00035 ppm.

Despite its purely superficial resemblance to the Josephson effect used as a voltage standard, the physical origins of the quantum Hall effect are quite different (Hartland, 1988), and in particular it is important to realize that the simple expression for R_H given above is exact only at the unattainable absolute zero of temperature, $T = 0$. However, fortunately, the approximation is sufficiently good for all practical purposes at temperatures between 0.3 and 4.2 K, depending on the particular device. A measure of the error involved is simply obtained by measuring the voltage drop along the direction of current flow, using extra connections made on the

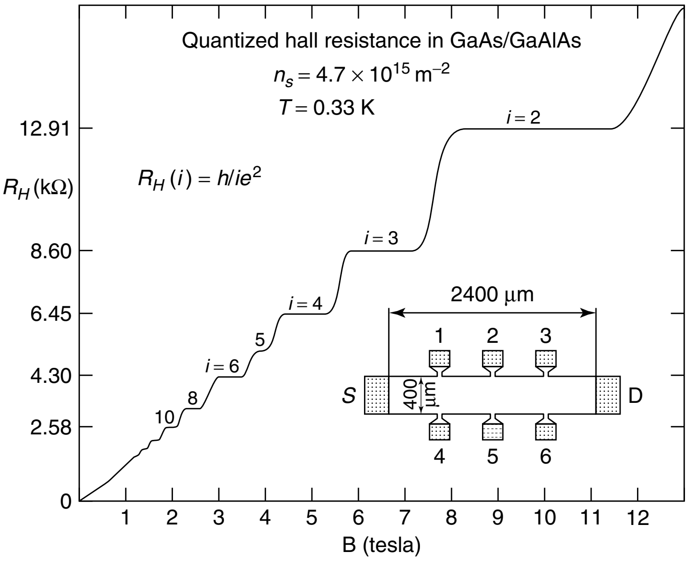

Fig. 8.9 A graph showing the variation of the voltage-to-current ratio as a function of magnetic field for the quantum Hall device shown in the inset.

same side of the layer between the current connections. This voltage drop is zero only at $T = 0$, but at finite temperatures its ratio to the perpendicular Hall voltage is of the same order of magnitude as the departure from the above expression for R_H. In practice, the temperature can usually be made low enough for the error to be less than 0.01 ppm.

The best resolution currently being obtained in relating R_H to the value of a conventional standard resistor at room temperature is a few times 0.001 ppm.

The measurement circuit used to attain the greatest accuracy is based on a superconducting current comparator (Harvey, 1972), a device whose accuracy depends on the Meissner effect of exclusion of magnetic flux from a superconductor. A long (in principle, infinite), superconducting tube is threaded by two windings of n_1 and n_2 turns carrying the two currents to be compared. The Meissner effect then ensures that any imbalance in their ampere-turns appears as a current flowing over the whole inside and outside surface of the tube so that the total current flowing through the inside of the tube is zero. The magnetic flux from the imbalance current $(n_1 I_1 - n_2 I_2)$ that flows uniformly back around the outside of the tube is independent of the positions of the windings within the tube and can be sensed with great sensitivity by a pickup coil coupled to a SQUID flux detector . A dc SQUID detector circuit contains a Josephson junction near which is a radio-frequency coil that can sense the changing impedance of the circuit when quanta of magnetic flux thread it. An ac SQUID circuit contains two Josephson junctions connected into a superconducting loop and the voltage across the loop is periodic in the number of flux quanta threading it. A dc SQUID is now more frequently employed, as it has greater sensitivity. By registering the state of the SQUID circuit when both the currents in n_1 and n_2 are zero, and maintaining this state with a feedback locking circuit as these currents are increased to their final value, flux balance from these currents is ensured so that $n_1 I_1 = n_2 I_2$. The need for an infinitely long superconducting tube is avoided by arranging its

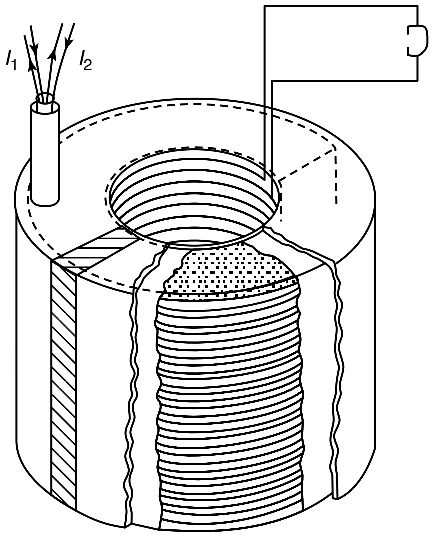

Fig. 8.10 A superconducting current comparator.

topology to be that of a snake swallowing its own tail for about three convolutions. The construction of a practical device is illustrated in Figure 8.10. The n_1 and n_2 turns carrying the currents I_1 and I_2 are wound on a bobbin, which is enclosed in a convoluted superconducting lead-and-insulation shield. The ends of the windings are taken out through a similarly constructed side tube whose layers are connected to the corresponding layers of the convoluted shield. The magnetic field caused by imbalance in the ampere-turns of the windings threads the center of the insulated bobbin where it is sensed by a coil connected to the SQUID.

The resistor and the quantum Hall device to be compared are connected to the windings of the current comparator as shown in Figure 8.11 with a direct connection between one set of potential terminals and a sensitive null voltage detector D between the others. When the voltage at the detector is nulled, either by a shim current in an auxiliary winding on the current comparator or by shunting one of the resistors with an adjustable high resistance, $I_1 R_H = I_2 R$ or $n_1/n_2 = R_H/R$.

As R_H can be equal to 25 812 Ω, 6453 Ω, and so on, 100 Ω is a good choice for the value of R_2. Hundred-ohm resistors are better than the 1-Ω resistors used hitherto as the starting point for comparing with the decade values of resistance in routine calibration work, both because of the relatively smaller effect that thermoelectric potentials have on the measurement circuit and because matching to the noise properties of null detectors is easier.

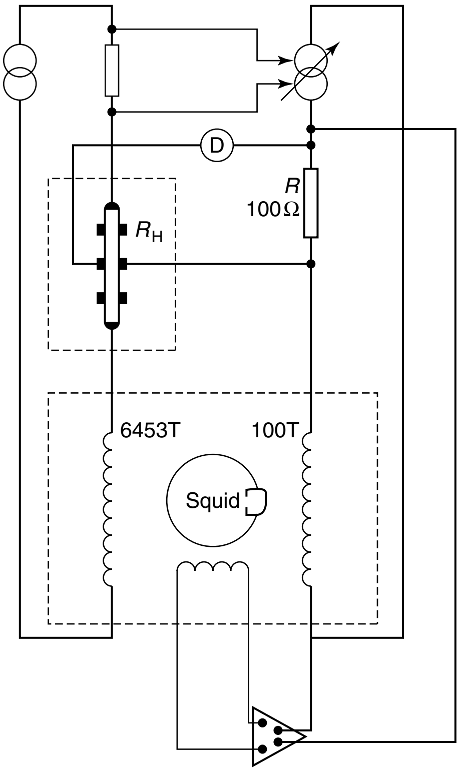

Fig. 8.11 A measurement circuit for comparing R_H with a resistor at room temperature.

8.3.3
Conventional Values Adopted for K_J R_K to Represent the SI Volt and Ohm

From 1 January 1990, the General Conference on Weights and Measures agreed to adopt exact conventional values $K_{J-90} = 483597.9\,\mathrm{GHz\,V^{-1}}$ and $R_{K-90} = 25812.807\ \Omega$, respectively, for the Josephson and von Klitzing constants to represent the SI volt and Ohm for international conformity in ordinary measurements. It must be understood that if the actual value of K_J or R_K in SI units is required, for example, for the comparison of measured values of fundamental constants, an additional uncertainty must be ascribed to the measurements.

8.4
Other Primary Standards of National Measurement Institutes

8.4.1
dc Voltage

Other primary working voltage standards, such as Zener diodes and Weston standard cells, can be measured against an array of Josephson junctions. An array yields a representation of the SI volt by using the conventionally agreed value for the frequency-to-voltage conversion constant governing the Josephson effect. Higher and lower dc voltages are easily measured using the measured resistance ratios of resistive voltage dividers.

8.4.2
dc Resistance

Stable wire resistance standards of (usually) 100-Ω value can be calibrated directly in terms of the quantum Hall effect using the verifiably accurate current ratios created by a superconducting current comparator. Standards of other decade values can be derived either by a superconducting current comparator or by Hamon resistors (see Section 8.2.1.1), or simply by connecting 10 resistors in series to generate standards of 10 kΩ and greater. Typical accuracies of decade values derived in this way are given in Table 8.1.

8.4.2.1 The ac Behavior of Standard Resistors

An ideal resistive circuit component under ac conditions will have the potential across it exactly in phase with the current passing through it. Its resistance will be independent of the ac frequency. The value of a real resistor $R(f)$ will be its resistance at the frequency f, and will depend only slightly on f through causes such as the tendency of the current to be deflected outwards to a path of smaller cross section at the surface of the conductor by its associated magnetic field (the ‘‘skin effect’’) or the ‘‘proximity effect’’ caused by additional loss mechanisms associated with currents magnetically induced in neighboring conductors. The magnetic field of these induced currents couples back into the original conductor and generates an opposing in-phase emf.

A practical resistor will also have small self-generated modifying currents and

voltages at 90°-phase associated with its accompanying magnetic and electric fields. These effects are quantified as the self inductance, L, and self capacitance, C, of the resistor and their effects can, up to quite high frequencies, be described by a single parameter, the time constant τ of the resistor. The ac impedance of the resistor is

$$Z(f) = R(f) + j \times 2\pi f \tau \tag{8.9}$$

τ is equal to LR^{-1}, or $-RC$ if the self capacitance or inductance, respectively, is negligible compared to the other. τ can be as small as 10^{-9} s, particularly for resistors in the range of values from 10 to 1000 Ω when the inductive and capacitive effects tend to cancel. τ is measured in a bridge network by comparison or substitution with standards having known or negligible values of τ, measured in quadrature bridge networks from well-designed gas-filled capacitors having very small departures from 90°-phase between current and voltage.

8.4.3
Capacitance

Primary standards of capacitance are calibrated either via an artifact – a very stable fixed-value capacitor whose value is established from time to time directly in terms of the Thompson–Lampard calculable capacitor – or from a resistance measured in terms of the quantum Hall effect, using a resistance-capacitance ac bridge (Kibble and Rayner, 1984). The value of the best capacitance standards can be constant to within 0.1 ppm over a few years. Either route depends on coaxial ac bridge techniques, which imply complete electrical definition of impedance standards at kilohertz frequencies. Coaxial ac bridge techniques are also used to scale the value of a primary capacitance standard to values of other standards at decade intervals from 1 pF to 1 F with the accuracies given in Table 8.2.

8.4.4
Inductance

Inductance is derived from capacitance. Either the parallel-resonance technique illustrated in Figure 8.12a is employed, in which the reactances of a capacitor and an inductor are observed to be equal at a particular measured frequency, or the ratio of these reactances is measured using the Maxwell–Wien ac bridge illustrated in Figure 8.12b. An inductive ratio-arm ac bridge can scale inductance to other decade values with little further loss of accuracy, and the typical 100-ppm or better accuracies obtained are sufficient for all present scientific or commercial needs.

8.4.4.1 The Frequency Dependence of Standard Inductors

Skin and proximity effects, by excluding magnetic flux from the conductors and any constructional metalwork of an inductor, will alter its value slightly in a frequency-dependent manner. Its reactance will also be modified by the capacitance associated with its surrounding electric field. These effects are investigated in calibrating standard inductors by comparing them with specially constructed inductors wound with thin, spaced conductors

whose self capacitance has been measured by observing their self-resonant frequency when the terminals are shorted.

8.4.5
Electric Fields and Dielectric Constants

Electrical field strengths can be inferred directly in volts per meter from the voltages on conducting surfaces between which the electric field is generated, because conducting surfaces define the field-boundary conditions accurately.

The relative permittivity of materials is measurable in terms of the change of capacitance that a sample of the material produces when inserted in a suitable test capacitor. Permittivities are also needed at frequencies as high as in the microwave region, and are then measured by a waveguide insertion or an interferometric technique (Kemp *et al.*, 1996).

8.4.6
Magnetic Quantities

In contrast to electric flux and permittivity, magnetic flux cannot in general be deduced with any accuracy from the currents generating it if the boundary conditions at the surfaces of any magnetic media are involved (the superconductivity Meissner effect excluded), and the units and basic measurement of total flux and flux density of magnetic fields must be provided in other ways.

8.4.6.1 Total Magnetic Flux

The SI unit is the weber, and it is defined and realized in terms of the emf V produced around a circuit resulting from the rate of change of the total magnetic flux in webers threading it. That is,

$$V = -d\Phi/dt \qquad (8.10)$$

which may be integrated to yield

$$\Phi = \int V dt \qquad (8.11)$$

Therefore, the weber can be realized by directly measuring total flux by integrating the voltage induced in a search coil, which encompasses all the flux. The voltage integral is measured as the flux is established, or as the coil is moved into position from a region where the flux is negligible, with an electronic integrating circuit that is calibrated in terms of a known direct current charging a capacitor of known value. If the flux is caused by an alternating current of known wave form, the voltage integral can either be measured directly as a mean rectified value or be inferred from the wave form and a measurement of the peak or root mean square voltage.

8.4.6.2 Magnetic Flux Density

This can be measured using a similar search coil method in which the search coil is small enough to encompass only a region over which the flux is uniform. The flux density measurements made by the search coil can be calibrated either by measuring the voltage induced in it when it is inserted into, or its sense is reversed in, a known flux density (derived from a current-carrying coil of measured geometry).

A much more accurate indirect method is to observe the precessional frequency of protons in the flux (Williams *et al.*, 1985).

8.4.7
ac Current and Voltage

These are not ‘‘basic’’ quantities in that they do not require separate definition of their units, but relating them at the highest accuracy level to the corresponding dc

quantities does need a specialized measurement technique that is only to be found in national measurement laboratories.

The basic concept is to equate the heating of a dissipating element by a direct current with the same heating power generated by an alternating current. To ensure that the distribution of heat in the dissipating element is independent of frequency up to at least 100 kHz (i.e., eddy-current, capacitive, and inductive effects are negligible), the physical dimensions of the element are kept very small – usually by making it from a fine, straight length of resistance wire. The design of a typical single-element device is illustrated in Figure 8.13 where the temperature of a heater wire is sensed by a thermocouple attached to its center by an insulating glass bead. Sensitivity and accuracy can be somewhat enhanced, at the expense of high-frequency performance, by putting several thermocouple temperature sensors in series along a heater element (Dix and Bailey, 1975). Devices deposited on a substrate by integrated circuit techniques have now superseded these wire-and-bead convertors (Klonz and Weimann, 1989; Scarioni, Klonz, and Funck, 2005).

If the two currents are also compared via the voltages they produce in turn across a resistor whose value is independent of frequency, then the alternating and direct currents and voltages can be separately related.

Glossary

ac Josephson Effect: A phenomenon in which microwaves of frequency f are shone on a thin insulating barrier between two superconductors. A current of electron pairs tunneling through the barrier interacts with the nth harmonic of the microwave frequency, resulting in a precise voltage equal to $nf(h/2e)$ appearing across the barrier, where e is the electronic charge and h is the Planck constant.

Farad: The electrical capacitance between electrodes having a potential difference of 1 V when charged with 1 C.

Quantum Hall Effect: This effect gives rise to fixed ratios of transverse voltage to the current flowing through a semiconducting device in which the electrons are confined to two-dimensional motion at very low temperatures in a strong perpendicular magnetic field. These ratios are often termed as *quantized Hall resistances*.

Realize (a Unit): Use appropriate apparatus to derive a value for a standard consistent with the abstract definition of a unit. This standard can then be used to calibrate further standards and instruments.

1.1
Introduction

Light has been a trusted probe of a variety of aspects of the universe since the beginning of scientific inquiry. Today, regardless of whether searching for gravitational waves, exploring the fundamental properties of quantum mechanics, or designing metamaterial, light continues to play a critical role in revealing nature and engineering tools to enhance life. In this chapter, we review a few key elements of classical and quantum light. A comprehensive review of light is well beyond the scope of this chapter. Thus, we have chosen to focus on the properties that are most often encountered in the laboratory while providing some context and history.

Light, an electromagnetic (EM) field, is an intimate coupling between time-dependent electric and magnetic fields. Classically, the EM field is described quantitatively through Maxwell's equations (Section 1.3.1), where it can be viewed as a wave1) – a disturbance – satisfying the wave equation,

$$\nabla^2\Psi = \varepsilon\mu\frac{\partial^2\Psi}{\partial t^2} \qquad (1.1)$$

In Eq. (1.1), ε and μ are the permittivity and permeability of the medium through which the light is traversing ($\sqrt{1/\varepsilon\mu} = v$ is the speed of light or phase velocity in the medium), and ∇^2 is the Laplacian.2) The form of the solution depends on the coordinate system – rectangular, spherical, and so on – in which ∇^2 is expressed, as we discuss in Section 1.3.2. However, in general, the solution for the so-called running wave in one dimension is

$$\Psi(\mathbf{x}, t) = f(\mathbf{x} \pm vt) \qquad (1.2)$$

---

1) Christiaan Huygens, a contemporary of Isaac Newton, viewed light as a wave prior to the mathematical formulation as we now know it. Newton, on the other hand, was convinced that light was a stream of corpuscles.

2) The Laplacian is shorthand for

$$\nabla \cdot \nabla$$

which can be written as

$$\frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} + \frac{\partial^2}{\partial z^2}$$

in rectangular coordinates.

Encyclopedia of Applied Spectroscopy. Edited by David L. Andrews.

ISBN: 978-3-527-40773-6

where **x** describes the distance that the disturbance moves as t increases. The "−"("+") sign indicates motion in the positive (negative) **x** direction.

In vacuum, $\varepsilon \to \varepsilon_0$, $\mu \to \mu_0$, and $v \to c = \sqrt{1/\varepsilon_0\mu_0}$, the vacuum light speed. Special relativity tells us that c sets a "speed boundary" across which information cannot flow. Specifically, those of us living in a "sub-c" universe are prohibited from achieving speeds equal to or larger than c as well as those living in a "super-c" universe from speeds lower than c. Light waves in vacuum are very special and differ from other waves that we encounter in everyday life. There is no rest frame for light and light travels at the same speed in all frames.

As is true of all waves, light is characterized by a wavelength (λ) and a frequency (ν). In vacuum, these quantities are linked by c,

$$\nu \equiv \frac{c}{\lambda} \tag{1.3}$$

In media different from vacuum $v = c/n$ where,

$$n = \sqrt{\left(\frac{\varepsilon}{\varepsilon_0}\right)\left(\frac{\mu}{\mu_0}\right)} \tag{1.4}$$

is the index of refraction and the quantities in parentheses are the electric and magnetic dielectric constants respectively; μ differs slightly for μ_0 for most cases of interest. The more general relationship between λ and ν is

$$\nu = \frac{v}{\lambda} = \frac{c}{\lambda_0} \tag{1.5}$$

where λ_0 is defined as the vacuum wavelength. By definition, ν is medium independent and maintains its vacuum value so

$$\lambda = \frac{\lambda_0}{n} \tag{1.6}$$

We note that it is possible for the speed of massive particles to exceed the speed of light in media. Shock waves that result are similar to a sonic boom for sound waves. In the case of light, it is called *Cherenkov radiation*.[3] The emitted light is confined to a cone, the half angle of which is defined by

$$\alpha = \cos^{-1}\left(\frac{c}{nv_p}\right) \tag{1.7}$$

where v_p is the particle speed.

The wavelength spectrum of light is vast, ranging from radio waves to γ-rays, with characteristic wavelengths as large as astrophysical objects to as small as nuclei, respectively (see Section 1.2). A narrow light source, such as a line-narrowed continuous wave (CW) laser, is often said to emit a "single frequency;" such light is termed *monochromatic light*. Monochromanicity, however, is a relative statement. Monochromatic as compared to what? All known sources of light emit within some bandwidth – a spread in wavelength ($\Delta\lambda$) or frequency ($\Delta\nu$) – be it as broad as the solar spectrum or as narrow as the resonance line of an atom.[4] While λ and ν are inversely proportional, it is helpful to

---

[3] The 1958 Nobel Prize in Physics went to Pavel A. Cherenkov for his discovery in 1934 that bears his name, which he shared with Ilya M. Frank and Igor Y. Tamm for their explanation (Cherenkov, Frank and Tamm, 1958).

[4] Microwave sources and state-of-the-art ultra-stable lasers can have widths of a fraction of a Hertz. Even still, $\Delta\nu \neq 0$!

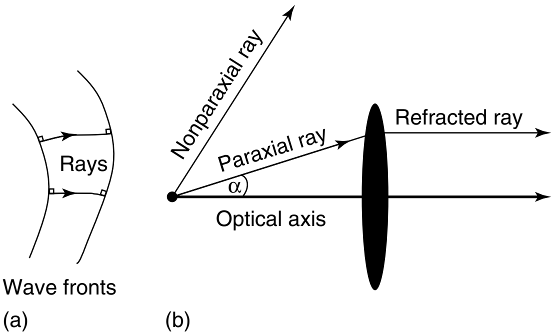

Fig. 1.1 Definition of rays and wave fronts (a) and paraxial rays (b) where $\alpha \ll 1$ rad.

recognize that

$$\left|\frac{\Delta\lambda}{\lambda}\right| = \left|\frac{\Delta\nu}{\nu}\right| \tag{1.8}$$

Classically, the treatment of light falls into two categories: geometrical and physical optics. In geometrical optics, the wave properties (e.g., diffraction) are ignored. Conceptually, we let $\lambda \to 0$ and instead discuss rays. While we do not review the usage of rays in this chapter, we do point out that ray tracing is employed extensively for designing optical systems. Rays are related to waves in that they are perpendicular lines joining the wave fronts (see Figure 1.1). The wave fronts turn out to be the surfaces of constant phase and so rays point in the direction of energy flow. Thus, rays from a point source are radial lines perpendicular to spherical surfaces. Typically, when dealing with rays, we focus on a subset of all the rays called *paraxial rays*. These rays are nearly parallel or form a small angle about a preferred direction. In the example shown in Figure 1.1, the ray traversing the center of the lens is the preferred direction and is called the *optical axis*. Paraxial rays deviate from the optical axis by such a small amount that $\sin\alpha \simeq \tan\alpha \simeq \alpha$. Rays are useful for describing refraction, the bending or redirection of light at the interface between two media with different indices of refraction, and reflection. Refraction, responsible for focusing of light by lenses and the angular spread of the $\Delta\lambda$ components after passing through prisms, is a result of momentum conservation and is succinctly stated through Fermat's principle: *light traverses a path from A to B that is an extremum of the optical path length (OPL)*.[5] That is,

$$\delta(OPL) \equiv \delta\left(\int_A^B n(s)ds\right) = 0 \tag{1.9}$$

where s is the geometric path. Fermat's Principle leads to two important properties of light. First, the law of reflection,

$$\theta_i = \theta_r \tag{1.10}$$

---

[5] The principle is often stated as the shortest path, that is, $\delta(OPL)$ would be a minimum. However, the calculus of variation only uses the fact that OPL is stationary; the second derivative is not considered. Thus, while usually the case, the path taken is not necessarily the minimum optical path.

where θ_i (θ_r) is the incident (reflected) angle. The second is Snell's Law,

$$n_1 \sin\theta_1 = n_2 \sin\theta_2 \qquad (1.11)$$

relating the incident (θ_1) and refracted (θ_2) angles for a ray refracted (i.e., bent) as it passes through an interface between two media with different indices of refraction.

It is interesting to note that Fermat's principle (ca 1657) is closely related to Maupertu's principle in mechanics (ca 1744) for self-contained systems obeying conservation laws,

$$\delta\left(\int_A^B p ds\right) = 0 \qquad (1.12)$$

where p is the momentum. Equation (1.12) is the principle of least action[6] when formulated more generally as

$$\delta\left(\int_A^B \mathcal{L}\, dt\right) = 0 \qquad (1.13)$$

with $\mathcal{L}$ being the Lagrangian.[7] These equations show that particles and rays of light assume rectilinear motions in free space or when there are no forces (fields[8]) and the index of refraction is constant. In general, the trajectories of particles and light are stationary. The index of refraction plays the role of a field causing rays to deviate from linearity when not constant just like forces (potentials) cause particle trajectories to bend.

The geometrical approximation is good when the variation of the physical features of the media are large in comparison to λ. When they become comparable to λ, the wave properties of the light must be considered. The realm of physical optics allows descriptions of elements such as apertures and grating. It further provides a framework to discuss fundamental concepts such as diffraction (the angular spread of a beam of light and the bending of light around obstacles Section 1.7), interference (the superposition of two or more waves, leading to constructive and destructive sums depending on the relative phase of the waves Section 1.8), and coherence (issues associated with how stable the phase is in time and across wave fronts).

The smallest unit of light is called the *photon*, light quanta after the German *Lichtquanten* meaning portions of light.[9] While centuries before the age of quantum physics, Isaac Newton championed the idea of light as a stream of corpuscles, photons are quantum entities whose behavior under certain conditions are well known. However, the answer to the question "*What is a photon precisely*" continues to be illusive. Over the years, the *definitions* tend to fall into one of three distinct categories:

- a fundamental particle;
- an elementary excitation of the EM field; or
- something registered by a photodetector.

---

[6] Like with Fermat's principle, least action is a bit of a misnomer; stationary action would be more appropriate as again only the first derivative is considered.

[7] We point out that Hamilton, Lagrange, Euler and others played a role in the development of the principle as well.

[8] Even in vacuum, the trajectory of light is deflected by a gravitational field. See, for example, Refs. Misner, Thorne and Wheeler (1973) and Hartle (2003) for a discussion of light in a gravitational field.

[9] Gilbert N. Lewis is given credit for coining this name (Lewis, 1926).

In this chapter, we do not argue for or against one view over another.

Massless photons, like massive particles, carry both energy, $h\nu$, and momentum, h/λ, where h is Planck's constant. However, the photon wavefunction must be constructed with care. There have been suggestions that the photon can be understood as simply a classical field plus vacuum fluctuations[10] – a semiclassical approach if you will. There are cases, however, where such an approach gives the wrong answer (as determined by experimental observation). Thus, we have two regimes: classical light and quantum light. By definition, quantum light is any behavior of light that cannot be explained by classical fields, that is, solutions to the wave equation. An example would be squeezed light (Henry and Glotzer, 1988).

The photon is considered to be a fundamental particle. It has an intrinsic spin, which is an integer of unit magnitude. Thus, it obeys Bose statistics, but it has only two states of helicity (aligned or antialigned with its direction of propagation) because being massless, it has no vacuum rest frame. In addition to spin, light has other nonclassical features, typically revealing themselves through intensity noise, correlations, and counting statistics. Finally, both classical fields as well as photons can carry orbital angular momentum and support vortices and solitons (Desyatnikov, Kivshar and Torner, 2005; Kivsha and Agrawol, 2003; Pismen, 1999).

We conclude this introduction by pointing out that if we substitute h/λ for p into Eq. (1.12), we get a different formulation of Fermat's principle,

$$\delta\left(h\int_A^B \frac{ds}{\lambda}\right) = 0 \tag{1.14}$$

The close analogy between Eqs (1.12) and (1.14) suggests an intimate connection between matter and light, from which one can postulate a wave equation for matter similar to that for light. As we discuss in Section 1.9, if we identify the wavelength of the particle as h/p (the de Broglie wavelength) and the index of refraction with $(U - V)/U$, where U and V are the total and potential energies, respectively, the time-independent Schrödiger equation emerges in a form that is not very different from the wave equation for light. Thus, photons, like matter, exhibit both wave and particle behavior.

With this overview as a backdrop, the remainder of this chapter is devoted to the details of selected characteristics of light. We start with the description of EM spectrum in Section 1.2 followed by a review of the wave equation and its solutions in Section 1.3. In Section 1.4, we consider radiometric issues and address the vector nature of light in Sections 1.5 and 1.6. We cover diffraction and interference in Sections 1.7 and 1.8 and conclude the chapter by further discussing the photon matter analogy in Section 1.9.

1.2
The Spectrum of Light

The EM spectrum is traditionally divided into the seven regions shown in Figure 1.2. It should be understood that the boundaries between these regions as well as those between subregions are

---

not hard and fast, nor are the number of subregions unique. The most familiar region of the spectrum, the visible region, consists of wavelengths that range from about 0.40 μm at the blue end to 0.78 μm at the red end. Table 1.1 shows the corresponding colors for the wavelengths between. The visible subregions are a good example of the nonuniqueness of subbands of regions; for example, some references include cyan between green and blue while others insert indigo between blue and violet. Breaking the spectrum into six rather than seven or eight bands is of little consequence typically, because most objects emit a range of colors (i.e., $\Delta\lambda$ is relatively broad) or multiple colors (e.g., $\lambda_1 + \lambda_2 + \cdots + \lambda_n$ again spanning a large $\Delta\lambda$), making the identification of a pure color a rare event. Of course, when $\Delta\lambda$ is small as it often is for some lasers, our eyes in fact do perceive a pure color. For example, consider the red Helium–Neon laser at 632.8 nm or the green doubled Nd : YAG laser at 532 nm.

Subbands also exist for the other regions of the EM spectrum. Tables 1.2–1.4 give some of the more familiar subbands for the other regions. More about the spectrum of light can be found in Ref. (HyperPhysics, 2006).

1.3
Basics of Electromagnetic Waves

As mentioned in the introduction, physical optics is concerned with the

Tab. 1.1 The approximate wavelength, frequency, and energy ranges for six primary visible color bands. Energies increase from left to right.

Color	Wavelengths (nm)	Frequencies (×10^{14} Hz)	Energies (eV)
Red	780–625	3.8–4.8	1.6–2.0
Orange	625–590	4.8–5.1	2.0–2.1
Yellow	590–565	5.1–5.3	2.1–2.2
Green	565–500	5.3–6.0	2.2–2.4
Blue	500–435	6.0–6.9	2.4–2.8
Violet	435–380	6.9–7.9	2.8–3.6

Tab. 1.2 The approximate wavelengths, frequencies, and energies of key radio bands.

Designation	Wavelengths (m)	Frequencies (MHz)	Energy (meV)
AM radio	560–190	0.540–1.600	$(2.33–6.62) \times 10^{-3}$
TV	5.5–0.33	54–890	0.223–3.68

wave properties of light, which we examine in this section. We first review how Maxwell's equations lead to the wave equation for the components of the E and B fields. We examine EM wave solutions and their properties, primarily focusing on laser light in homogeneous media in the absence of charge and current sources.

1.3.1
Maxwell's Equations

As we alluded to in the introduction, a wave theory of light predates Maxwell's treatment. In the late 1800s, it was believed that the *aether*, an omnipresent elastic medium, supported light propagation much like the atmosphere or material supports sound waves. Although the theory based on the *aether* had consistency issues and required ad hoc assumptions to sustain it, its belief was so pervasive that even the null result of the experiments by Michelson and Morley could not easily dethrone it.11) It was not until Maxwell showed that his

---

11) The Michelson-Morley experiment was designed to measure a shift in interference fringes (see Section 1.8.1 for a discussion of interference) caused by a change in the speed of light moving with and perpendicular to the *aether*. The experiment is discussed in Refs. Michelson (1881) and Michelson and Morley (1887a,b).

Tab. 1.4 The approximate wavelength, frequency, and energy ranges of the three primary ultraviolet (UV) bands.

Designation	Wavelengths (nm)	Frequencies ($\times 10^{14}$ Hz)	Energies (eV)
UVA	400–320	7.45–9.37	3.10–3.88
UVB	320–280	9.37–10.7	3.88–4.43
UVC	280–200	10.7–15.0	4.43–6.2
Vacuum UV	200–50	15.0–60.0	6.2–24.8
Extreme UV	80–2.5	$37.5–1.2 \times 10^3$	15.5–500
Soft X-ray	4.5–0.15	$(0.7–2) \times 10^4$	$275–8.3 \times 10^3$

mathematical formulation of Gauss's, Ampere's and Faraday's laws (Maxwell's equations) lead naturally to an EM wave equation that could account for observed phenomena without resorting to arbitrary assumptions that the *aether* idea was abandoned.

Maxwell's equations in a medium with sources (represented by ρ, the charge density) and currents (represented by $\mathbf{j}$, the current density) can be written as

$$\nabla \cdot \mathbf{D} = \rho \tag{1.15}$$

$$\nabla \cdot \mathbf{H} = 0 \tag{1.16}$$

$$\nabla \times \mathbf{E} = \mathbf{j} - \frac{\partial \mathbf{B}}{\partial t} \tag{1.17}$$

$$\nabla \times \mathbf{H} = \frac{\partial \mathbf{D}}{\partial t} \tag{1.18}$$

where

$$\mathbf{D} = \varepsilon \mathbf{E} \tag{1.19}$$

$$\mathbf{B} = \mu \mathbf{H} \tag{1.20}$$

These equations are simplified in the absence of sources, $\rho \to j \to 0$, and are the only cases we consider in this chapter.

1.3.2
Wave Equation

It is very straightforward to show that $\mathbf{E}$ and $\mathbf{H}$ of the EM field satisfy Maxwell's equations and the wave equation simultaneously in a homogeneous medium where $\nabla\varepsilon = \nabla\mu = 0$, by taking the curl of Eqs (1.17) and (1.18). Using the vector identity, $\nabla \times \nabla \times \mathbf{V} = \nabla(\nabla \cdot \mathbf{V}) - \nabla^2 \mathbf{V}$, and the fact that $\nabla \cdot \nabla \times \mathbf{V} = 0$ leads to

$$\nabla^2 \mathbf{E} = \varepsilon\mu \frac{\partial^2 \mathbf{E}}{\partial t^2} \tag{1.21}$$

$$\nabla^2 \mathbf{H} = \varepsilon\mu \frac{\partial^2 \mathbf{H}}{\partial t^2} \tag{1.22}$$

which, by inspection, are the same as Eq. (1.1) because $\varepsilon\mu = n^2\varepsilon_0\mu_0 = 1/v^2$. Of course, the general solution is of the form of Eq. (1.2), however, the specifics depend on the geometry and constraints of the problem.

1.3.2.1 Plane Waves

The simplest solution for EM waves is that of a plane wave, where each component of $\mathbf{E}$ and $\mathbf{H}$ is a function of $\xi = \hat{u} \cdot \mathbf{r} - vt$. Recall that $\hat{u} \cdot \mathbf{r} =$ constant defines a plane with $\hat{u}$ being a dimensionless unit vector perpendicular to that plane. It is straightforward then to show that

$$\frac{\partial \mathbf{E}}{\partial t} = -v\frac{\partial \mathbf{E}}{\partial \xi} \tag{1.23}$$

$$\nabla \times \mathbf{E} = \hat{u} \times \frac{\partial \mathbf{E}}{\partial \xi} \tag{1.24}$$

and similarly for **H**. Because **E** and **H** must satisfy Eqs (1.15)–(1.18) (again assuming a homogeneous medium), we can further write

$$\hat{u} \times \frac{\partial \mathbf{E}}{\partial \xi} = \sqrt{\frac{\mu}{\varepsilon}}\frac{\partial \mathbf{H}}{\partial \xi} \tag{1.25}$$

$$\hat{u} \times \frac{\partial \mathbf{H}}{\partial \xi} = -\sqrt{\frac{\varepsilon}{\mu}}\frac{\partial \mathbf{E}}{\partial \xi} \tag{1.26}$$

Integrating Eqs (1.25) and (1.26) and setting the constant to zero (no contribution from the background) leads to

$$\mathbf{E} = -\sqrt{\frac{\mu}{\varepsilon}} \quad \hat{u} \times \mathbf{H} \tag{1.27}$$

$$\mathbf{H} = \sqrt{\frac{\varepsilon}{\mu}} \quad \hat{u} \times \mathbf{E} \tag{1.28}$$

This implies that **E**, **H**, and $\hat{u}$ form a right-handed orthogonal triad and that light is a transverse field, that is, **E** and **H** oscillate in a plane normal to the propagation direction, in homogeneous media (including vacuum) without sources.

1.3.2.2 Scalar Harmonic Waves

The most common building block for the EM wave is a wave that is harmonic in both time and space. These exhibit sinusoidal variation. Typically, a scalar wave can be expressed as either a real quantity[12)]

$$\Psi(\mathbf{r}, t) = A(\mathbf{r}, t)\cos(\mathbf{k}\cdot\mathbf{r} \pm \omega t + \varphi) \tag{1.29}$$

or a complex quantity,

$$\Psi(\mathbf{r}, t) = A(\mathbf{r}, t)e^{i(\mathbf{k}\cdot\mathbf{r}\pm\omega t+\varphi)} \tag{1.30}$$

where A is an amplitude that is a slowly varying function of position and time (compared with the rapid variation of the sinusoidal arguments), **k** is the wavevector ($|\mathbf{k}| = 2\pi/\lambda$) and ω ($= 2\pi\nu$) is the angular frequency. Now it should be clear that $\hat{u}$. The harmonic time dependence of the wave allows the wave equation to be written as

$$\nabla^2\psi + k^2\psi = 0 \tag{1.31}$$

Because **E** and **B** are vectors, the EM wave is actually a vector wave. Generally, each component of the field satisfies the wave equation (Eq. 1.31) and has solutions like those in Eq. (1.29) and (1.30).

The argument of the harmonic wave consists of two phase terms, $\overline{\xi}_\pm \equiv \mathbf{k}\cdot\mathbf{r} \pm \omega t$, the dimensionless version of ξ, and φ. A constant $\overline{\xi}_-$ ($\overline{\xi}_+$) defines a profile or phase of the wave that moves toward more positive (negative) r as time evolves at a speed

$$v = \frac{\omega}{|\mathbf{k}|} \tag{1.32}$$

known as *the phase velocity*. The second phase term is often referred to as the *relative phase of the wave*. It can be a fixed constant or time dependent. When it is a constant or has a well defined time dependence, it gives rise

---

12) Note, we have multiplied ξ by $|\mathbf{k}|$ ($|\mathbf{k}|v = \omega$ because $|\mathbf{k}| = n\omega/c$) to make the argument dimensionless.

to coherence. When it varies randomly with time, the light is said to be incoherent. Furthermore, when $\varphi(t) = \text{const}{\cdot}t^n$, the frequency changes with time. A linear dependence simply shifts the frequency while higher powers chirp the frequency – as the wave passes the frequency either increases or decreases, depending on the sign of the constant. More complicated functions are possible as well.

1.3.2.3 Waves with Curved Phase Fronts

Although plane waves are highly convenient to use, they are appropriate only when dealing with light that is effectively far from its source.[13] Many situations do not fall into this category. It is beyond the scope of this chapter to discuss nonplanar waves extensively, but we will give two examples. For a more extensive discussion, the reader is directed to the text by Cowan, 1968. First, when the fronts are not planes, the solutions in Eq. (1.30) must be modified to correspond to the Laplacian being expressed in a different coordinate system. For example, a spherical wave takes the form

$$\Psi(r, t) = \frac{A}{r} e^{i(kr \pm \omega t + \varphi)} \tag{1.33}$$

where kr = constant. The phase fronts are clearly spheres. A bit more complicated example would be a cylindrical wave, which follows

$$\Psi(\rho, z, \theta, t) = A J_m(k\rho) e^{\pm i k_z z} e^{\pm i m\theta} e^{-i(\omega t + \varphi)} \tag{1.34}$$

where $J_m(k\rho)$ is the mth order Bessel function of the first kind (which are regular at the origin)[14] with m being a positive integer, and

$$k^2 = \left(\frac{\omega}{c}\right)^2 + k_z^2 \tag{1.35}$$

The surfaces of constant phase are just cylinders in this case.

1.4
Energy, Intensity, Power, and Brightness

Because the EM field is composed of E and B fields, its *Energy Density* is given by

$$u = \frac{1}{2}\left(\varepsilon|\mathbf{E}|^2 + \mu|\mathbf{H}|^2\right) \tag{1.36}$$

As a wave, this energy flows as described by the Poynting Vector,

$$\mathbf{S} = \mathbf{E} \times \mathbf{H} \tag{1.37}$$

The *Intensity* of the light is defined as the time average of **S**,

$$I = |\langle \mathbf{S} \rangle| \equiv \frac{1}{2}|\mathbf{E} \times \mathbf{H}| = \frac{n}{2\mu c}|\mathbf{E}|^2 \tag{1.38}$$

which has dimensions of watt per square centimeter.[15] In Eq. (1.38) we used the fact that $\omega/|\mathbf{k}| = c/n$. In vacuum, using the fact that $\varepsilon_0\mu_0 = 1/c^2$, we can write

$$I = \frac{1}{2\mu_0 c}|\mathbf{E}|^2 = \frac{1}{2}\varepsilon_0 c|\mathbf{E}|^2 \tag{1.39}$$

$$\simeq \frac{|\mathbf{E}|^2}{240\pi} \tag{1.39a}$$

---

[13] By far field, we mean that the phase fronts are planes. This can be achieved near the source with lenses.

[14] The boundary conditions of the problem might dictate a different Bessel solution. For example, if the origin were excluded, Bessel functions of the second kind, which are singular at the origin, would have to be considered as well.

[15] Technically, the SI unit is watt per square meter but in the United States, it is typically expressed as watt per square centimeter .

In this form, I has dimensions of watt per square centimeter (watt per square meter) when the dimensions of $\mathbf{E}$ are volt per centimeter (volt per meter). The *Power, P*, delivered is the integrated intensity over the exposed area,

$$I = \frac{P}{A} \tag{1.40}$$

where A is the area.[16] A related quantity, the *Brightness*, which is sometimes referred to as the *Radiance*, takes into account the solid angle, $\Delta\Omega$, through which the intensity is delivered and is given by

$$B = \frac{I}{\Delta\Omega} \tag{1.41}$$

which has dimensions watts per steradian per square centimeter. It is interesting to note that an unfocused laser delivering 1 mW of power at 780 nm is considerably brighter than a 100 W light bulb, 1.7×10^7 W/sr-cm^2 for a typical laser beam[17] with $w_0 = 1$ mm and $\Delta\Omega = 2 \times 10^{-7}$ sr compared with 0.6 W/sr-cm^2 for a light bulb at a distance of 1 m radiating into 4π. Thus, a laser is considered very bright, which can do real damage to an unprotected eye. Finally, laser light can be further characterized by its *spectral brightness*, the brightness per unit optical bandwidth,

$$SB = \frac{B}{\Delta\nu} \tag{1.42}$$

with units as watts per steradian per square centimeter hertz. The *brightness* and *spectral brightness* are often confused with each other as well as with the *Luminance*, a photometric quantity referring to a perceived brightness related more to how the eye responds.

1.5
Polarization

As mentioned earlier, EM waves are actually vector waves, because $\mathbf{E}$ and $\mathbf{B}$ point in specific directions. *Polarization* captures this feature, and is defined in terms of the direction of $\mathbf{E}$.[18] The most general case is elliptical polarization, which has two limiting cases, linear and circular polarization. These names are so chosen because they describe the geometric shapes $\mathbf{E}$ that sweeps out while looking at the light along (parallel or antiparallel to) $\mathbf{k}$. We have already discussed that $\mathbf{E}$, $\mathbf{B}$, and $\mathbf{k}$ form a right-handed Cartesian triad so polarization also specifies the direction of $\mathbf{B}$. We will take $\hat{k} \equiv \hat{z}$ and focus on light that is perfectly polarized in the discussion that follows.

In general $\mathbf{E}$ will have two orthogonal components,

$$\begin{aligned} \mathbf{E}_1 &= \hat{x}E_{01}e^{i(kz-\omega t+\varphi_1)} \\ &= \hat{x}E_{01}e^{i(\bar{\xi}+\varphi_1)} \end{aligned} \tag{1.43}$$

$$\begin{aligned} \mathbf{E}_2 &= \hat{y}E_{02}e^{i(kz-\omega t+\varphi_2)} \\ &= \hat{y}E_{02}e^{i(\bar{\xi}+\varphi_2)} \end{aligned} \tag{1.44}$$

We will first consider the case where E_{01}, E_{02}, φ_1, and φ_2 are all real and

---

[16] The area of a laser beam is given by πw_0^2, where w_0 is the beam radius.

[17] For a diffraction limited laser beam, $\Delta\Omega = \pi\theta_d^2$ where $\theta_d = \lambda/\pi w_0$.

[18] Another reason for considering only $\mathbf{E}$ is the magnitude of $\mathbf{B}$ relative to $\mathbf{E}$ is down by a factor of c. Thus at low intensities, $< 10^{14}$ W/cm^2, $\mathbf{E}$ dominates the physics.

Tab. 1.5 Various electromagnetic field quantities.

Quantity	Name	SI Unit
$c = 2.99792458 \times 10^8$	Light vacuum speed[a]	m/s
$\mu_0 = 4\pi \times 10^{-7}$	Vacuum permeability[a]	T-m/A (kg-m/A^2-s^2)
$\varepsilon_0 = 8.854187817\ldots \times 10^{-7}$	Vacuum permittivity	F/m (A^2-sec^4/kg-m^3)
$\mathbf{E}$	Electric field[b]	V/m (kg-m/A-s^3)
$\mathbf{D}$	Electric displacement	C/m^2
$\mathbf{B}$	Magnetic induction[c]	T (kg/A-s^2)
$\mathbf{H}$	Magnetic field	A/m
ρ	Charge density[b]	C/m^3
$\mathbf{j}$	Current density[b]	A/m^2
P	Power	W (kg/m^2-s^3)
$\mathbf{S} \equiv \mathbf{E} \times \mathbf{H}$	Poynting vector	W/m^2 (kg/m^4-s^3)
$I \equiv \langle \lvert\mathbf{S}\rvert \rangle$	Intensity[b]	W/cm^2

[a] All defined to be exact.

[b] In the US, the explicit length measures for these quantities are given in centimeters, for example, volt per centimeter, watt per square centimeter, and so on.

[c] Sometimes called the *magnetic-flux density*.

time independent. Taking the real part of these fields,

$$\mathbf{E}_1 = \hat{x}E_{01}\cos(\bar{\xi} + \varphi_1) \tag{1.45}$$

$$\mathbf{E}_2 = \hat{y}E_{02}\cos(\bar{\xi} + \varphi_2) \tag{1.46}$$

leads to an equation of a conic section

$$\left(\frac{|\mathbf{E}_1|}{E_{01}}\right)^2 + \left(\frac{|\mathbf{E}_2|}{E_{02}}\right)^2 - 2\left(\frac{|\mathbf{E}_1|}{E_{01}}\right)\left(\frac{|\mathbf{E}_2|}{E_{02}}\right)\cos\varphi = \sin^2\varphi \tag{1.47}$$

and $\varphi = \varphi_2 - \varphi_1$. Equation (1.47) describes an ellipse when

$$\frac{\sin^2\varphi}{E_{01}^2 E_{02}^2} \geq 0 \tag{1.48}$$

Because the numerator and denominator are positive definite, Eq. (1.48) is always true.

Special Linear Case # 1: $\varphi = 0$ or $\varphi = \pi$
Equation (1.47) reduces to

$$\frac{|\mathbf{E}_1|}{E_{01}} = \frac{|\mathbf{E}_2|}{E_{02}} \tag{1.49}$$

which describes a straight line. Because the two component oscillate in phase, this case leads to linear polarization. The case for $\varphi = 0$ and $\varphi = \pi$ are orthogonal to each other.

Special Circular Case # 2: $\varphi = \pm\pi/2$ and $E_{01} = E_{02}$
The equation reduces to

$$|\mathbf{E}_1|^2 + |\mathbf{E}_2|^2 = E_{01}^2 \tag{1.50}$$

the equation of a circle of radius E_{01}. The two components are out of phase by half a wavelength (or period) but the magnitude of the resultant, E_{01}, is constant but sweeps out a circle leading to circular polarization. The sense of rotation depends on the sign of φ, with the minus (plus) sign producing light with positive (negative) helicity, where positive helicity obeys the right-hand rule, so if you look in the direction of propagation, the E-field rotates clockwise.[19]

Special Elliptical Case # 3: $\varphi = \pm\pi/2$ *and* $E_{01} \neq E_{02}$

Equation (1.47) reduces to

$$\left(\frac{|\mathbf{E}_1|}{E_{01}}\right)^2 + \left(\frac{|\mathbf{E}_2|}{E_{02}}\right)^2 = 1 \tag{1.51}$$

which is an ellipse with the major axis aligned with the horizontal (vertical) axis when $E_{01} > E_{02}$ ($E_{01} < E_{02}$). The sense of rotation is the same as in special case # 2.

General Elliptical Case $E_{01} \neq E_{02}$

In the general elliptical polarization case, one has a rotated ellipse where the angle, α, of the major axis away from the $\hat{E}_1$ direction is given by

$$\tan 2\alpha = \frac{2E_{01}E_{02}}{E_{01}^2 - E_{02}^2}\cos\varphi \tag{1.52}$$

Note, when $E_{01} = E_{02}$, Eq. (1.52) cannot be used and one must go back to Eq. (1.47) to determine α.

1.5.1
Polarization Bookkeeping

There are several approaches to keeping track of the polarization of light, which is particularly important when light interacts with media that can either decrease the intensity or delay the transit time of one polarization or helicity relative to the other. Here, we mention two matrices, namely, the Jones and Mueller matrices. A more in depth discussion can be found in Ref. Goldstein, 2003. The Jones approach involves a set of 2 × 2 matrices with complex elements that transform two-element vectors that describe the complex amplitude and phase of the light. Every Jones vector corresponds to a physically realizable polarization configuration. The Mueller approach uses a set of 4 × 4 matrices with real elements, which have values of either 0 or ±1, to transform the Stokes vectors (see Section 1.5.3). However, some matrices do not represent real configurations.

1.5.2
Jones Matrices

In the Jones calculus Clark Jones, 1941, an initial complex field **E** is transformed to the final complex field **E**′ via matrix multiplication

$$\begin{pmatrix} E'_x e^{i\phi'_x} \\ E'_y e^{i\phi'_y} \end{pmatrix} = \begin{pmatrix} j_{11} & j_{12} \\ j_{21} & j_{22} \end{pmatrix} \cdot \begin{pmatrix} E_x e^{i\phi_x} \\ E_y e^{i\phi_y} \end{pmatrix} \tag{1.53}$$

where the components of the matrix **J** for common elements are given in Table 1.6.

1.5.3
Mueller Matrices

The general Muller calculus is also a matrix operation,

$$\mathbf{S}' = \mathbf{M} \cdot \mathbf{S} \tag{1.54}$$

where **M** is a 4 × 4 matrix and **S** is the four-element Stokes vector, credited to Sir George Gabriel Stokes for their invention. Given the electric fields in Eqs (1.45) and (1.46), the four

---

[19] It should be noted that some references define circular polarization in terms of right-hand and left-hand circular polarization. This definition traditionally corresponds to looking antiparallel to **k** so $\varphi = -\pi/2$ would lead to left-hand circular polarization.

components of **S** are defined as

$$S_0 = |E_{01}|^2 + |E_{02}|^2 \tag{1.55}$$

$$S_1 = |E_{01}|^2 - |E_{02}|^2 \tag{1.56}$$

$$S_2 = |2E_{01}E_{02}\cos\varphi| \tag{1.57}$$

$$S_3 = |2E_{01}E_{02}\sin\varphi| \tag{1.58}$$

The Mueller matrices are given in Table 1.7.

1.6
Longitudinal Field Component

Another manifestation of the vector nature of light is that it has a longitudinal component, even though it is customary to ignore it. It must be noted that a pure plane wave exists over all space and has no transverse variation. The finite extent of the field turns out to be acceptable in many cases but one runs into problems with very intense light, particularly when focused. Lax, Louisell, and McKnight (1975) showed that a purely transverse field is not an exact solution to Maxwell's equations, but rather it is the zeroth-order solution to the paraxial approximation to Maxwell's equations. The exact solutions require a longitudinal component given by

$$E_z(x, y, z) = \frac{1}{ik}\nabla_\perp \cdot \mathbf{E}_\perp \tag{1.59}$$

where $k = |\mathbf{k}| = \sqrt{k_x^2 + k_y^2 + k_z^2}$ and the $\perp$ symbol indicate the transverse components of the ∇ operator and **E** field. Using Fourier analysis of the fields, Scully and Zubairy (1991) showed a field obeying the paraxial approximation,

$$k_x, k_y \ll k \tag{1.60}$$

$$k_z \simeq k\left(1 - \frac{1}{2}\frac{k_x^2 + k_y^2}{k^2}\right) \tag{1.61}$$

implies Eq. (1.59).

1.7
Diffraction

When light passes a sharp edge, it does not produce a sharp shadow. Also, when it passes through a circular hole, it does not produce a disk of the same size. Under the right conditions, it produces not only a larger spot but also rings. Furthermore, the transverse size of a laser beam expands as it propagates. These observations are elegantly described by diffraction theory. Diffraction falls into two classes – Fraunhofer and Fresnel. Fraunhofer diffractions describes what happens when the phase fronts are near plane waves, where the curvature of the field can be ignored. Fresnel diffraction takes curvature into account.

Huygens, in the late seventeenth century, suggested a description for wave propagation as a collection of individual spherical sources called *secondary sources*, the sum of which would make up the wavefront. It is a straightforward exercise to convince oneself that Huygens's principle can be used to construct a plane as well as other simple geometries. When applied to a hole, Huygens's approach leads to an emerging spherical wave, because part of the plane wave is blocked. This would appear to account for the observed spread. However, there is a difficulty. If the secondary waves are spherical, then there should also be part of the wave going backward. Huygens had to ignore this part of the wave. It turns that when considered more mathematically, this problem is corrected by what is call the *obliquity factor*.

The mathematical statement of the principle for a wave propagating in free space is the Fresnel-Kirchhoff integral formula,[20)]

$$\psi_P = -\frac{ik}{4\pi}\psi_0 \iint \frac{e^{ik(r+\bar{r})}}{r\bar{r}} \times [\cos\theta(\mathbf{n},\mathbf{r}) - \cos\theta(\mathbf{n},\bar{\mathbf{r}})]\,dA \tag{1.62}$$

where the integral is over the area of the aperture. The distances, r and $\bar{r}$, between the aperture and observation point and aperture and source, respectively, are defined in Figure 1.3 as is $\mathbf{n}$, the normal to the surface, pointing toward the source. The angles between the vectors and the normal are represented by $\theta(\mathbf{n},\mathbf{r})$ and $\theta(\mathbf{n},\bar{\mathbf{r}})$.

Let's consider an example of an aperture. In the Fraunhofer limit, s and p are effectively a long way from the aperture. In this case, we can take the surface of the aperture to be a spherical cap such that F is constant. Thus, $\bar{r}$ and $\mathbf{n}$ are antiparallel always and $\cos\theta(\mathbf{n},\bar{\mathbf{r}}) = -1$.[21)] Equation (1.62) then reduces to

$$\psi_P = -\frac{ik}{4\pi}A\psi_0 \int \frac{e^{ik(r+\bar{r})}}{r\bar{r}} \times [\cos\theta(\mathbf{n},\mathbf{r}) + 1]\,dA \tag{1.63}$$

[20)] The Fresnel-Kirchhoff integral formula of Eq. (1.62) can be derived from Green's theorem (see, for example, Fowles, 1968) for two functions that are continuous, integrable and satisfy the wave equation,

$$\iint (V\nabla_\perp U - U\nabla_\perp V)\,dA = \iiint (V\nabla^2 U - U\nabla^2 V)\,dV$$

where the first integral is over any closed surface and the second is over the volume enclosed.

[21)] When $\bar{r}$ and r are much larger than the aperture size, a spherical surface is not much different from a flat surface.

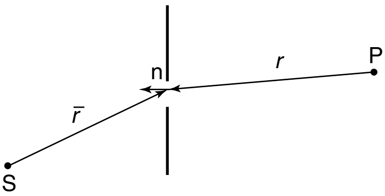

Fig. 1.3 Geometry for the Fresnel-Kirchhoff integral formula.

where $\cos\theta(\mathbf{n},\mathbf{r})+1$ is the obliquity factor mentioned above, which is zero for the wave that is going backwards, towards the source. Table 1.8 gives a few key results derived from Eq. (1.63).

From Table 1.8, we draw an important conclusion. The smaller the aperture, the larger the diffraction. In general, the diffraction angle is given by

$$\text{Slit} \longrightarrow \theta \sim \lambda/b \tag{1.64}$$

$$\text{Circle} \longrightarrow \theta \sim 1.22\lambda/2r \tag{1.65}$$

1.8
Interference

Interference is concerned with the superposition of waves. In general, the sum of wave solutions is also a solution to the wave equation. Here, we consider three examples: summing two waves of the same frequency, the general case of summing multiple waves of different frequencies and generation of short pulses of light by summing many frequencies with a precise phase relationship.

Tab. 1.8 Diffraction patterns from key apertures.*

Aperture	**Intensity**
Slit, width b	$I_0\,(\sin\beta/\beta)^2$
Rectangular slit, area $a \times b$	$I_0\,(\sin\alpha/\alpha)^2$ $(\sin\beta/\beta)^2$
Circular aperture, radius r	$I_0\left(2J_1(\rho)/\rho\right)^2$
N slits, h spacing	$N^2 I_0\,(\sin\beta/\beta)^2$ $(\sin N\gamma/N_{\sin}\gamma)^2$

*$\alpha = (\pi a/\lambda)\sin\phi$
$\beta = (\pi b/\lambda)\sin\theta$
$\gamma = (\pi h/\lambda)\sin\theta$
$\rho = (2\pi r/\lambda)\sin\theta$
ϕ diffraction angle, y direction.
θ diffraction angle, x direction.

1.8.1
Superposition: Single Frequency

This is straightforward to see with plane waves. Consider first two plane waves of the same frequency but with different real amplitudes and a relative phase between them,

$$A_T(\mathbf{r},t,\varphi_o) = a_1 e^{i(\mathbf{k}\cdot\mathbf{r}-\omega t+\varphi_1)} + a_2 e^{i(\mathbf{k}\cdot\mathbf{r}-\omega t+\varphi_2)} \tag{1.66}$$

The sum produces a new sinusoidal wave,

$$A_T(\mathbf{r},t,\varphi) = A_0 e^{i(\mathbf{k}\cdot\mathbf{r}-\omega t+\varphi_0)} \tag{1.67}$$

where

$$A_0 e^{i\varphi_0)} = a_1 e^{i\varphi_1} + a_2 e^{i\varphi_0} \tag{1.68}$$

We can determine A_0 and φ_0 in terms of $a_{1,2}$ and $\varphi_{1,2}$ by expanding the exponentials such that

$$\begin{aligned} A_0(\cos\varphi_0 + i\sin\varphi_0) &= a_1(\cos\varphi_1 + i\sin\varphi_1) \\ &\quad + a_2(\cos\varphi_2 + i\sin\varphi_3) \end{aligned} \tag{1.69}$$

Equating the cosine (sine) terms on the left with those on the right and then dividing the sine terms by the cosine terms leads to

$$\tan\varphi_0 = \frac{a_1\sin\varphi_1 + a_2\sin\varphi_2}{a_1\cos\varphi_1 + a_2\cos\varphi_2} \tag{1.70}$$

At the same time, taking the modulus squared of Eq. (1.68) produces

$$\begin{aligned}|A_0|^2 &= |a_1|^2 + |a_2|^2 \\ &\quad + \left(a_1 a_2^* e^{i\Delta\varphi_0} + c.c.\right) \\ &= a_1^2 + a_2^2 + 2a_1a_2\cos\Delta\varphi_0 \end{aligned}\tag{1.71}$$

where $\Delta\varphi_0 = \varphi_1 - \varphi_2$. Given $a_{1,2}$ and $\varphi_{1,2}$, A_0 (the intensity) and φ_0 can be found from Eqs (1.70) and (1.71). Equation (1.71) is known as the *coherent sum of the two waves.* That is, one adds the amplitudes before squaring to get the total intensity. The intensity is proportional to the square of the amplitude so it is also possible to write Eq. (1.71) as

$$I_T = I_1 + I_2 + 2\sqrt{I_1 I_2}\cos\Delta\varphi_0 \tag{1.72}$$

The third term in (Eqs 1.71 and 1.72) is sometimes called the *interference term* and plays an important role in describing the intensity of the resultant wave. Consider the case where $a_1 = a_2$ so $I_1 = I_2 = I$. When $\Delta\varphi_0 = 2m\pi$ $(m = 0, 1, 2, \ldots)$, the two waves are said to be in phase, in which case

$$I_T = (a_1 + a_2)^2 = 4I \tag{1.73}$$

When $\Delta\varphi_0 = (2m+1)\pi/2$, we have the opposite extreme,

$$I_T = (a_1 - a_2)^2 = 0 \tag{1.74}$$

When $a_1 \neq a_2$, the two extremes give resultants with maximum and minimum I_T respectively.

In the more general case of many waves, all with the same frequency, we have

$$\begin{aligned}A_T(\mathbf{r}, t, \varphi_0) &= A_0 e^{i(\mathbf{k}\cdot\mathbf{r} - \omega t + \varphi_0)} \\ &= \sum_{j=1}^{N} a_j e^{i(\mathbf{k}\cdot\mathbf{r} - \omega t + \varphi_j)}\end{aligned}\tag{1.75}$$

where

$$\begin{aligned}I_T = |A_0|^2 = \sum_{j=1}^{N} |a_j|^2 + \frac{1}{2}\sum_{j\neq k}^{N} \\ \left(a_j a_k^* e^{i(\varphi_j - \varphi_k)} + c.c.\right)\end{aligned}\tag{1.76}$$

and

$$\tan\varphi_0 = \frac{\sum_{j=1}^{N} a_j \sin\varphi_j}{\sum_{j=1}^{N} a_j \cos\varphi_j} \tag{1.77}$$

Again, the resultant is a sinusoidal wave with an intensity given by a coherent sum. In the case where all the amplitudes are the same so that each wave has an intensity I,

$$I_T = N^2 I \tag{1.78}$$

In the case where $\Delta_{j,k} = \varphi_j - \varphi_k$ is not well defined but varies randomly with time, it is straightforward to show that the second sum in Eq. (1.76) vanishes by writing the exponentials in terms of sines and cosines and using the fact that the time average of $\sin\Delta_{j,k} \to 0$ as does that of $\cos\Delta_{j,k}$. Thus, the interference terms vanish. In the case where all amplitudes are the same, the resultant wave corresponds to an incoherent sum of the contributors,

$$I_T = NI \tag{1.79}$$

For an incoherent sum, one squares first and then adds the intensities.

1.8.1.1 Interferometry

An entire field of study with industrial applications is built upon an equation similar to Eq. (1.72). The most general situation is where a beam of light is divided into two with each traveling different paths and brought back together. Because the two beams came from the same source, and if the path length difference is not too large, so that the two beams are still in phase, the resultant intensity will be the same as Eq. (1.72) except that $\Delta\varphi_0 \to \delta$ in the argument of the interference term where

$$\delta = k\Delta l \tag{1.80}$$

with Δl being the path length difference between the two arms. In this case, constructive interference occurs when $\Delta l = n\lambda$, whereas destructive interference occurs when $\Delta l = (2n+1)\lambda/2$, where n is a positive integer. Two-beam interferometry exploits interference patterns to measure inhomogeneities and defects in material.

1.8.2
Superposition: Multiple Frequencies

Superposition involving waves of different frequencies leads to some very interesting possibilities such as ultrashort busts of light. The general principle of summing waves with different frequencies can be understood in the special case where the amplitude and phase are the same for each wave:

$$\begin{aligned} A_T(\mathbf{r}, t) &= A_0 \exp[i(\mathbf{k}_1 \cdot \mathbf{r} - \omega_1 t)] \\ &\quad + A_0 \exp[i(\mathbf{k}_2 \cdot \mathbf{r} - \omega_2 t)] \\ &= 2A_0 \exp\left[\frac{i}{2}(\Delta\mathbf{k} \cdot \mathbf{r} - \Delta\omega t)\right] \\ &\quad \times \exp\left[\frac{i}{2}(\mathbf{k}_m \cdot \mathbf{r} - \omega_m t)\right] \end{aligned} \tag{1.81}$$

where

$$\Delta\mathbf{k} = \frac{1}{2}(\mathbf{k}_1 - \mathbf{k}_2) \tag{1.82}$$

$$\mathbf{k}_m = \frac{1}{2}(\mathbf{k}_1 + \mathbf{k}_2) \tag{1.83}$$

$$\Delta\omega = \frac{1}{2}(\omega_1 - \omega_2) \tag{1.84}$$

$$\omega_m = \frac{1}{2}(\omega_1 + \omega_2) \tag{1.85}$$

Equation (1.81) represents a wave oscillating at the mean of the two frequencies, ω_m, and modulated by a temporal and spatial envelope given by $2A_0 \exp[\frac{i}{2}(\Delta\mathbf{k} \cdot \mathbf{r} - \Delta\omega t)]$. Figure 1.4 shows examples of adding two waves with different frequencies. Unlike the case of equal frequencies, in this case, the two sinusoidal waves produce a wave that is periodic but not sinusoidal. Such waves are called *anharmonic*. For the sum of two waves, we have two different speeds. As with a single frequency, we again have a phase velocity – the ratio between the average frequency and wavenumber, $v_{ph} = \omega_m/|\mathbf{k}|$. But, we have a new speed that goes by the name of the group velocity, the speed with which the envelope moves, $v_g = \Delta\omega/\Delta|\mathbf{k}|$.

When a wave is composed of many frequencies, $\omega \to \omega(k)$. Typically, the frequencies are grouped around a central frequency, $\omega(k_0)$, allowing $\omega(k)$ to be expanded into a Taylor series,

$$\omega(k) = \omega(k_0) + (k - k_0) \left.\frac{d\omega}{dk}\right|_{k_0} + \cdots \tag{1.86}$$

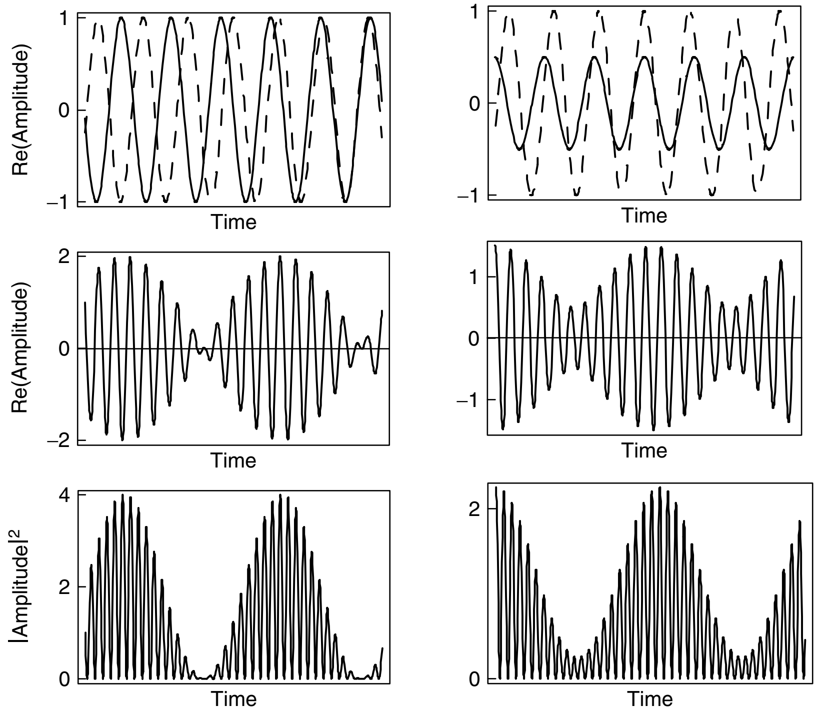

Fig. 1.4 Superposition of two waves, $A_1 \exp[i(\mathbf{k}_1 \cdot \mathbf{r} - \omega_1 t) + \varphi_1] + A_2 \exp[i(\mathbf{k}_2 \cdot \mathbf{r} - \omega_2 t) + \varphi_2]$ where the top row corresponds to the individual amplitudes (A_1 solid curves), the middle row to the resultant sum of amplitudes and the bottom row to the square of the modulus of the resultant amplitudes: (left column) $A_1 = A_2$, $\Delta\varphi = \pi/2$ and $\omega_1/\omega_2 = 0.9$; (right column) $A_1 = A_2/2$, $\Delta\varphi = 0$ and $\omega_1/\omega_2 = 0.9$, where $\Delta\varphi = \varphi_1 - \varphi_2$.

In this case, the addition of the various frequency components is more easily handled via Fourier analysis (see, for example Arfken and Weber (2000) and Boas (2006) for a review), where the amplitude $A(t)$ $(A(z))$ in the time (coordinate space) domain is linked to $\tilde{A}(\omega)$ $(\tilde{A}(k))$ in the frequency (spatial frequency) domain through

$$A(t) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{\infty} \tilde{A}(\omega) e^{-i\omega t} d\omega \quad (1.87)$$

$$\tilde{A}(\omega) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{\infty} A(t) e^{i\omega t} dt \quad (1.88)$$

for time-frequency and

$$A(z) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{\infty} \tilde{A}(\mathbf{k}) e^{-ikz} dk \quad (1.89)$$

$$\tilde{A}(k) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{\infty} A(z) e^{ikz} dz \quad (1.90)$$

for coordinate space - frequency space. Thus, in Fourier components, the electric field for a scalar wave propagating in the z-direction can be written as

$$E(z, t) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{\infty} \tilde{E}(k) e^{-i[kz + \omega(k)t]} dk \quad (1.91)$$

In many cases, $d\omega/dk$ is the appropriate and more general expression for the group velocity. This can be seen by substituting the first two terms of Eq. (1.86) into Eq. (1.91),

$$E(z,t) = \frac{1}{\sqrt{2\pi}} e^{i[k_0(d\omega/dk)|_{k_0} - \omega(k_0)]t} \times \int_{-\infty}^{\infty} \tilde{E}(k) e^{-i[z+(d\omega/dk)|_{k_0} t]k} dk \tag{1.92}$$

However, Eq. (1.90) implies

$$\tilde{E}(k) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{\infty} E(z, t=0) e^{ikz} dz \tag{1.93}$$

which allows Eq. (1.92) to be written as

$$E(z,t) = \frac{e^{i[k_0(d\omega/dk)|_{k_0} - \omega(k_0)]t}}{2\pi} \times \int_{-\infty}^{\infty} E(z', 0) dz' \times \int_{-\infty}^{\infty} e^{i(z' - z - (d\omega/dk)|_{k_0} t)k} dk \tag{1.94}$$

where we do the k integration first. The last integral is just $\delta\left(z' - z - \frac{d\omega}{dk}\Big|_{k_0} t\right)$, from which we get

$$E(z,t) = \frac{1}{2\pi} E(z + d\omega/dk|_{k_0} t, 0) \times e^{-i[\omega(k_0) - k_0(d\omega/dk)|_{k_0}]t} \tag{1.95}$$

By inspection, it is clear that the envelope in Eq. (1.95) moves with speed $d\omega/dk|_{k_0}$ and the carrier oscillates with frequency $\omega(k_0) - k_0 \frac{d\omega}{dk}|_{k_0}$ under the envelope. Thus, we define the group velocity as

$$v_g = \frac{d\omega}{d|\mathbf{k}|} \tag{1.96}$$

In vacuum $v_{ph} = v_g$. However, if the medium through which the wave propagates is dispersive, $n \to n(\lambda)$ so that $dn/d|\mathbf{k}| \neq 0$, the two velocities can be very different. Thus, it is often convenient to write v_g in a form that includes the dispersion explicitly,

$$v_g = \frac{c}{n}\left(1 - \frac{|\mathbf{k}|}{n}\frac{dn}{d|\mathbf{k}|}\right) \tag{1.97}$$

The group velocity is typically the speed with which information is transmitted. It is important to remember that the group velocity is actually only the first term in a series and in cases where $dn/d|\mathbf{k}|$ changes very rapidly or is anomalous (i.e., negative), higher order terms must be kept to determine the speed with which information travels correctly.

1.8.3
Short Pulses

Figure 1.4 shows the basic idea for generating pulses of light of short duration. Specifically, in this case, two frequencies with well-defined relative phase (i.e., fixed in time) are summed in the frequency domain to provide a new wave with beats in the time domain. As additional frequencies are added, the temporal width of the beat envelope narrows. To gain a better understanding of the relationship between the length of the pulse train and its *bandwidth* or number of frequencies required to sum in order to produce it, we will turn the problem around and start with an idealized pulse train in the time domain. Figure 1.5, for example, shows two finite length, idealized, pulse trains, one with three cycles and the other with six cycles.

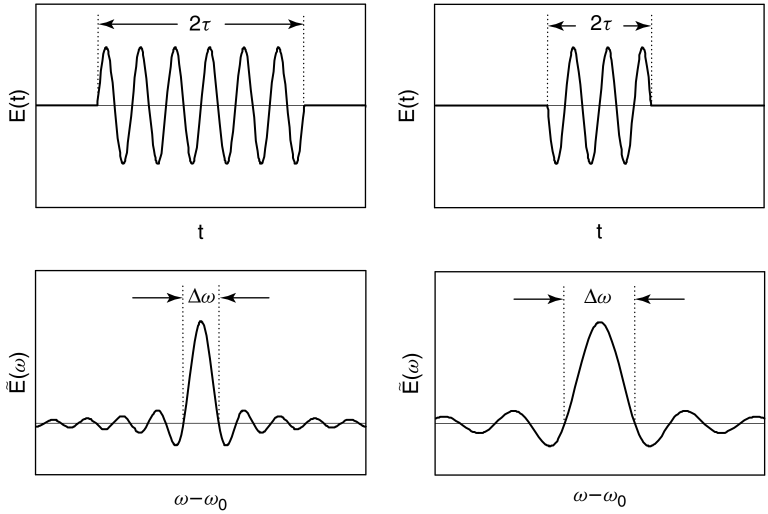

Fig. 1.5 Idealized short pulses formed by finite unit amplitude N-cycle pulse trains (top) with $N = 6$ (left) and $N = 3$ (right). Their respective Fourier transforms appear below with peak amplitudes of $\sqrt{\pi/2}N/\omega_0$ and the first zeros occurring at $\omega = \omega_0(1 \pm 1/N)$.

Mathematically, these obey

$$E(t) = \begin{cases} E_0 \sin \omega_0 t & \text{for } -\tau \le t \le \tau \\ 0 & \text{at other times.} \end{cases} \tag{1.98}$$

The length of this pulse is 2τ, where $\tau = N\pi/\omega_0$ with N being the number of cycles in the train. Using a Fourier analysis similar to that described above, the frequency spectrum is given by

$$\tilde{E}(\omega) = \frac{E_0}{\sqrt{2\pi}}\left[\frac{\sin \tau(\omega - \omega_0)}{\omega - \omega_0} - \frac{\sin \tau(\omega + \omega_0)}{\omega + \omega_0}\right] \tag{1.99}$$

At optical or near IR frequencies, because the second term is much smaller than the first, we can apply the Fourier transform to just the first term, which is also plotted in Figure 1.5. Clearly, the number of frequencies involved in the shorter pulse is larger than the number needed for the longer pulse. This inverse relationship between the length of the pulse in the time domain and the spread in the frequency domain is conveniently captured in the time-bandwidth product, $\tau\Delta\nu$. From Figure 1.5 and Eqs (1.98) and (1.99), it is clear that $\tilde{E}(\omega) = 0$ when $N\pi(\omega - \omega_0)/\omega_0 = \pm\pi$. Thus, $\Delta\omega = \omega_+ - \omega_- = 2\omega_0/N = 2\pi/\tau$, where $\omega_\pm = \omega_0 (1 \pm 1/N)$, which leads to

$$\tau\Delta\nu = 1 \tag{1.100}$$

It is interesting to note that if we multiply Eq. (1.100) by h, this time-bandwidth product satisfies the Heisenberg uncertainty principle,

$$\Delta t \Delta E \ge \frac{\hbar}{2} \tag{1.101}$$

where $\Delta E = h\Delta\nu$, $\hbar = h/2\pi$ and we substituted Δt for τ. The minimum is reached when the so-called minimum uncertainty wavepacket is prepared.[22]

Ultrashort pulses are achieved by "locking" the frequency components that extends over a wide frequency range. The minimum width achievable by this technique corresponds to one complete cycle of light. At 800 nm, near the peak of the Ti : Sapphire laser, this is ~ 2.7 femtoseconds. For a more complete discussion on mode locking and the generation of ultrashort pulses, the reader is directed to the classic text by Siegman Siegman, 1986

1.9
Photons and Particles

We conclude by discussing the analogy between light and particle waves a bit further. Equations (1.13), (1.14) and (1.31) can be used to motive the time-independent Schrödinger wave equation,

$$-\frac{\hbar^2}{2m}\nabla^2\psi + V\psi = \mathcal{E}\psi \qquad (1.102)$$

$$\nabla^2\psi + \frac{2m}{\hbar^2}(\mathcal{E} - V)\psi = 0 \qquad (1.103)$$

where $\hbar = h/2\pi$. Because λ for the particle is h/p, in free space, we postulate that k $(= 2\pi n/\lambda)$ in Eq. (1.31) must be proportional to p. Thus, in the absence of a potential (when $n = 1$)

$$k^2_{n=1} = \frac{p^2}{h^2/4\pi^2} \qquad (1.104)$$

But,

$$p^2 = 2m\mathcal{E} \qquad (1.105)$$

so

$$k^2_{n=1} = \frac{2m}{\hbar^2}\mathcal{E}, \quad \text{which lead to Eq. 1.102.} \qquad (1.106)$$

To account for the potential we let $n^2 = (\mathcal{E} - V)/\mathcal{E} \neq 1$ so that $k^2 = n^2 k^2_{n=1}$ is just the coefficient of the second term in Eq 1.103.

Space does not permit a more in depth discussion of the quantum nature of light. The interested reader is directed to a recent review Smith and Raymer, 2007 and references therein.

---

[22] The minimum spread criterion applies to conjugate variables such as time frequency and position momentum.

INTRODUCTION

Rapid advances have been made in recent years in applying electromagnetic wave propagation in natural or man-made environments to telecommunication and to remote sensing. The purpose of this article is to familiarize readers with the fundamental concepts and theories regarding both guided and unguided electromagnetic waves.

1. BACKGROUND

Consider first the macroscopic Maxwell equations governing the behavior of the vector electric field $\mathbf{E}(\mathbf{r},t)$ and the vector magnetic field $\mathbf{H}(\mathbf{r},t)$ in free space due to a known distribution of current and charge sources (Stratton, 1941; Jackson, 1975; Kraus, 1984; Johnk, 1988; see also ELECTRODYNAMICS, CLASSICAL):

$$\epsilon_0\nabla\cdot\mathbf{E}=\rho, \tag{1a}$$

$$\nabla\times\mathbf{E}=-\mu_0\frac{\partial}{\partial t}\mathbf{H}, \tag{1b}$$

$$\mu_0\nabla\cdot\mathbf{H}=0, \tag{1c}$$

$$\nabla\times\mathbf{H}=\mathbf{J}+\epsilon_0\frac{\partial}{\partial t}\mathbf{E}. \tag{1d}$$

Here μ_0 and ϵ_0 are, respectively, the permeability and permittivity of free space: in MKS units, $\mu_0 = 4\pi \times 10^{-9}$ H/m and $\epsilon_0 \simeq 1/36\pi \times 10^{-9}$ F/m. The terms $\mathbf{J}(\mathbf{r},t)$ and $\rho(\mathbf{r},t)$, on the other hand, are respectively the volume densities of electric current and charge which satisfy the charge continuity equation:

digital Encyclopedia of Applied Physics
Copyright © WILEY-VCH Verlag GmbH & Co KGaA. All rights reserved.

$$\nabla\cdot\mathbf{J}+\frac{\partial}{\partial t}\rho=0. \tag{2}$$

Of course various types of wave propagation represent possible solutions of the Maxwell equations in a source-free region. In most applications, we are interested in the steady-state solution for harmonic sources operating at an angular frequency of ω. Since the field responses also have to be harmonic in nature, we can for each component of the vector field or each scalar function [say $A(\mathbf{r},t)$] designate a complex function $A(\mathbf{r};\omega)$, such that

$$A(\mathbf{r},t)=A_0\cos(\omega t+\Phi_0)=\mathrm{Re}\{A(\mathbf{r};\omega)e^{j\omega t}\};$$

$$A(\mathbf{r};\omega)=A_0(\mathbf{r};\omega)e^{j\Phi_0(\mathbf{r};\omega)}; \tag{3}$$

so that Maxwell's equations in the frequency domain now take the form

$$\epsilon_0\nabla\cdot\mathbf{E}=\rho, \tag{4a}$$

$$\nabla\times\mathbf{E}=-j\omega\mu_0\mathbf{H}, \tag{4b}$$

$$\mu_0\nabla\cdot\mathbf{H}=0, \tag{4c}$$

$$\nabla\times\mathbf{H}=\mathbf{J}+j\omega\epsilon_0\mathbf{E}. \tag{4d}$$

The time dependence of $\exp(j\omega t)$ is then suppressed and is understood implicitly hereafter. Even in the case of time-varying sources, we often find that it is convenient to convert the problem from the time domain to the frequency domain via a Fourier transform defined as

$$A(\mathbf{r};\omega)=\frac{1}{\pi}\int_{-\infty}^{\infty}A(\mathbf{r},t)e^{-j\omega t}\,dt, \tag{5a}$$

and then convert the solution back to the time domain by an inverse Fourier transform,

$$A(\mathbf{r},t)=\frac{1}{2}\int_{-\infty}^{\infty}A(\mathbf{r};\omega)e^{+j\omega t}\,d\omega. \tag{5b}$$

The constraint that a physically observable function must be both casual and real can be restated in the frequency domain as follows (Nussenzveig, 1972):

$A(\mathbf{r};\omega)=A^*(\mathbf{r};-\omega)$;

$A(\mathbf{r};\omega)$ is analytic in the upper half of the complex ω plane. (6)

In Sec. 2, we shall examine in some detail how different materials can influence the propagation of a plane wave.

2. PLANE WAVES IN MEDIA

2.1. Propagation in Linear, Non-dispersive, and Isotropic Media

When current and charge sources are situated inside a material region, they act as primary (impressed) sources to generate electric and magnetic fields which are capable of polarizing, or reorienting the charges in, the molecules or atoms of the medium, or forcing the free electrons to flow in the same or, in some cases, a different direction depending upon the nature of the material. The net effect, on the macroscopic scale, is to produce continuously distributed current and charge densities, which then act as secondary sources and which, in turn, set up secondary fields. In the case of a dielectric material, the volume density of electric polarization **P** is proportional to the applied electric field, i.e., $\mathbf{P}=\chi_e\epsilon_0\mathbf{E}$, where χ_e is the dielectric susceptibility of the medium. It is not difficult to show that spatial and time variations of the polarization density are in fact equivalent to having charge and current densities equal to $\nabla\cdot\mathbf{P}$ and $j\omega\mathbf{P}$, respectively. In order to incorporate these secondary sources into the Maxwell equations properly, we find it convenient to introduce an electric flux density **D** and the permittivity of a material ϵ, as follows:

$$\mathbf{D}=\epsilon_0\mathbf{E}+\mathbf{P}=\epsilon_0(1+\chi_e)\mathbf{E}=\epsilon\mathbf{E}. \tag{7a}$$

Likewise in the case of magnetic material, we can define a volume density of magnetization **M**, and a magnetic susceptibility χ_m, according to $\mathbf{M}=\chi_m\mathbf{H}$. While there is no net charge density induced by the magnetization, the equivalent current density can be shown to be $\nabla\times\mathbf{M}$. The effect of such a secondary current on the Maxwell equations can be accounted for by introducing a magnetic flux density **B** and a permeability μ so that

$$\frac{\mathbf{B}}{\mu_0}-\mathbf{M}=\mathbf{H},\quad\text{or}\quad\mathbf{B}=\mu_0(1+\chi_m)\mathbf{H}=\mu\mathbf{H}. \tag{7b}$$

Finally, in the case of conducting material, the induced current density is simply characterized by $\sigma\mathbf{E}$, where σ is the conductivity of the material. Using the definitions for the material parameters ϵ, μ, and σ and their associated equivalent sources in Eq. (4) immediately yields the appropriate Maxwell equations in a material region in the form

$$\nabla\cdot\epsilon\mathbf{E}=\rho, \tag{8a}$$

$$\nabla\times\mathbf{E}=-j\omega\mu\mathbf{H}, \tag{8b}$$

$$\nabla\cdot\mu\mathbf{H}=0, \tag{8c}$$

$$\nabla\times\mathbf{H}=\mathbf{J}+(\sigma+j\omega\epsilon)\mathbf{E}. \tag{8d}$$

Often, we simplify these expressions through the introduction of a complex permittivity $\hat{\epsilon}=\epsilon-j\sigma/\omega$.

To see what basic types of waves can exist, we first consider the case where the only significant variation of the field is along a given, locally constant, direction (denoted here as the z direction in a rectangular coordinate system). We look at a region in which sources are absent, the ones which produce the field being assumed to lie either to the left or to the right of this region. In this case, the Maxwell curl equations (8b) and (8d) reduce to

$$(\sigma+j\omega\epsilon)E_z=0; \quad j\omega\mu H_z=0, \tag{9a}$$

$$\begin{aligned}&\frac{\partial}{\partial z}(\mathbf{e}_z\times\mathbf{E}_t)=-j\omega\mu\mathbf{H}_t;\\&\frac{\partial}{\partial z}(\mathbf{e}_z\times\mathbf{H}_t)=(\sigma+j\omega\epsilon)\mathbf{E}_t.\end{aligned} \tag{9b}$$

Here $\mathbf{e}_z$ is a unit vector in the z-direction, $\mathbf{E}=\mathbf{E}_t+\mathbf{e}_zE_z$, and $\mathbf{H}=\mathbf{H}_t+\mathbf{e}_zH_z$. Equation (9a) indicates that the longitudinal components of both the electric and magnetic field will have to vanish everywhere if the frequency is not zero. Assuming that we can cast the solution in the form of $\mathbf{E}_t=\mathbf{E}_0\exp\{\pm\gamma z\}$ where γ is a yet undetermined constant, the two equations in Eq. (9b) can be used together to obtain

$$\gamma\times\gamma\times\mathbf{E}_t+j\omega\mu(\sigma+j\omega e)\mathbf{E}_t=0, \quad \gamma=\mathbf{e}_z\gamma, \tag{9c}$$

whose solution is readily found to be

$$\begin{aligned}&\mathbf{E}_t=\mathbf{E}_0^+e^{-\gamma z}+\mathbf{E}_0^-e^{+\gamma z};\\&\mathbf{H}_t=\eta^{-1}\mathbf{e}_z\{\mathbf{E}_0^+e^{-\gamma z}-\mathbf{E}_0^-e^{+\gamma z}\},\\&\gamma=[j\omega\mu(\sigma+j\omega\epsilon)]^{1/2}, \quad \eta=j\omega\mu/\gamma,\end{aligned} \tag{10a}$$

$$\text{where } \mathrm{Re}(\gamma)\geqslant 0 \text{ and } \mathrm{Re}(\eta)\geqslant 0, \tag{10b}$$

and $\mathbf{E}_0^\pm$ are two yet-undetermined complex amplitudes. We note that γ is often referred to as the complex propagation constant and η, the characteristic impedance.

Equations (10) underlie some of the most fundamental aspects regarding the propagation of electromagnetic waves. First and foremost, we see that the field components of these waves are basically transverse in nature; in fact, not only are the electric field and the magnetic field orthogonal to each other, but they are also orthogonal to the direction of the propagation as well. Furthermore, the characteristic impedance of these waves, defined as the ratio of the electric to the magnetic field amplitude, remains constant everywhere, and depends only upon the properties of the medium the wave is propagating through and the operating frequency of the source(s). Expressing the complex propagation constant γ in terms of its real and imaginary parts,

$$\gamma=\alpha+j\beta,$$

$$\alpha=\frac{\omega\sqrt{\mu\epsilon}}{\sqrt{2}}\left[\sqrt{1+\left(\frac{\sigma}{\omega\epsilon}\right)^2}-1\right]^{1/2},$$

$$\beta=\frac{\omega\sqrt{\mu\epsilon}}{\sqrt{2}}\left[\sqrt{1+\left(\frac{\sigma}{\omega\epsilon}\right)^2}+1\right]^{1/2},$$

we can readily write down the form of the solution for the electric field in the time domain as

$$\begin{aligned}\mathbf{E}_t^+(z,t)=&\,\mathbf{e}_xE_{0x}^+e^{-\alpha z}\cos(\omega t-\beta z+\Phi_x^+)\\&+\mathbf{e}_yE_{0y}^+e^{-\alpha z}\cos(\omega t-\beta z+\Phi_y^+),\end{aligned} \tag{11a}$$

$$\begin{aligned}\mathbf{E}_t^-(z,t)=&\,\mathbf{e}_xE_{0x}^-e^{+\alpha z}\cos(\omega t+\beta z+\Phi_x^-)\\&+\mathbf{e}_yE_{0y}^-e^{+\alpha z}\cos(\omega t+\beta z+\Phi_y^-).\end{aligned} \tag{11b}$$

The term involving E_{0x}^+ is plotted in Fig. 1, as a function of βz, for a fixed instant of time t, with an indication of the movement of the wave as t increases. As we will discuss in more detail later, a wave which possesses only an x

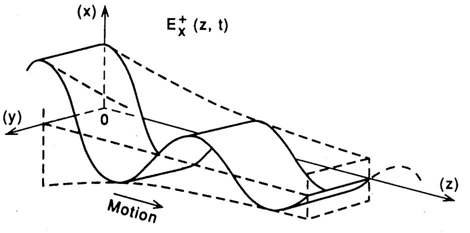

FIG. 1. A forward-propagating wave in a dissipative medium.

component of electric field is often referred to as a wave polarized linearly in the x direction. The velocity of the forward-moving pattern for such a wave can be determined easily by holding the phase constant, giving

$$\omega t-\beta z+\Phi_x^+=\text{constant}\Rightarrow$$

$$\text{phase velocity } v_p=\frac{\partial z}{\partial t}=\frac{\omega}{\beta}. \tag{12}$$

On the other hand, the distance at which the pattern repeats itself is called the wavelength, and is found from

$$\beta\lambda=2\pi\Rightarrow\text{wavelength } \lambda=2\pi/\beta. \tag{13}$$

These two results, when combined together, yield $v_p = \lambda f$, where f is the frequency of the propagating wave. In addition to propagation, the wave may also decay exponentially in the forward direction. The distance $\delta=1/\alpha$ at which the wave has decayed by a factor of e^{-1} is often referred to as the skin depth. This notion is often applied in the case of a good conductor, $\sigma\gg\omega\epsilon$, for which $\alpha\approx\beta\approx[\omega\mu\sigma/2]^{1/2}$.

From the above discussion, it is not difficult to construct a physical picture of a plane wave propagating either in the $+z$ or $-z$ direction with a phase velocity of v_p. For a lossless and dispersionless dielectric material, $\sigma = 0$ and ϵ is a constant, and the phase velocity reduces to the simple expression $[1/\mu\epsilon]^{1/2}$, which is independent of the operating frequency; we sometimes refer to it as the speed of light in the medium. It is of interest to note that when both forward- and backward-propagating waves are present, they can be combined together to form a standing wave pattern. In particular, the magnitude of the total electric field linearly polarized in the x direction is given as

$$|E_x(z)|=|E_{0x}^+|\{1+|\Gamma|^2+2|\Gamma|\cos(2\beta z+\Phi_\Gamma)\}^{1/2}, \tag{14a}$$

where

$$\Gamma=|\Gamma|e^{j\Phi_\Gamma}=E_{0x}^-/E_{0x}^+. \tag{14b}$$

When the backward-traveling wave arises as the result of a reflection of the forward-traveling wave, the complex quantity Γ, defined as the ratio of backward and forward wave amplitudes, is referred to as the reflection coefficient. As seen in Fig. 2, the magnitude of the total electric field oscillates between $1+|\Gamma|$ and $1-|\Gamma|$. The ratio of maximum to minimum values in the standing wave pattern thus provides a measure of how strong the reflection is, and it is called the standing wave ratio (SWR):

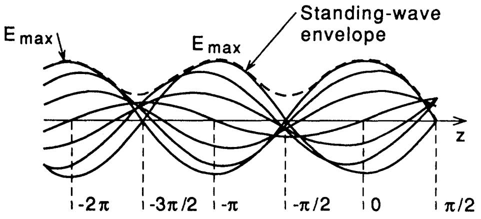

FIG. 2. Standing wave pattern.

$$\text{SWR}=\frac{1+|\Gamma|}{1-|\Gamma|}. \tag{15}$$

The discussion so far has been restricted to linearly polarized waves, when only one of the two components of the electric field is excited. For many applications, both components are often present, and depending upon their relative magnitudes and phases this results in various kinds of polarization. To see how this may occur, we now assume that the solution in the region of interest consists of only a forward-propagating wave, so that at a fixed observation point, say $z = 0$, the electric field in the frequency domain is given as

$$\mathbf{E}_t=\mathbf{e}_xE_x+\mathbf{e}_yE_y,$$

$$E_x=E_{0x}\,e^{j\Phi_x} \text{ and } E_y=E_{0y}\,e^{j\Phi_y}, \tag{16a}$$

or in the time domain,

$$\mathbf{E}_t=\mathbf{e}_xE_{0x}\cos(\omega t+\Phi_x) +\mathbf{e}_yE_{0y}\cos(\omega t+\Phi_y). \tag{16b}$$

We can clearly see from Eq. (16b) that both the direction and magnitude of the electric field vary as functions of ωt. In fact, the equation that governs the relationship between the x and y components can be derived from Eq. (16b) as

$$\left(\frac{E_x}{E_{0x}}\right)^2+\left(\frac{E_y}{E_{0y}}\right)^2-2\cos(\Phi_x-\Phi_y)\left(\frac{E_x}{E_{0x}}\right)\left(\frac{E_y}{E_{0y}}\right) =\sin^2(\Phi_x-\Phi_y), \tag{17a}$$

which describes a tilted ellipse with major and minor axes L_0 and l_0, respectively, where

$$2L_0^2=E_{0x}^2+E_{0y}^2+[E_{0x}^4+E_{0y}^4+2E_{0x}^2E_{0y}^2\cos 2(\Phi_x-\Phi_y)]^{1/2}, \qquad (17b)$$

$$2l_0^2=E_{0x}^2+E_{0y}^2-[E_{0x}^4+E_{0y}^4+2E_{0x}^2E_{0y}^2\cos 2(\Phi_x-\Phi_y)]^{1/2}, \qquad (17c)$$

and with a tilt angle τ given by

$$2\tau=\pi-\tan^{-1}\left[\frac{2E_{0x}E_{0y}\cos(\Phi_x-\Phi_y)}{E_{0x}^2+E_{0y}^2}\right]. \qquad (17d)$$

We should note that although Eqs. (17a)–(17c) depend only upon the magnitude, but not upon the sign, of the phase difference $\Phi_x-\Phi_y$, it is not difficult to show that the $+$sign traces the ellipse in the clockwise, or right-hand, direction, while the $-$ sign traces the ellipse in the counterclockwise, or left-hand, direction. The polarization state of a plane wave, thus, depends not only on the ratio of E_{0x}^2 to E_{0y}^2, but on the phase difference of the two components as well. Figure 3, for instance, shows a right-hand circularly polarized wave vs a left-hand circularly polarized wave when $E_{0x}^2=E_{0y}^2$ and $\Phi_x-\Phi_y=\pm\pi/2$.

2.2 Wave Propagation in Dispersive Media

Our discussion on plane-wave propagation so far has been confined to harmonic sources with a single operating frequency. In principle, we can always obtain the field response due to arbitrarily time-varying sources by superposition so long as the medium in which it propagates is linear. However, because characteristics of plane waves such as the phase velocity are dependent on the operating frequency, the frequency content in a resultant field can vary from one location to another and, consequently, cause dispersion in the signal we intend to transmit. Before we can see how this could happen, let us first look at the case of a lossless dielectric medium and familiarize ourselves initially with the propagation of an impulse signal which does not exhibit the dispersion phenomenon. Suppose that we have a linearly polarized wave propagating in the forward z direction and behaving like an impulse function initially at $z=0$, i.e., $E_x(0,t)=\delta(t)$. We can find an expression for this wave at other locations from Eqs. (5a), (5b), and (10) for a lossless medium as

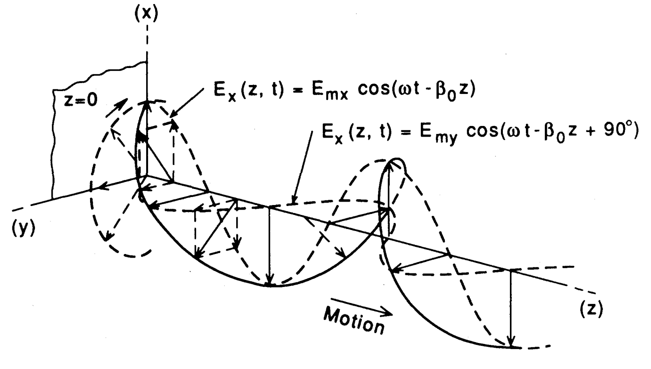
$$E_x(z,t)=\frac{1}{2\pi}\int_{-\infty}^{\infty} e^{-j\beta z+j\omega t}\,d\omega=\delta\left(t-\frac{z}{v_p}\right), \qquad (18)$$

since $\sigma=0$, $\gamma=j\beta=j\omega/v_p$, $\alpha=0$, and $v_p=(\mu\epsilon)^{-1/2}$. What Eq. (18) says is that we can expect the impulse signal to remain essentially intact when it propagates in a lossless medium, assuming that both the permittivity ϵ and the permeability μ are not functions of frequency. However, for a lossy medium where the conductivity is nonvanishing, the corresponding solution for the electric field becomes

$$E_x(z,t)=\frac{1}{2\pi}\int_{-\infty}^{\infty} e^{-\gamma z+j\omega t}d\omega, \qquad (19a)$$

$$\gamma=\frac{j}{v_0}[\omega(\omega-j\Delta)]^{1/2},$$

where $v_0=(\mu\epsilon)^{-1/2}$ and $\Delta=\sigma/\epsilon$. By deforming the integration contour in Eq. (19a) from the real axis, we can readily show (Stratton, 1941) that for $t<z/v_0$, $E_x(z,t)$ is zero, and for $t>z/v_p$,



(x)
z=0
$E_x(z, t) = E_{mx}\cos(\omega t-\beta_0 z)$
$E_x(z, t) = E_{my}\cos(\omega t-\beta_0 z + 90°)$

FIG. 3. A right-hand circularly polarized wave.

$$E_x(z,t)=\frac{j}{2\pi}\int_0^{\Delta}\left[\exp\left(-j\frac{z}{v_0}[\nu(\Delta-\nu)]^{1/2}\right)-\exp\left(+j\frac{z}{v_0}[\nu(\Delta-\nu)]^{1/2}\right)\right]e^{-\nu t}\,d\nu$$
$$=\left(\frac{\Delta}{2v_0}\right)\frac{z/v_0}{[t^2-(z/v_0)^2]^{1/2}}I_1\left(\frac{\Delta}{2}[t^2-(z/v_0)^2]^{1/2}\right)e^{-\Delta t/2},\qquad (19b)$$

where I_1 is the modified Bessel function of the first kind and order one. While the behavior of such a field response is rather complicated upon its arrival, i.e., at $t\approx z/v_0$, it turns out that, at later times when $t^2 \gg (z/v_0)^2$ and $t\Delta \gg 1$, then $E_x(z,t) \sim t^{-3/2}$ and thus the field decays only algebraically as the result of the dispersion in a conducting medium.

The dispersion phenomenon we have discussed so far has assumed very particular forms for the frequency dependences of the attenuation and phase velocity of the constituents of the transient waves. Specifically, we have assumed that the material parameters ϵ, σ, and μ remain constant throughout the entire frequency spectrum of interest. It turns out that these assumptions, while valid for signals of mainly low-frequency content, become less accurate at higher frequencies as a result of molecular and other resonances in the material. As an example, the complex relative permittivity $\hat{\epsilon}_r=\hat{\epsilon}/\epsilon_0=\epsilon_r'-j\epsilon_r''$ for a dielectric material that can be characterized by only a single molecular resonance frequency is given as

$$\epsilon_r'=1+\left(\frac{N_e q^2}{\epsilon_0 m}\right)\frac{(\omega_0^2-\omega^2)}{(\omega_0^2-\omega^2)^2+(\omega\nu/m)^2},$$
$$\epsilon_r''=\left(\frac{N_e q^2}{\epsilon_0 m}\right)\frac{(\omega\nu/m)}{(\omega_0^2-\omega^2)^2+(\omega\nu/m)^2},\qquad (20)$$

where q, m, and ν are, respectively, the charge, effective mass, and damping coefficient of a polarized molecule; N_e is the number of polarized molecules per unit volume. The frequency ω_0, on the other hand, is the resonant frequency of the molecules, and it is related to the elastic coefficient s and the effective mass m according to $\omega_0 = (s/m)^{1/2}$. The investigation of wave dispersion in media where the constitutive parameters cannot be regarded as frequency-independent follows the same principles as laid out earlier in this section, but the more cumbersome analytical details are beyond the scope of this article.

Regardless of the specific form of their frequency dependence, the permittivity and permeability characterize physical systems whose inputs and outputs are physical quantities like **E**, **B**, etc., which must satisfy the constraints listed in Eq. (6), and it is not difficult to show (Nussenzveig, 1972) from causality considerations that their real and imaginary parts, as functions of frequency, must satisfy the so-called Kramers–Kronig relations, which can be stated in the following form:

$$\kappa'(\omega)=1+\frac{2}{\pi}\int_0^{\infty}\frac{\omega'\kappa''(\omega')}{(\omega')^2-\omega^2}d\omega',$$
$$\kappa''(\omega)=\frac{2\omega}{\pi}\int_0^{\infty}\frac{1-\kappa'(\omega')}{(\omega')^2-\omega^2}d\omega',\qquad (21)$$

where $\kappa=\kappa'+j\kappa''$ stands for either the relative permittivity ϵ_r $(=\epsilon/\epsilon_0)$ or the relative permeability. We have also assumed that $\epsilon \rightarrow \epsilon_0$ and $\mu \rightarrow \mu_0$ as $\omega \rightarrow \infty$, on the basis that a real medium will not be able to respond substantially to a field of high enough frequency.

2.3 Wave Propagation in Anisotropic Media

In addition to dispersion, complication also arises when electromagnetic waves propagate in a medium which is anisotropic (i.e., where **B** and **H** and/or **D** and **E** are not parallel in general). In such media, the permeability and/or permittivity is given as a tensor. The Maxwell equations in Eqs. (8a)–(8d) are modified for a dielectrically anisotropic material to read

$$\nabla\times\mathbf{E}=-j\omega\mu_0\mathbf{H},\quad \nabla\times\mathbf{H}=j\omega\epsilon_0\epsilon_r\cdot\mathbf{E},\qquad (22)$$

so that the sum of the displacement and polarization currents, $j\omega\epsilon_0\epsilon_r\cdot\mathbf{E}$, is no longer necessarily parallel to the direction of the applied electric field. Many types of materials exhibit anisotropy: ferrites, crystalline materials such as calcite or fluorspar, and plasmas in the presence of a dc magnetic field, for example (Yariv and Yeh, 1984; Kong, 1986).

A plasma medium biased by the dc magnetic field $\mathbf{e}_z H_0$ exhibits the tensor relative permittivity (Ishimaru, 1991)

$$\epsilon_r=[\epsilon_r]=\begin{bmatrix}\epsilon_t & ja & 0\\ -ja & \epsilon_t & 0\\ 0 & 0 & \epsilon_z\end{bmatrix}, \tag{23a}$$

where

$$\epsilon_t=1-\frac{(\omega_p/\omega)^2[1-j(\nu/\omega)]}{[1-j(\nu/\omega)]^2-(\omega_c/\omega)^2},$$

$$a=\frac{-(\omega_p/\omega)^2(\omega_c/\omega)}{[1-j(\nu/\omega)]^2-(\omega_c/\omega)^2}, \tag{23b}$$

$$\epsilon_z=1-\frac{(\omega_p/\omega)^2}{1-j(\nu/\omega)}$$

and ω_p and ω_c are, respectively, the plasma and cyclotron frequencies, given by

$$\omega_p=\left(\frac{N_e q^2}{m\epsilon_0}\right)^{1/2}, \quad \omega_c=\frac{q\mu_0 H_0}{m}. \tag{23c}$$

To see how waves propagate in such a material, assume that a plane wave has the form $\exp(j\boldsymbol{\beta}\cdot\mathbf{r})$, where $\boldsymbol{\beta}$ is a yet-undetermined vector propagation constant pointing in the direction of propagation. Substitution of this expression into Eq. (22) yields the following governing equation:

$$\boldsymbol{\beta}\times\boldsymbol{\beta}\times\mathbf{E}+\omega^2\mu_0\epsilon_0\epsilon_r\cdot\mathbf{E}=0. \tag{24}$$

We will consider two special categories of solutions to this equation:

(i) those which propagate parallel to the direction of the dc magnetization field,

(ii) those which propagate perpendicularly to the direction of the dc magnetization field.

General oblique propagation involves considerably more cumbersome expressions, and will not be considered here. In this case, the propagation direction as defined by the propagation of a narrow beam or by the vector group velocity (cf. Secs. 3 and 5.1) is not necessarily the same as the normal to planes of constant phase, a common occurrence in anisotropic media.

In the first case, $\boldsymbol{\beta}=\mathbf{e}_z\beta$, and Eq. (24) in matrix form becomes

$$\begin{bmatrix}-\beta^2+k_0^2\epsilon_t & jk_0^2a & 0\\ -jk_0^2a & -\beta^2+k_0^2\epsilon_t & 0\\ 0 & 0 & k_0^2\epsilon_t\end{bmatrix}\begin{bmatrix}E_x\\ E_y\\ E_z\end{bmatrix}=0,$$

$$k_0^2=\omega^2\mu_0\epsilon_0,$$

which can have a nontrivial solution only when the determinant of the matrix is zero. Solving for β yields two sets of acceptable solutions:

Ordinary wave, $\beta=\beta_+=k_0(\epsilon_t-a)^{1/2}$,

$$E_x=-jE_y, \quad E_z=0; \tag{25a}$$

Extraordinary wave, $\beta=\beta_-=k_0(\epsilon_t+a)^{1/2}$,

$$E_x=+jE_y, \quad E_z=0. \tag{25b}$$

Thus, instead of one, there are actually two possible types (ordinary and extraordinary) of plane waves that may exist. The ordinary wave is left-hand circularly polarized, while the extraordinary wave is right-hand circularly polarized. Indeed, the phase velocity is seen to depend on the polarization of the wave, as is also often the case in anisotropic media.

In the case of a collision-free plasma ($\nu=0$), the ordinary wave can propagate in the forward z direction only if $\epsilon_t-a>0$, or $\omega>\omega_1$, where $\omega_1=[\omega_p^2+(\omega_c/2)^2]^{1/2}-\omega_c/2$. The extraordinary wave, on the other hand, can propagate in the forward z direction only if $\epsilon_t+a>0$, or for frequencies in the range of either $0<\omega<\omega_c$ or $\omega>\omega_2$, where $\omega_2=[\omega_p^2+(\omega_c/2)^2]^{1/2}+\omega_c/2$. It is of interest to note that such a phenomenon can be used advantageously in many applications. Figure 4 shows regions in a β–ω diagram for each type of wave discussed above.

A second category of waves occurs when the propagation is orthogonal to the dc bias

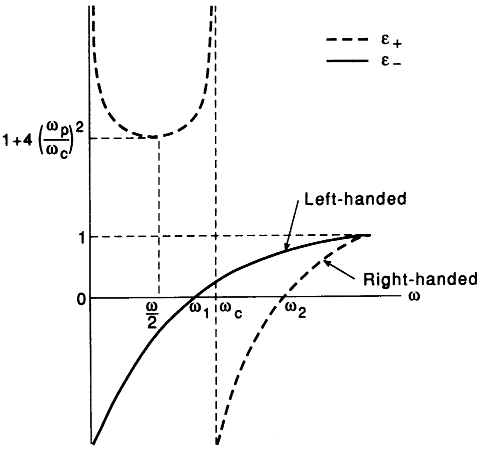

FIG. 4. The ω–β diagram for the left- and right-hand polarized plane waves in an anisotropic medium.

field. Substituting $\boldsymbol{\beta}=\mathbf{e}_x\beta$ into Eq. (24), the matrix equation becomes

$$\begin{bmatrix} k_0^2\epsilon_t & jk_0^2 a & 0 \\ -jk_0^2 a & k_0^2\epsilon_t-\beta^2 & 0 \\ 0 & 0 & k_0^2\epsilon_z-\beta^2 \end{bmatrix} \begin{bmatrix} E_x \\ E_y \\ E_z \end{bmatrix} = 0,$$

which again has two acceptable types of solutions:

$$\text{Transverse wave,}\quad \beta=\beta_t=k_0\epsilon_z^{1/2},$$

$$E_x=E_y=0, \quad\text{and}\quad E_z\neq 0; \tag{26a}$$

$$\text{Longitudinal wave,}\quad \beta=\beta_l=k_0\left(\frac{\epsilon^2-a^2}{\epsilon}\right)^{1/2},$$

$$E_x=\left(\frac{-ja}{\epsilon}\right)E_y, \quad\text{and}\quad E_z=0. \tag{26b}$$

The transverse wave is in fact similar to an ordinary plane wave in an isotropic medium since its propagation constant is independent of the dc magnetization field. This is hardly surprising since in this case the sum of the polarization and displacement currents, $j\omega\epsilon_0\epsilon_z E_z$, is in the direction of the dc bias and is thus unaffected by its presence. The longitudinal wave, on the other hand, can exist only when both $\epsilon_t + a$ and $\epsilon_t - a$ are greater than zero. Unlike a plane wave in an isotropic medium, the electric field of this wave has a component in the direction of propagation and is elliptically polarized.

2.4 Wave Propagation in Chiral Media

In recent years a class of materials of considerable interest has been the so-called chiral materials (Lakhtakia *et al.*, 1989) which exhibit a bi-isotropic behavior. Typically, a chiral material is characterized by long molecules in the form of a helix. When the pitch of the helix is neither too great nor too small (so that it does not resemble either a circular loop or a string), an applied electric field or magnetic field alone produces volume densities of both polarization and magnetization—the "handedness" of the helix results in terms proportional to the applied field itself, but also in terms proportional to its curl. Such a property can best be described in terms of how the electric and magnetic flux densities **D** and **B** are related to the electric and magnetic field intensities **E** and **H**, even though the detailed constituent relationships are very involved, and not as well understood as those of isotropic or conventional anisotropic media:

$$\mathbf{D}=(\epsilon+\kappa^2\mu)\mathbf{E}-j\kappa\mu\mathbf{H}, \quad \mathbf{B}=j\kappa\mu\mathbf{E}+\mu\mathbf{H}, \tag{27a}$$

where κ is called the chirality parameter of the medium. Clearly, when $\kappa=0$, Eq. (27a) reduces to the constitutive relations for an isotropic medium. The corresponding Maxwell equations in a source-free region for this case become

$$\begin{aligned} \nabla\times\mathbf{E}&=-j\omega(j\kappa\mu\mathbf{E}+\mu\mathbf{H}), \\ \nabla\times\mathbf{H}&=j\omega[(\epsilon+\kappa^2\mu)\mathbf{E}-j\kappa\mu\mathbf{H}]. \end{aligned} \tag{27b}$$

Thus for a plane wave of the form $\exp(j\boldsymbol{\beta}\cdot\mathbf{r})$, the governing equation readily reduces to

$$\boldsymbol{\beta}\times\boldsymbol{\beta}\times\mathbf{E}+j2\omega\kappa\mu\boldsymbol{\beta}\times\mathbf{E}+\omega^2\mu_0\epsilon_0\mathbf{E}=0, \tag{28}$$

which, upon assuming $\boldsymbol{\beta}=\mathbf{e}_z\beta$, again yields a matrix equation of the following form:

$$\begin{bmatrix} -\beta^2+k_0^2 & j2\omega\kappa\mu\beta \\ -j2\omega\kappa\mu\beta & -\beta^2+k_0^2 \end{bmatrix} \begin{bmatrix} E_x \\ E_y \end{bmatrix} = 0.$$

Setting the determinant equal to zero and solving for β gives two sets of acceptable solutions:

right-hand circularly polarized wave,

$$\beta=\beta_+=\omega\mu\kappa+[(\omega\mu\kappa)^2+k_0^2]^{1/2},$$

$$E_x=jE_y, \quad E_z=0; \tag{29a}$$

left-hand circularly polarized wave,

$$\beta=\beta_-=-\omega\mu\kappa+[(\omega\mu\kappa)^2+k_0^2]^{1/2},$$

$$E_x=-jE_y, \quad E_z=0. \tag{29b}$$

The behavior of these two types of waves in many ways resembles that of the ordinary and extraordinary waves in an anisotropic medium, except that no dc bias field is required. While new device concepts have actively been explored in recent years, the major challenge for microwave applications appears to be the lack of either natural or synthetic materials which exhibit a strong chirality at these frequencies.

3. PROPAGATION OF GAUSSIAN BEAMS

In Sec. 2, propagation of electromagnetic waves was discussed in the context of plane waves under the assumption that field quantities vary only in one direction. This may be a valid assumption when the region of interest is sufficiently remote from the excitation sources. However, the infinite extent of a plane wave in the transverse direction naturally limits our ability to apply it to situations where the field distribution is initially highly collimated in a cross section of finite extent. A good example is a linearly polarized "beam" which initially at $z=0$ has a Gaussian envelope (Arnaud, 1976; Solimeno *et al.*, 1986; Ishimaru, 1991):

$$E_x(x,y;0)=E_0 \exp\{-(x^2+y^2)/2w^2\}. \qquad (30)$$

Here w is the beamwidth used to specify the spatial confinement in the transverse direction. Such a distribution is typically encountered for waves emanating from a laser, in the near field of a reflector antenna, or in a lens waveguide. What we need to know is the behavior of this beam as it propagates in the forward z direction.

For convenience, we first consider the case of a one-dimensional beam in free space: $E_x(x;0)=E_0\exp[-(x^2/2w^2)]$. This aperture field distribution can be rewritten as an inverse Fourier transform integral with respect to the x variable:

$$E_x(x;0)=\left(\frac{1}{2\pi}\right)^{1/2} E_0 w \times \int_{-\infty}^{\infty} e^{-\beta_x^2 w^2/2} e^{-j\beta_x x}\, d\beta_x.$$

We interpret this expression as a superposition of spatial harmonics in the x direction, analogous to the representation of an arbitrary function of time as a superposition of temporal harmonics. For each spatial harmonic β_x, the propagation vector assumes the form $\boldsymbol{\beta}=\mathbf{e}_x\beta_x+\mathbf{e}_z\beta_z$. Substituting into the governing equations in Eq. (9) immediately yields $\beta_z=(k_0^2-\beta_x^2)^{1/2}$ for $\beta_x<k_0$, and $=-j(\beta_x^2-k_0^2)^{1/2}$ for $\beta_x>k_0$. Here, $k_0=\omega(\mu_0\epsilon_0)^{1/2}$ is the wave number in free space. Consequently, we can formally write down the solution in the region $z>0$ as

$$E_x(x;z)=\left(\frac{1}{2\pi}\right)^{1/2} E_0 w \int_{-\infty}^{\infty} e^{-\beta_x^2 w^2/2} \times e^{-j(\beta_x x+\beta_z z)}\, d\beta_x. \qquad (31)$$

What this means is that the wave solution in general consists of a continuous spectrum of homogeneous and inhomogeneous plane waves. In the range $-k_0<\beta_x<k_0$, the waves are propagating without attenuation at an angle $\tan^{-1}(\beta_x/\beta_z)$ with respect to the z axis, and they are called homogeneous plane waves. For $|\beta_x|>k_0$, the waves are propagating in the x direction while decaying exponentially in the z direction and they are called inhomogeneous plane waves. Since the amplitude spectrum of these waves has a Gaussian distribution in β_x, the most important contribution to the spectral integral comes from sufficiently small values of β_x. Thus a beam wave which has a large beamwidth, i.e., $k_0 w \gg 1$, is composed mainly of plane waves which propagate almost parallel to the z axis. But since these constituents are not all propagating exactly parallel to z, as the beam wave moves forward it also has a tendency to lose its original property of being concentrated near the z axis; the beam is said to diverge.

To put the above observations on a more analytical foundation, we use the so-called paraxial approximation, $\beta_z \approx k_0-\beta_x^2/2k_0$, in Eq. (31) to obtain

$$E_x(x;z)=E_0\left(\frac{w}{w_e}\right)\exp\left(-\frac{x^2[1+jz/(k_0w^2)]}{2w_e^2}\right) \times e^{-jk_0 z},$$

$$w_e=w\left[1+\left(\frac{z}{k_0w^2}\right)^2\right]^{1/2}. \qquad (32)$$

Thus, the width of the beam wave is broadened from w to w_e as it propagates with a propagation constant equal to k_0. In addition, the constant-phase front which is usually associated with the propagation of a plane wave also needs to be suitably modified.

The question of how long a beam wave can remain reasonably intact without being noticeably distorted is answered by examining further the validity of the paraxial approximation. The two-term Taylor series expansion is in principle a good approximation if $\beta_x^2 z/2k_0 \ll 1$. Since the values of β_x are confined to $\beta_x w<5$, say, we can define a characteristic length $D_0 = k_0w^2$, so that the paraxial approximation applies so long as $z < D_0$. We sometimes refer to this region as the near-field or the Fresnel zone even though it may be very large compared with the free-space wavelength.

A topic of considerable interest in recent years is the development of a focused beam in free space without the usual divergence effect. It is not difficult to show that if, in addition to a Gaussian amplitude, we also introduce a quadratic phase front in the initial aperture distribution, i.e.,

$$E_x(x;0)=E_0\exp\left\{-\frac{x^2}{2w^2}+j\frac{k_0x^2}{2R_0}\right\} \tag{30a}$$

the effective beamwidth w_e after a distance z is then

$$w_e=w\left[\left(1-\frac{z}{R_0}\right)^2+\left(\frac{z}{D_0}\right)^2\right]^{1/2},\quad D_0=k_0w^2. \tag{31}$$

It is in fact not difficult to show that the smallest beamwidth then occurs at $z=z_{\min}$, where

$$z_{\min}=\left(\frac{D_0^2}{R_0^2+D_0^2}\right)R_0,$$

and the ratio of w_e to w is given by $R_0/(R_0^2+D_0^2)^{1/2}$ in this case. Thus, the challenge of producing a focused beam lies in one's ability to produce an aperture field with a suitable, yet physically realizable, phase distribution.

4. REFLECTION AND TRANSMISSION OF PLANE WAVES AT AN INTERFACE

Our discussion up until now has been confined to various types of waves that can exist in different media. We come now to the question of what a wave will do when it encounters a different medium along the path of propagation. For a solution to be physically acceptable, certain boundary conditions must be met at an interface between two dissimilar media. They can be derived directly from applying the integral form of Maxwell's equations to differentially small volumes and surfaces that enclose both sides of the interface. Defining a unit vector $\mathbf{e}_n$ normal to the interface and pointing from medium No. 2 to medium No. 1, we can write down the boundary conditions as follows:

$$\mathbf{e}_n\cdot(\epsilon_1\mathbf{E}_1-\epsilon_2\mathbf{E}_2)=\rho_s,\quad \mathbf{e}_n\times(\mathbf{E}_1-\mathbf{E}_2)=0, \tag{32a}$$

$$\mathbf{e}_n\cdot(\mu_1\mathbf{H}_1-\mu_2\mathbf{H}_2)=0,\quad \mathbf{e}_n\times(\mathbf{H}_1-\mathbf{H}_2)=\mathbf{J}_s, \tag{32b}$$

where $\mathbf{E}_{1,2}$ and $\mathbf{H}_{1,2}$ are the electric and magnetic fields on the two sides of the interface; ρ_s and $\mathbf{J}_s$ are, respectively, the surface charge density and surface current density at the interface, which are nonvanishing only when one of the media is perfectly conducting.

Suppose that a linearly polarized plane wave in medium No. 1 is incident obliquely from above onto a plane interface at an angle θ with respect to the y axis (which is normal to the interface). As shown in Fig. 5, two types of polarization can exist; in one case, the electric field is in the plane of incidence (the xy plane), and in the other, perpendicular to the plane of incidence. We now further define in medium No. 1 an incident vector propagation constant as γ_i, a reflected one as γ_r, and in medium No. 2, a transmitted one as γ_t, so that

$$\gamma_i=\gamma_1\mathbf{e}_i,\quad \gamma_r=\gamma_1\mathbf{e}_r,\ \text{and}\ \gamma_t=\gamma_2\mathbf{e}_t,$$

where $\gamma_{1,2}=[j\omega\mu_{1,2}(\sigma_{1,2}+j\omega\epsilon_{1,2})]^{1/2}$, and $(\mathbf{e}_i,\mathbf{e}_r,\mathbf{e}_t)$ are unit vectors in the directions of the incident, reflected, and transmitted wave, respectively, i.e.,

$$\mathbf{e}_i=\mathbf{e}_x\sin\theta_i-\mathbf{e}_y\cos\theta_i,$$

$$\mathbf{e}_r=\mathbf{e}_x\sin\theta_r+\mathbf{e}_y\cos\theta_r,$$

$$\mathbf{e}_t=\mathbf{e}_x\sin\theta_t-\mathbf{e}_y\cos\theta_t.$$

The solution in each region is then, for *perpendicular polarization,*

$$\begin{aligned} y>0:\quad &\mathbf{E}_1(\mathbf{r})=\mathbf{e}_z\{E^ie^{-\gamma_i\cdot\mathbf{r}}+E^re^{-\gamma_r\cdot\mathbf{r}}\},\\ &\mathbf{H}_1(\mathbf{r})=\frac{1}{\eta_1}\{(\mathbf{e}_i\times\mathbf{e}_z)E^ie^{-\gamma_i\cdot\mathbf{r}}\\ &\qquad+(\mathbf{e}_r\times\mathbf{e}_z)E^re^{-\gamma_r\cdot\mathbf{r}}; \end{aligned} \tag{33a}$$

$$\begin{aligned} y<0:\quad &\mathbf{E}_2(\mathbf{r})=\mathbf{e}_zE^te^{-\gamma_t\cdot\mathbf{r}},\\ &\mathbf{H}_2(\mathbf{r})=\frac{1}{\eta_2}(\mathbf{e}_t\times\mathbf{e}_z)E^te^{-\gamma_t\cdot\mathbf{r}}; \end{aligned} \tag{33b}$$

and for *parallel polarization,*

FIG. 5. Plane wave obliquely incident onto an interface.

$$y>0: \quad \mathbf{E}_1(\mathbf{r}) = \{(\mathbf{e}_i \times \mathbf{e}_z) E^i e^{-\gamma_i \cdot \mathbf{r}} + (\mathbf{e}_r \times \mathbf{e}_z) \times E^r e^{-\gamma_r \cdot \mathbf{r}}\},$$

$$\mathbf{H}_1(\mathbf{r}) = -\frac{\mathbf{e}_z}{\eta_1}\{E^i e^{-\gamma_i \cdot \mathbf{r}} + E^r e^{-\gamma_r \cdot \mathbf{r}}\}, \tag{34a}$$

$$y<0: \quad \mathbf{E}_2(\mathbf{r}) = (\mathbf{e}_t \times \mathbf{e}_z) E^t e^{-\gamma_t \cdot \mathbf{r}},$$

$$\mathbf{H}_2(\mathbf{r}) = -\frac{\mathbf{e}_z}{\eta_2} E^t e^{-\gamma_t \cdot \mathbf{r}}. \tag{34b}$$

The requirement that the tangential electric and magnetic field be continuous at $y=0$ provides the equations for obtaining the following solution:

$$\gamma_1 \sin \theta_i = \gamma_1 \sin \theta_r = \gamma_2 \sin \theta_t \quad \text{(Snell's law)}. \tag{35}$$

For perpendicular polarization,

$$\Gamma_\perp = \frac{E^r}{E^i} = \frac{\eta_2 \cos \theta_i - \eta_1 \cos \theta_t}{\eta_2 \cos \theta_i + \eta_1 \cos \theta_t},$$

$$T_\perp = \frac{E^t}{E^i} = \frac{2\eta_2 \cos \theta_i}{\eta_2 \cos \theta_i + \eta_1 \cos \theta_t}. \tag{36}$$

For parallel polarization,

$$\Gamma_\parallel = \frac{E^r}{E^i} = \frac{\eta_2 \cos \theta_t - \eta_1 \cos \theta_i}{\eta_2 \cos \theta_t + \eta_1 \cos \theta_i},$$

$$T_\parallel = \frac{E^t}{E^i} = \frac{2\eta_2 \cos \theta_i}{\eta_2 \cos \theta_t + \eta_1 \cos \theta_i}. \tag{37}$$

Often, and especially for nonmagnetic media where $\mu=\mu_0$, we introduce the refractive index of the medium as $n=\epsilon_r^{1/2}$ and replace the various characteristic impedances η in Eqs. (36) and (37) by $n^{-1}\eta_0$. The fact that the reflection coefficients Γ and the transmission coefficients T are different for the two polarizations, even though they are both linearly polarized waves, may have many interesting applications. For instance, the amount of depolarization in the reflected wave for a circularly polarized incident wave can be used as a sensing mechanism for finding the electrical properties of an unknown material (see ELLIPSOMETRY).

4.1 Total Reflection, Critical Angle, and Brewster Angle

There are two especially interesting physical phenomena associated with a plane wave obliquely incident onto an interface. In one case, the waves are totally reflected with no power transmitted to the second medium, and in the second case, the waves are totally transmitted into the second medium with no power reflected. We shall discuss in some detail below the conditions for the occurrence of these effects.

Let us first look at how the angle of the transmitted wave varies according to the incident angle. According to Snell's law in Eq. (35), a transmitted wave will become more grazing when a wave is incident from a denser medium, i.e., $n_1>n_2$, since $\theta_t=\sin^{-1}[(n_1/n_2)\sin \theta_i]$. This means that when the incident angle is increased beyond the so-called critical angle,

$$\theta_c = \sin^{-1}(n_1/n_2), \tag{38}$$

the transmitted angle reaches $\pi/2$ and thereafter must become complex: the wave can no longer propagate freely in the second medium in the form of a homogeneous plane wave. The complex wave vector corresponding to this angle of transmission is given by

$$\begin{aligned}\gamma_t &= jk_0 n_2 \mathbf{e}_t \\ &= j\mathbf{e}_x k_0 n_1 \sin\theta_i - \mathbf{e}_y k_0 [n_1^2 \sin^2\theta_i - n_2^2]^{1/2}.\end{aligned}$$

The transmitted wave, as given by Eqs. (33b) and (34b) for either polarization, becomes an inhomogeneous plane wave. In other words, the transmitted wave, while propagating with the same phase velocity as the incident and reflected waves, nevertheless decays exponentially away from the interface; it is said to be evanescent. For instance, for the perpendicular polarization, we have

$$\begin{aligned}\mathbf{E}_2(\mathbf{r}) &= \mathbf{e}_z T_\perp E^i \exp\{k_0[n_1^2 \sin^2\theta_i - n_2^2]^{1/2} y\} \\ &\quad \times \exp(-jk_0 n_1 x \sin\theta_i);\end{aligned} \tag{39a}$$

$$\begin{aligned}\mathbf{H}_2(\mathbf{r}) &= \frac{1}{\eta_2}\left\{\mathbf{e}_x\left(\frac{n_1}{n_2}\right)\sin\theta_i \right. \\ &\quad \left. + j\mathbf{e}_y\left[\left(\frac{n_1}{n_2}\right)^2 \sin^2\theta_i - 1\right]^{1/2}\right\} \times \mathbf{E}_2(\mathbf{r}) .\end{aligned} \tag{39b}$$

A similar expression can be derived for the parallel polarization. We should note that this physical phenomenon is often referred to as total reflection, not because there is no longer any electromagnetic field in medium No. 2, but because it is no longer possible to transmit any time-average power into this medium, i.e., $P_{\text{av}} = \frac{1}{2}\text{Re}\{E_z H_x^*\} = 0$.

The second phenomenon of interest is that of total transmission. By setting the reflection coefficient $\Gamma_\parallel$ equal to zero for the case of parallel polarization, we can find explicitly the angle of incidence necessary for this to occur to be

$$\theta_b = \sin^{-1}\left\{\frac{n_2}{(n_1^2 + n_2^2)^{1/2}}\right\} \tag{40}$$

and this angle is called Brewster's angle. It is not difficult to show that the angle for the transmitted wave under this condition is given by $\pi/2 - \theta_b$. This means that the dipoles (molecules) in the second medium, which either are polarized or reoriented in the same direction as the electric field in that medium, are all aligned parallel to the direction the reflected wave would be propagating in (were it not zero in amplitude), and hence do not produce any net radiation in that direction. This helps explain why the reflection is zero at this angle, and, for that matter, why such a phenomenon can occur only in the case of parallel polarization, and not when the incident wave is perpendicularly polarized. The general behaviors for both types of polarization are sketched in Fig. 6 for comparison.

4.2 Reflection of a Gaussian Beam: Goos–Hänchen Shift

The total reflection phenomenon for a wave incident at an angle greater than the critical angle also brings about another interesting physical consequence when the incident wave is in the form of a Gaussian beam. As we explained in Sec. 3, a plane wave with a Gaussian envelope can be viewed as a collimated collection of plane waves propagating at angles slightly different from each other and, as a result, has the tendency to diverge after a certain propagation distance. Recognizing that the direction of propagation for the incident wave is now at an angle θ_i with respect to the direction normal to the inter-

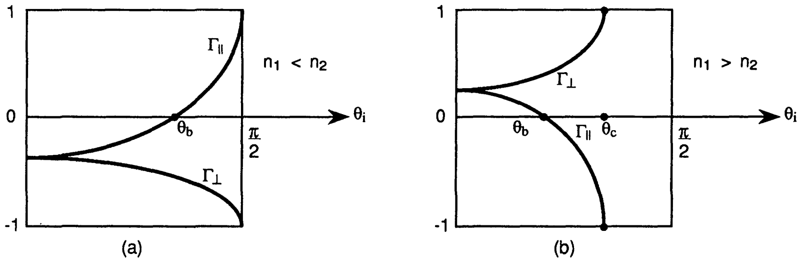

FIG. 6. Reflection coefficients as a function of incident angle.

face in the xy plane, we can rewrite the spectral representation (31) for a perpendicularly polarized incident Gaussian beam by replacing z with $x \sin \theta_i - y \cos \theta_i$, and replacing x with $x \cos \theta_i + y \sin \theta_i$, to yield

$$\mathbf{E}^i(\mathbf{r}) = \mathbf{e}_z \frac{E_0 w}{(2\pi)^{1/2}} \int_{-\infty}^{\infty} e^{-\beta_x^2 w^2/2} \times \exp\{-jk_0 n_1 [x \sin(\theta_i + \theta_{\beta_x}) - y \cos(\theta_i + \theta_{\beta_x})]\} d\beta_x, \tag{41a}$$

where $\theta_{\beta_x} = \sin^{-1}(\beta_x / k_0 n_1)$ represents the angle of propagation for a plane-wave spectral component β_x. A similar expression can be obtained for the parallel polarization case.[1] Now since the angle of spread is typically very small, we can use a small-angle approximation to obtain $\theta_{\beta_x} \simeq \beta_x / k_0 n_1$, so that at the interface $y = 0$, the incident electric field is given approximately as

$$\mathbf{E}^i(\mathbf{r}) = \mathbf{e}_z \frac{E_0 w}{(2\pi)^{1/2}} \times \exp\{-jk_0 n_1 x \sin \theta_i\} W_i(x, 0), \tag{41b}$$

where

$$W_i(x, 0) = \int_{-\infty}^{\infty} e^{-\beta_x^2 w^2/2} e^{-j\beta_x x \cos \theta_i} \, d\beta_x \tag{41c}$$

is the projection of the Gaussian beam along the interface. The projection of the reflected Gaussian beam, on the other hand, is given by

$$W_r(x, 0) = \int_{-\infty}^{\infty} \Gamma_\perp(\theta_i + \theta_{\beta_x}) \times e^{-\beta_x^2 w^2/2} e^{-j\beta_x x \cos \theta_i} \, d\beta_x, \tag{42}$$

where $\Gamma_\perp(\theta_i + \theta_{\beta_x})$ is the reflection coefficient given in Eq. (36). For waves which are incident at an angle greater than the critical angle, the magnitude of $\Gamma_\perp$ is unity, i.e.,

$$\Gamma_\perp(\theta_i + \theta_{\beta_x}) = \exp\{-j\Psi(\theta_i + \theta_{\beta_x})\},$$

$$\Psi(\theta) = 2 \tan^{-1} \left\{ \frac{(n_1^2 \sin^2 \theta - n_2^2)^{1/2}}{n_1 \cos \theta} \right\}.$$

Expanding in a Taylor series with respect to the incident angle θ_i,

$$\Gamma_\perp(\theta_i + \theta_{\beta_x}) \approx \Gamma_\perp(\theta_i) e^{-j\beta_x \Delta \cos \theta_i},$$

$$\Delta = \left(\frac{1}{k_0 n_1 \cos \theta_1} \right) \frac{\partial \Psi}{\partial \theta} \bigg|_{\theta = \theta_1}, \tag{43}$$

and substituting Eq. (43) into Eq. (42) yields the following result:

$$W_r(x, 0) = \Gamma_\perp(\theta_i) W_i(x + \Delta, 0).$$

The reflected Gaussian beam therefore has an amplitude of $\Gamma_\perp(\theta_i)$ as might be expected. It also has a projected envelope similar to that of the incident beam, except that it is shifted by an amount Δ in the x direction, commonly referred to as the Goos–Hänchen shift (Arnaud, 1976; Solimeno *et al.*, 1986; Ishimaru, 1991). This shift is caused by the slightly different phases of the spectral components making up the reflected wave, even though they are all totally reflected from the interface.

4.3. Wave Propagation in a Multilayer Medium

Analysis of plane waves in a multilayer medium follows basically the same approach as in the two-layer case, except that the solutions in the intermediate layers contain both forward and backward propagating waves bouncing between the two interfaces. For convenience, we will consider only the case of a linearly polarized plane wave incident normally onto a multilayer medium as shown in Fig. 7 so that for the νth layer, having a thickness d_ν and refractive index n_ν, the general plane-wave solution can be written in the following form:

$$\mathbf{E}_\nu(z) = \mathbf{e}_x \{E_\nu^+ \, e^{-j\beta_\nu z} + E_\nu^- \, e^{+j\beta_\nu z}\},$$

$$\mathbf{H}_\nu(z) = \mathbf{e}_y \frac{1}{\eta_\nu} \{E_\nu^+ e^{-j\beta_\nu z} - E_\nu^- e^{+j\beta_\nu z}\}, \tag{44}$$

where $\beta_\nu = n_\nu k_0$ is the propagation constant and $\eta_\nu = \eta_0 / n_\nu$ is the characteristic impedance of the νth layer. Before proceeding to find the wave amplitudes $E_\nu^\pm$ it is sometimes more convenient first to define a reflection coefficient $\Gamma_\nu(z)$ as the ratio of the backward to the forward wave, and a total-field impedance $Z_\nu(z)$ as the ratio of the total electric field to the total magnetic field, so that

---

[1] The reader is reminded that we have changed the coordinate system for the plane of incidence from the xz plane in Eq. (31) to the xy plane in Eq. (41a) in order to be consistent with the equations we have derived in this section.

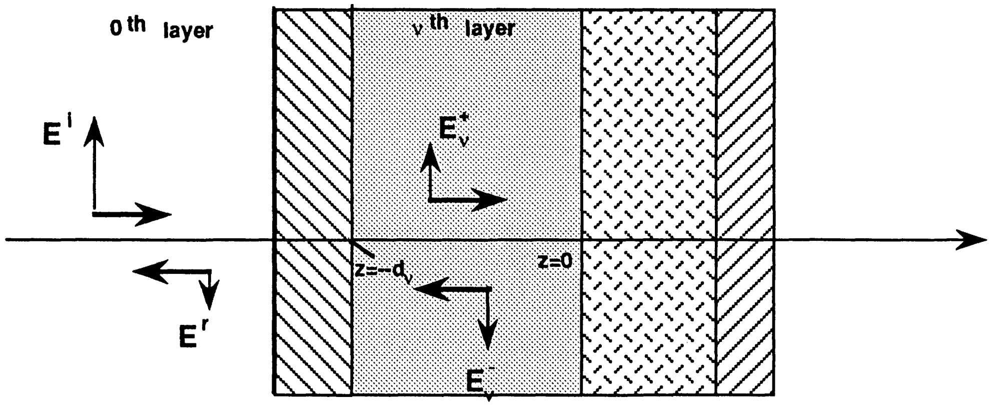

FIG. 7. Wave propagation in a multilayer medium.

$$\begin{aligned}&\Gamma_v(z_1)=\Gamma_v(z_2)e^{j2\beta_v(z_1-z_2)},\\&Z_v(z)=\eta_v\left\{\frac{1+\Gamma_v(z)}{1-\Gamma_v(z)}\right\}.\end{aligned}\tag{45}$$

Equation (45) provides us a convenient way to relate the solution in the v th layer to those in the $(v\pm1)$th layers. For instance, using a local coordinate system with $z=0$ set at the right-hand side of each layer shown in Fig. 7, it is not difficult to show from Eq. (45) that at the interface on the left, i.e., $z=-d_v$, the total-field impedance is given by

$$Z_v(-d_v)=\eta_v\left\{\frac{Z_v(0)+j\eta_v\tan\beta_vd_v}{\eta_v+jZ_v(0)\tan\beta_vd_v}\right\}.\tag{46}$$

Since the boundary conditions that the tangential electric and magnetic fields at an interface between two layers be continuous imply the continuity of the total-field impedance there, i.e., $Z_v(0)=Z_{v+1}(-d_{v+1})$ and $Z_{v-1}(0)=Z_v(-d_v)$, we can therefore obtain the value of Z in any layer if it is known in another layer. In particular, since there is no reflected wave in the last (say the Mth) layer, $\Gamma_M=0$ and $Z_{M-1}(0)=\eta_M$, and we can then proceed to track the value of Z, and hence the reflection coefficient Γ , back to the incident region, and then obtain the amplitude of the reflected wave in that region.

A useful device that illustrates these principles is the quarter-wave transformer. As seen from Eq. (45), the relation between $Z_v(0)$ and $Z_v(-d_v)$ reduces to a very simple one when the thickness d_v equals a quarter of the wavelength in that medium, i.e., $\beta_vd_v=2\pi d_v/\lambda_v=\pi/2$. In this situation, $Z_v(-d_v)=\eta_v^2/Z_v(0)$. This means we can match the total-field impedance at the input end to any positive real value, if the total-field impedance at the other end is positive real and if we can suitably choose the material parameters and thus the characteristic impedance η_v in that medium. For instance, we may wish to minimize the amount of reflection when a plane wave is incident from one medium onto another. A possible solution is to insert an intermediate layer with material parameters chosen in such a way that the characteristic impedance in that layer is given by $\eta_2=(\eta_1\eta_3)^{1/2}$, where η_1 and η_3 are, respectively, the characteristic impedances for the incident and transmitted regions. No reflection will then be encountered when the thickness of the matching layer thickness is 1/4 of the wavelength in that layer, since according to Eq. (44), $\Gamma_1=0$ when $Z_1(0)=\eta_1$.

5. GUIDED WAVES (I)

5.1 Parallel-Plate Waveguides: TE, TM, and TEM Modes

In Secs. 2–4, we have discussed how plane waves propagate in different environments; in most cases, we assumed that the regions of interest were unbounded in extent perpendicular to the direction of propagation. Obviously such an assumption restricts the kind of problems we can tackle, particularly those where we wish to guide the wave propagation in some prescribed manner. In this and the following section, we will discuss physical phenomena associated with guided waves which are supported by guiding structures in either a closed or an open environment (Ramo *et al.*, 1984; Pozar, 1990).

A parallel-plate waveguide consists of a region bounded by two infinite parallel metallic plates separated by a distance a as shown in Fig. 8. Although we are still interested in regions away from any source, possible solutions of the Maxwell equation are now subject to the boundary conditions on the metallic walls; e.g., the tangential electric field must vanish if we assume the two walls are perfectly conducting.

We start by examining the case of a plane wave propagating in the z direction, parallel to the walls. Assuming that the parallel-plate waveguide, i.e., the region between the two walls, is filled with a lossless dielectric material of permittivity ϵ, and at an operating frequency ω, the field of a forward-propagating plane wave is

$$E_x(z)=E_0e^{-j\beta z}, \quad H_y(z)=\frac{E_0}{\eta}e^{-j\beta z}, \tag{47}$$

where $\beta=k=\omega(\mu\epsilon)^{1/2}$ is the propagation constant, and $\eta=(\mu/\epsilon)^{1/2}$ is the characteristic impedance of the material. Now since the only electric field component here is in the x direction, the boundary condition of vanishing tangential electric field is automatically satisfied. In other words, the insertion of the two walls does not physically perturb the propagation of a plane wave propagating in the z direction. We sometimes refer to this type of solution as the TEM mode since both E_x and H_y are perpendicular or transverse to the direction of propagation.

The reason why the TEM mode is an acceptable solution can also be explained by the fact that the direction of propagation, often defined as a ray in geometrical theories of electromagnetic and optical wave propagation, is parallel to the walls, and thus will bounce neither toward nor away from them. This of course will change if the rays are propagating in some other direction. For instance, let us consider the case when a plane wave of amplitude A_1 is perpendicularly polarized, incident onto the lower wall at an angle θ. According to the analysis given in Sec. 4.1 for the case when $\sigma_2 \to \infty$ and $\eta_2 = 0$, a reflected wave will be generated with an amplitude equal but opposite to that of the incident wave so that the total field in the region is given as

$$E_y(x,z)=A_1\, e^{-jk(-x\cos\theta+z\sin\theta)} + A_2\, e^{-jk(x\cos\theta+z\sin\theta)}, \tag{48}$$

where $A_2=-A_1$. The wave or ray that bounces from the lower wall will become an incident wave onto the upper wall at $x=a$ at the same angle θ, which in turn, generates a reflected wave in the same direction as the original incident wave. A constructive interference of all those subsequent waves that are propagating up and of all those propagating down can occur only if the two types of waves also satisfy the boundary condition at $x=a$ simultaneously:

$$A_2=-A_1, \quad A_1\, e^{jka\cos\theta}=-A_2\, e^{-jka\cos\theta},$$

which implies

$$\theta_m=\cos^{-1}\left(\frac{m\pi}{ka}\right), \quad m=1,2,3,\ldots. \tag{49}$$

In other words, only those waves that are propagating at an angle $\theta=\theta_m$, $m=1,2,3\ldots$, can form acceptable solutions in a parallel-plate waveguide. The substitution of Eq. (49) into Eq. (48) yields the following expression:

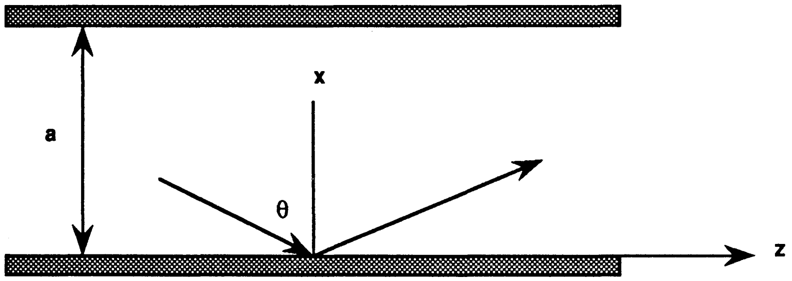

FIG. 8. A ray description for a TE mode in a parallel waveguide.

$$E_y(x,z) = \sum_{m=1}^{\infty} E_{ym} \sin\left(\frac{m\pi}{a} x\right) e^{-\gamma_m z},$$

$$\gamma_m = j\beta_m = j\left[k^2 - \left(\frac{m\pi}{a}\right)^2\right]^{1/2}. \tag{50a}$$

In deriving Eq. (50a), we have replaced the term $-j2A_1$ by E_{ym} to stress the point that the amplitude of each solution is yet undetermined because we do not know the nature of excitation. Moreover, since the electric field component in this case is always transverse to the direction of propagation, we designate this type of solution as TE$_m$ modes. It is not difficult to show that solutions corresponding to parallel-polarized plane waves are characterized by

$$H_y(x,z) = \sum_{m=0}^{\infty} H_{ym} \cos\left(\frac{m\pi}{a} x\right) e^{-\gamma_m z},$$

$$\gamma_m = j\beta_m = j\left[k^2 - \left(\frac{m\pi}{a}\right)^2\right]^{1/2}, \tag{50b}$$

and are designated as the TM$_m$ modes. The special case of $m = 0$ clearly corresponds to the TEM mode referred to earlier. While not written out explicitly here, we should nevertheless also note that the magnetic field of a TE$_m$ mode can be obtained directly from the Maxwell equation: $\mathbf{H} = (-j\omega\mu)^{-1}\nabla E_y \times \mathbf{e}_y$, and likewise for the electric field of a TM$_m$ mode.

Several important aspects of TE and TM modes are the following

1. Cutoff frequency: As suggested by Eqs. (50a) and (50b), each mode in a parallel-plate waveguide propagates with a different complex propagation constant γ_m. For those modes where $k > (m\pi/a)$, γ_m is purely imaginary, i.e., $\gamma_m = j\beta_m$; the wave behaves like $\cos(\omega t - \beta_m z)$ and thus propagates down the waveguide without decay. However, for those modes where $k < (m\pi/a)$, γ_m is purely real, i.e., $\gamma_m = \alpha_m$; the wave behaves like $\exp(-\alpha_m z)\cos \omega t$, and thus decays exponentially in the z direction like an inhomogeneous plane wave. From the point of view of signal transmission, it is not difficult to show from Poynting's theorem that no time-average power can be transmitted from one cross section z=constant to another in the case of a single exponentially decaying wave. Thus, for any operating frequency ω, there are only a finite number of modes that can propagate. The frequency below which a mode ceases to propagate is called the cutoff frequency and is given by $\omega_{cm} = m\pi/a\sqrt{\mu\epsilon}$.
2. Fast waves: A propagating mode in a parallel-plate waveguide is often called a fast-wave mode. The reason for this designation comes from the observation that the phase velocity along the direction of propagation is given by $v_{pz} = \omega/\beta_m$, which is always greater than the speed of light $c = (\mu\epsilon)^{-1/2}$, since $\beta_m < k$ and $k = \omega/c$. This does not mean that any known physical principle has been violated. Rather it is because the phase velocity defined in this manner overlooks the fact that the underlying plane waves are all propagating in directions other than along the z axis. Nevertheless, such an observation does underline an important physical realization, and that is: the phase velocity associated with either a mode or a single plane wave is only a measure of how fast a phase front is moving as observed along a certain direction. For instance, the phase velocity would have been infinity had we chosen to observe along a constant phase front, no matter how fast the wave were actually moving. In fact, since the component plane waves travel down the waveguide in a zig-zag manner, it can be shown that the signal velocity (as defined by the so-called group velocity $v_g = \partial\omega/\partial\beta_m$) is slower rather than faster than the speed of light for all propagating modes.
3. Characteristic impedance of a mode: We have seen that it is often convenient to introduce the concept of impedance to characterize the relationship between the electric field and the magnetic field of a plane wave; the value of this impedance depends only upon the material properties, but not upon where the field is observed. This is also true in the case of TEM, TE, and TM modes, if we define the characteristic impedance to be the ratio of the transverse electric field $\mathbf{E}_t$ to the transverse magnetic field $\mathbf{H}_t$:

$$\mathbf{H}_t = \frac{1}{\eta_m}(\mathbf{e}_z \times \mathbf{E}_t), \tag{51a}$$

where

$$\eta_m = j\omega\mu/\gamma_m, \quad (\text{TE}_m \text{ modes}),$$

$$\eta_m = \gamma_m/j\omega\epsilon \quad (\text{TM}_m \text{ modes}). \qquad (51\text{b})$$

In contrast to the case of a plane wave, however, the characteristic impedance of a mode is purely real if the mode is above cutoff but is purely imaginary below cutoff.

4. Dispersion: The parallel-plate waveguide, in either a TE or TM mode of operation, is a dispersive structure. This is because the propagation constant β_m as given by Eq. (49), and consequently the phase velocity v_{pz}, exhibit a strong dependence on frequency. A signal which is rich in frequency content will disperse after traveling a sufficient distance along the waveguide because the phase relation between the various spectral components is no longer the same. Consider, for instance, the electric field of a TE_1 mode which is amplitude-modulated so that initially, at the $z=0$ plane, we have

$$8qE_y(x,0;t) = E_0\{1+\Delta_m \cos \omega_m t\} \times \sin(\pi x/a) \cos \omega_0 t,$$

where Δ_m is the amplitude of modulation, and ω_m and ω_0 are the modulation and carrier frequencies, respectively. Its envelope will eventually evolve into a different shape because its carrier frequency ω_0 and the two sideband frequencies $\omega^\pm = \omega_0 \pm \omega_m$ will have different phase shifts:

$$E_y(x,z;t) = E_0\left\{\cos(\omega_0 t - \beta_0 z) + \frac{\Delta_m}{2}[\cos(\omega^+ t - \beta^+ z) + \cos(\omega^- t - \beta^- z)]\right\} \sin\left(\frac{\pi x}{a}\right).$$

For many applications, the sidebands are very narrow, i.e., $\omega_m \ll \omega_0$. A good approximation for $\beta^\pm$ can be obtained by keeping only the first two terms in the Taylor series: $\beta^\pm z \simeq (\beta_0 \pm \omega_m/v_g)z$, where $v_g = \partial\omega/\partial\beta$, evaluated at $\omega = \omega_0$. We can then further simplify the expression for E_y to obtain

$$E_y(x,z;t) = E_0\left\{1+\Delta_m \cos \omega\left(t - \frac{z}{v_g}\right)\right\} \times \sin\left(\frac{\pi x}{a}\right) \cos \omega\left(t - \frac{z}{v_{pz}}\right),$$

$$v_{pz} = \frac{\omega_0}{\beta_0}, \qquad (52)$$

which clearly shows that the carrier is propagating at the phase velocity v_{pz}, while the envelope or modulation is moving at the group velocity v_g which according to Eq. (49) equals c^2/v_{pz} (see Fig. 9). Thus, so long as the bandwidth of a signal is narrow, we see that the basic characteristics of the signal are retained, at least initially, before it begins to be dispersed. The dispersion distance, in the case of amplitude modulation, can be shown to be proportional to $(\omega_0/\omega_m)^2$.

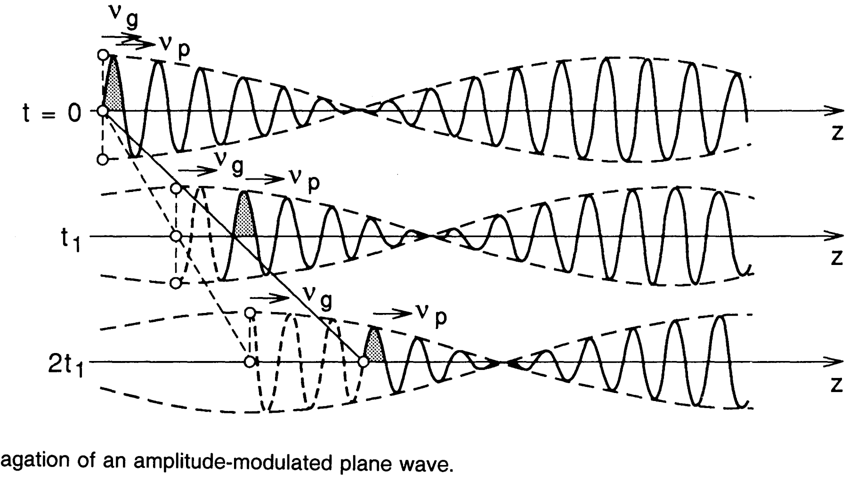

FIG. 9. Propagation of an amplitude-modulated plane wave.

5.2 Rectangular Waveguides

A rectangular waveguide differs physically from a parallel-plate waveguide in that the cross section is now finite in both the x and y directions as shown in Fig. 10. Recalling that a parallel-plate waveguide is capable of propagating a TEM mode without cutoff basically because the insertion of the two walls does not perturb the field distribution of that mode, we see that this is no longer true in the case of a rectangular waveguide. However, the ray approach we used is still applicable. For instance, for a TM mode characterized by the longitudinal component of the electric field E_z, we can first assume a set of forward-propagating plane waves moving at an angle θ with respect to the z axis, which bounce around between the four surrounding walls at $x=0,a$ and $0<y<b$, and at $y=0,b$ and $0<x<a$.

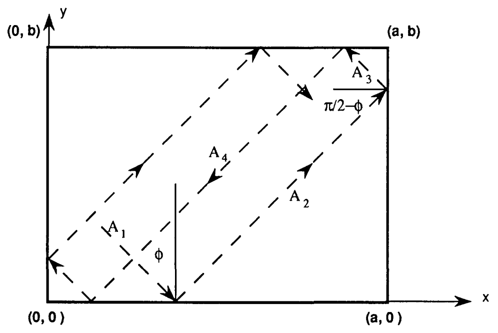

FIG. 10. Rays in a rectangular waveguide.

We further assume that the projection of the incident angle of one wave (one impinging on the wall at $y=0$, say) in the xy plane is ϕ, so that the sum of all possible waves resulting from repeated reflections of this original wave is

$$E_z(x,y,z)=\{A_1\exp[-jk\sin\theta(x\sin\phi-y\cos\phi)]+A_2\exp[-jk\sin\theta(x\sin\phi+y\cos\phi)]$$
$$+A_3\exp[+jk\sin\theta(x\sin\phi-y\cos\phi)]+A_4\exp[+jk\sin\theta(x\sin\phi+y\cos\phi)]\}$$
$$\times e^{-jkz\cos\theta}. \tag{53}$$

Again, for these waves to interact constructively with each other, they must be oriented in such a way to produce a vanishing tangential field at all four walls. For example, as shown in Fig. 10, for the wall at $y=0$, ray No. 1 and ray No. 4 are incident waves, while ray No. 2 and ray No. 3 are reflected rays, so that $A_2=-A_1$ and $A_4=-A_3$. Proceeding with the conditions at the remaining walls, the following relationships are obtained:

$$A_1=-A_2=A_3=-A_4;$$
$$e^{-jka\sin\theta\sin\phi}=e^{+jka\sin\theta\sin\phi}, \tag{54}$$
$$e^{-jkb\sin\theta\cos\phi}=e^{+jkb\sin\theta\cos\phi},$$

which can then be translated into a set of solutions for θ and ϕ:

$$\theta_{mn}=\sin^{-1}\left[\left(\frac{m\pi}{a}\right)^2+\left(\frac{n\pi}{b}\right)^2\right]^{1/2};$$
$$\phi_{mn}=\sin^{-1}\left(\frac{m\pi}{a\sin\theta_{mn}}\right), \tag{55}$$

where $m,n=1,2,3\ldots$. Using these values of θ and ϕ, we can rearrange Eq. (53) into a more familiar form:

$$E_z(x,y,z)=\sum_{m,n}E_{mn}\sin\left(\frac{m\pi}{a}\right)\sin\left(\frac{n\pi}{b}\right)e^{-\gamma_{mn}z}, \tag{56a}$$

where

$$\gamma_{mn}=j\beta_{mn}=j\left\{k^2-\left(\frac{m\pi}{a}\right)^2-\left(\frac{n\pi}{b}\right)^2\right\}^{1/2}; \tag{56b}$$

and each such solution is called a TM$_{mn}$ mode. The amplitude of each mode, i.e., E_{mn}, is again yet to be determined from the actual excitation of the waveguide. The derivation for TE$_{mn}$ modes follows in essentially the same manner, except that either m or n, but not both, can be zero:

$$H_z(x,y,z)=\sum_{m,n}H_{mn}\cos\left(\frac{m\pi}{a}\right)$$
$$\times\cos\left(\frac{n\pi}{b}\right)e^{-\gamma_{mn}z}, \tag{57a}$$

where

$$\gamma_{mn}=j\beta_{mn}=j\left\{k^2-\left(\frac{m\pi}{a}\right)^2-\left(\frac{n\pi}{b}\right)^2\right\}^{1/2}. \tag{57b}$$

As in the case of a parallel-plate waveguide, we can again conclude that only a finite number of propagating modes exist for which $\gamma_{mn}=j\beta_{mn}$ is purely imaginary. For most applications, the operating frequency is set to be above the cutoff frequency of a TE_{10} mode, but below the cutoff frequencies of all the other modes, so that a single mode of operation is assured. To complete our discussion on waveguide modes, we should also point out that both the transverse electric and transverse magnetic field components can be readily obtained once the longitudinal components are known. This is because the two Maxwell curl equations decouple when a functional dependence of $\exp(-\gamma z)$ is assumed:

$$-\gamma\mathbf{e}_z\times\mathbf{E}_t+\nabla_tE_z\times\mathbf{e}_z=-j\omega\mu\mathbf{H}_t,$$

$$-\gamma\mathbf{e}_z\times\mathbf{H}_t+\nabla_tH_z\times\mathbf{e}_z=j\omega\epsilon\mathbf{E}_t,$$

which after some manipulation yield the following result for a TE mode:

$$\mathbf{E}_t=\left(\frac{-\gamma}{k^2+\gamma^2}\right)\nabla_tE_z,\quad \mathbf{H}_t=\left(\frac{1}{\eta_{TE}}\right)\mathbf{e}_z\times\mathbf{E}_t,$$

where $\eta_{TE}=\gamma/(j\omega\epsilon)$ is the characteristic impedance of a TE mode. A similar expression also exists for the TM mode. Without further elaboration, it suffices for us to state that these modes share the fast-wave, dispersive properties of the TE and TM modes in a parallel-plate waveguide.

6. GUIDED WAVES (II)

6.1 Dielectric Waveguides: Surface-Wave Modes

The waveguides we have discussed so far are closed waveguides, i.e., the electromagnetic field exists only inside the metallic waveguide structure. The dimensions of such waveguides are made comparable to the wavelength of a plane wave if they are to be operated in the single-mode regime. This makes fabrication difficult when the operating frequency is in the millimeter-wave or optical range, and prompts the question of whether electromagnetic waves can be guided in single-mode fashion on a structure of larger dimension, possibly in an open environment without a metallic wall. Consider a dielectric slab in air, of thickness $2d$ and refractive index n, as shown in Fig. 11, which is an analog of the parallel-plate waveguide discussed in Sec. 5.1. We again start with a perpendicularly polarized plane wave inside the dielectric region and incident onto the air-dielectric interface at $z=d$ at an angle θ . This plane wave of course will normally be partially transmitted and partially reflected, unless the incident angle is greater than the critical angle, in which case the wave will be totally reflected from the boundary. Assuming that to be the case, we can write down the general expression for the transverse electric field as

$$E_y(x,z)=A_1\,e^{-jk_0n[(x-d)\cos\theta+z\sin\theta]}+A_2\,e^{-jk_0n[(d-x)\cos\theta+z\sin\theta]}, \tag{58}$$

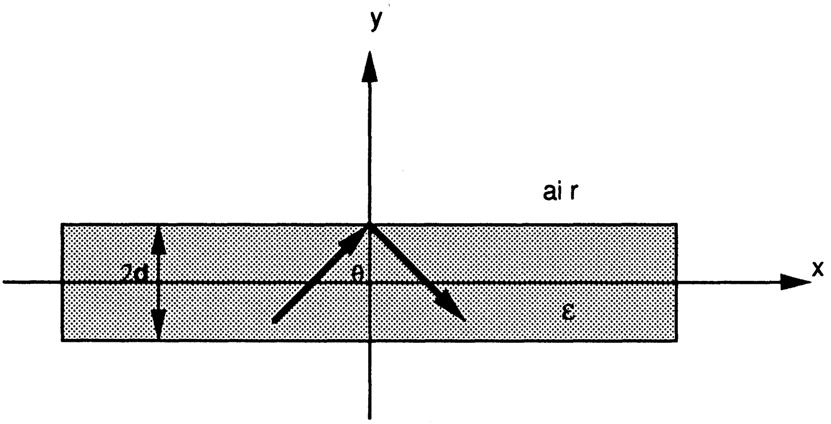

FIG. 11. Geometry of a dielectric slab waveguide.

where

$$A_2=A_1\, e^{-j2\Psi},$$

$$\Psi(\theta)=\tan^{-1}\left\{\frac{[n^2\sin^2\theta-1]^{1/2}}{n\cos\theta}\right\}.$$

Now since the structure is symmetric in the x direction, we can divide the solutions of this problem into even and odd modes. For the even modes, we require that $A_1\, e^{jk_0 n\cos\theta} = A_2\, e^{-jk_0 n\cos\theta}$ so that the field distribution will be symmetric. Constructive interference of waves inside the dielectric region occurs when

$$nk_0 d\cos\theta=m\pi-\Psi(\theta)\Rightarrow$$

$$\tan(nk_0 d\cos\theta)=\frac{[n^2\sin^2\theta-1]^{1/2}}{n\cos\theta} \qquad (59a)$$

which can be used to solve for θ . In order to discuss the nature of the solution more fully, it is convenient to define two new parameters: $h(\theta)=nk_0\cos\theta$, and $p(\theta)=k_0(n^2\sin^2\theta-1)^{1/2}$. As seen from Eq. (58), $h(\theta)$ is a transverse wave number telling how fast the field varies in the x direction inside the dielectric slab. On the other hand, $p(\theta)$ is a measure of the rate of field decay with x in the air. The equation to solve for θ in Eq. (59a) now becomes

$$h\tan hd=p, \quad (hd)^2+(pd)^2=V^2, \qquad (59b)$$

where $V=k_0(n^2-1)^{1/2}$ is often referred to as the normalized frequency of the dielectric slab waveguide. Equation (59b) suggests that a solution occurs whenever the curve $pd=hd\tan hd$ intersects a circle whose radius is V centered at the origin of the hd–pd plane. As shown in Fig. 12, only a finite number of solutions can exist for a given value of V, and each solution corresponds to a TE mode of operation. Using the definitions of h and p, it is not difficult to show that the transverse electric field in this case can be rewritten in a more familiar form:

$$E_y(x,z)=\sum_m E_m\Phi_m(x)e^{-j\beta_m z};$$

$$\beta_m=[(nk_0)^2-h_m^2]^{1/2}=[p_m^2+k_0^2]^{1/2}, \qquad (60)$$

and

$$\Phi_m(x)=\cos h_m x/\cos h_m d \text{ for } 0<x<d$$

and

$$\Phi_m(x)=e^{-p_m(x-d)} \text{ for } x>d.$$

We shall now discuss some of the most important features of the modes supported by a dielectric slab.

1. Surface-wave modes: The guided-wave modes that propagate along a dielectric slab are often referred to as surface-wave modes, and the dielectric slab is also known as a slow-wave structure. The reason for

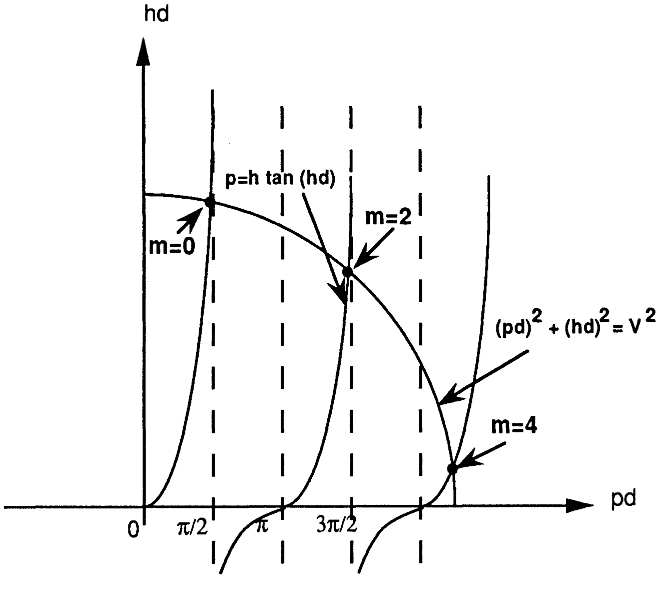

FIG. 12. Surface wave solution(s) for a dielectric waveguide.

the term surface wave comes from the recognition that the field decays exponentially as we move away from the surface outside of the dielectric slab. Thus, it has the appearance of existing only in the vicinity of that surface. For the same reason, the phase velocity of the *m*th surface-wave mode is given by the expression $v_{pz} = \omega/\beta_m = c/[1 + (cp/\omega)^2]^{1/2}$, where c is the speed of light measured in air. Thus, it is a slow wave compared to an ordinary plane wave in air. It is important to realize, however, that even though such a designation is semantic in nature, it does underline a very important difference between guided waves supported by a metallic structure and those supported by a dielectric structure. In a metallic waveguide, waves are bouncing back completely from its walls with the phase of a reflected wave differing by either 0 or π from that of the incident wave. In a dielectric waveguide, waves are totally reflecting because of the critical-angle phenomenon, and the phase of the reflected wave varies according to its incident angle. As a result, the field distribution of a surface-wave mode depends in a complicated manner on the operating frequency via the expression for the normalized frequency V. This of course is in contrast to the modes in a metallic waveguide, whose transverse field structure is independent of frequency.

2. Cutoff frequency: The number of surface-wave modes that can be supported by an open dielectric waveguide depends upon the value of the normalized frequency, $V = (n^2 - 1)^{1/2}k_0d$. The frequency for which a mode ceases to exist is called the cutoff frequency. As seen in Fig. 12, the TE_0 mode clearly does not have a cutoff, even though as V decreases, the value of pd also decreases and thus the mode is less confined in the air region. The second mode, on the other hand, no longer exists when $V \leqslant \pi$, giving a cutoff frequency of $\omega_{c,2} = \pi c/(n^2 - 1)^{1/2}d$. This means that the operating frequency must be lower than $\omega_{c,2}$ if single-mode operation is desired. It is of interest to note that, since the value of V depends on the contrast in refractive index between the dielectric and the air, we often can maintain single-mode operation even when the dimension of the dielectric slab is much greater than the wavelength of a plane wave in either region.

The above discussion points to an important difference between the discrete modes in a metallic waveguide and those of a dielectric waveguide regarding the concept of cutoff. In a metallic waveguide, higher-order modes can still exist even though they are under cutoff: they merely decay exponentially along the waveguide. In a dielectric waveguide, a mode under cutoff simply cannot exist physically. The general solution for a dielectric waveguide turns out to contain, instead of discrete cutoff modes, a continuous spectrum of modes. These modes are commonly referred to as radiation modes since they form a spectrum of plane waves in air and thus are not confined to the vicinity of the guiding structure. To complete our discussion on the dielectric-slab waveguide, we should point out that the structure is also dispersive. The analysis of this, however, is basically similar to that for the metallic waveguide and will not be repeated here.

6.2 Dielectric-Rib Waveguide and Other Surface-Wave Structures

Figure 13 shows the geometry of the so-called dielectric-rib waveguide commonly encountered in integrated optical and millimeter-wave circuits. The analysis of the modes for this structure is substantially more complicated than for the slab structure; however, we can once again follow the basic concept of total reflection to gain some insight as to how surface waves can be supported. This can be done by first dividing the cross section into three separate regions consisting of dielectric slabs of different thicknesses. Assuming that only one surface-wave mode of TE type can exist in each of the separate slabs, we can write down the general expression for a surface wave in any of the slab regions as

$$\mathbf{E}(x,y,z) = \mathbf{a}_e\{A_1\, e^{-j\beta(x\cos\theta + z\sin\theta)} + A_2\, e^{-j\beta(-x\cos\theta + z\sin\theta)}\}\Phi(y), \tag{61}$$

where $\Phi(y)$ is the modal electric field distribution of the surface wave and β is its propagation constant as determined from $\beta = (k_0^2 + p^2)^{1/2}$; $p > 0$ in Eqs. (59) and (60). The surface wave in this case is assumed to be

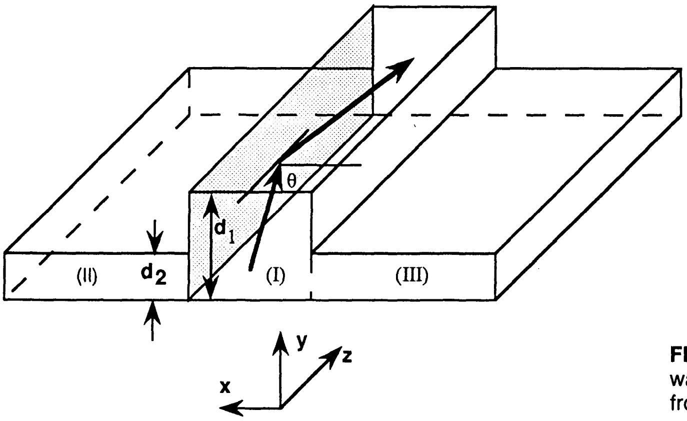

FIG. 13. A ray description of a surface-wave mode in the core region reflected from the interface on the left.

propagating in the lateral direction (xz plane) at an angle θ with respect to the x axis. The unit vector $\mathbf{a}_e$ is perpendicular to both the direction of propagation and the y axis. The situation is not unlike that of an obliquely incident plane wave, particularly if we choose to observe the field inside the dielectric region. The requirement that the phase variations in the z direction of waves on either side of the rib interface should match each other again results in Snell's law, $\beta_1 \sin \theta_1 = \beta_2 \sin \theta_2 = \beta_3 \sin \theta_3$ for the three slab regions. Now since we know that the value of p increases as the normalized frequency $V = k_0 d(n^2 - 1)^{1/2}$ increases, we can readily conclude that $\beta_1 > \beta_{2,3}$. Thus, for some incident angle θ_1, it is indeed possible to produce the condition $\beta_{2,3} \cos \theta_{2,3} = j[(\beta_1 \sin \theta_1)^2 - \beta_{2,3}^2]^{1/2}$ so that the waves in regions No. 2 and No. 3 will decay away from the rib region in the x direction as well. What this means is that at some appropriate angle, a total reflection indeed can occur, when the surface waves in the core region, which are already confined in the y direction, impinge onto the interface separating it from the surrounding slabs. The governing equation for finding the angles corresponding to the surface-wave modes supported by the rib waveguide can be derived approximately if we use the same expression for the reflection coefficient derived for plane waves.

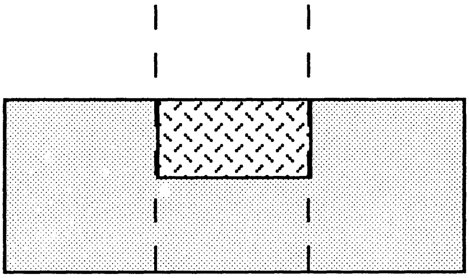
The procedure described above works well for a commonly encountered class of planar dielectric waveguide structures. Some of those are shown in Fig. 14. A more detailed discussion is beyond the scope of this review.

7. MULTICONDUCTOR TRANSMISSION LINES

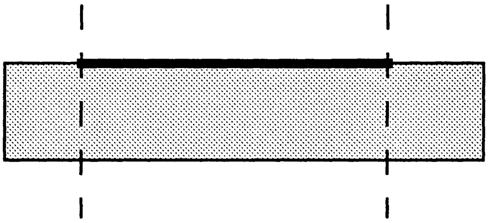
7.1 TEM-Mode Transmission Lines

The metallic waveguide modes we have discussed so far are of either TE or TM type with specific cutoff frequencies depending upon the dimensions of the waveguide and the properties of the material in the waveguiding region. The only exception to this was the TEM mode propagating in a parallel-plate waveguide, which does not have a cutoff. It turns out that the existence of one or more TEM modes is in fact a general property of multiconductor systems immersed in a homogeneous medium. Other than having the ability to propagate at all frequencies, these modes also have the interesting property that their fields behave like static fields in any given transverse cross section, while exhibiting a wave behavior along the direction of propagation. In fact, we often call these modes transmission-line modes, because many of the physical phenomena associated with these modes can be derived from an equivalent circuit representation consisting of distributed series inductances and shunt capacitances. Nevertheless, the conductors are merely the boundary of a waveguide in which power transmission is actually taking place.

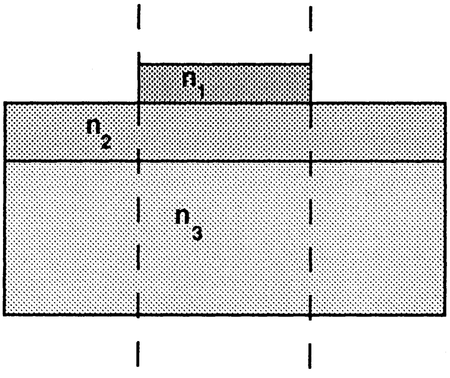
Assuming TEM fields behaving like $\exp(-\gamma z)$, where γ is a yet undetermined TEM-mode propagation constant, the two curl equations become $\gamma \mathbf{e}_z \times \mathbf{E}_t = -j\omega\mu \mathbf{H}_t$ and $-\gamma \mathbf{e}_z \times \mathbf{H}_t = j\omega\epsilon \mathbf{E}_t$. Elimination of either $\mathbf{E}_t$ or $\mathbf{H}_t$ from these equations yields



dielectric channel waveguide



microguide



dielectric strip guide

FIG. 14. Some planar dielectric waveguides.

$$\mathbf{H}_t=\left(\frac{1}{\eta}\right)\mathbf{e}_z\times\mathbf{E}_t,\quad \gamma=j\beta=j\omega(\mu\epsilon)^{1/2},\ \text{and}$$
$$\eta=\left(\frac{\mu}{\epsilon}\right)^{1/2}. \tag{62}$$

Thus, a TEM mode, if one exists, will behave exactly like a plane wave, except that both $\mathbf{E}_t$ and $\mathbf{H}_t$ may have some yet-unspecified transverse distribution.

The reason why a TEM does not have a nonzero cutoff frequency can be seen directly from the Maxwell equations. To find out whether the TEM mode can or cannot exist for a given structure, we now take the z component of $\nabla\times\mathbf{E}=-j\omega\mu\mathbf{H}$ to obtain $\mathbf{e}_z\cdot\nabla_t\times\mathbf{E}_t=0$. Thus, the transverse electric field in a given cross section can always be obtained from the gradient of a potential function, i.e., $\mathbf{E}_t=-\nabla_t\Phi$, which (as far as x and y dependences are concerned) is a static field. Now since we know that the static problem has exactly $M-1$ independent solutions for Φ corresponding to various voltage differences applied among the conductors in an M-conductor system, we can conclude that the same is true in the case of TEM modes supported by the same structure. This is why a coaxial cable or a two-wire transmission is so often used to transmit electromagnetic waves at lower frequencies.

Consider the example, shown in Fig. 15, of two infinitely long conductors of arbitrary cross section. The circuit interpretation can be demonstrated if we use the voltage $V(z)$ across this pair of conductors, and the total current $I(z)$ flowing on one of the two conductors, as a characterization of a transmission-line mode. For a forward-propagating TEM wave, the voltage is given by

$$V(z)=\left\{\int_P \mathbf{E}_t\cdot d\mathbf{l}\right\}e^{-j\beta z},$$

where P is a path in a plane of constant z between the two conductors. Using the relationship between $\mathbf{E}_t$ and $\mathbf{H}_t$ in Eq. (62), we can show that the voltage between the two conductors is related to the total magnetic flux per unit length Ψ_m cutting across the integration path P according to $V=v_p\Psi_m$, where $v_p=(\mu\epsilon)^{-1/2}$ is the phase velocity. As in a magnetostatic problem, we can define a distributed series inductance L_e per unit length as the ratio of Ψ_m to the current I so that the voltage and the current are now related to each other by $V/I=v_pL_e$. If, on the other hand, we start with the current as equal to the integration of the tangential magnetic field around a conductor, we can show again from Eq. (62) that $I=v_pQ$, where Q is the total charge per unit length on the conductor. As in an electrostatic problem, we can define a distributed shunt capacitance C_e per unit length as the ratio of Q to the voltage V between the two conductors so that $I/V=v_pC_e$. Combining the two equations relating V and I finally gives

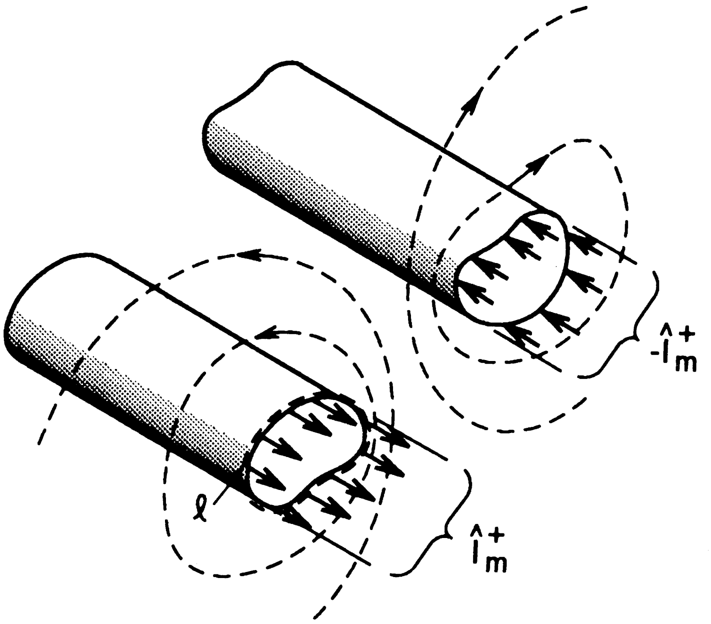


FIG. 15. A two-wire transmission line.

us the well-known result that $L_e C_e = \mu\epsilon$ for a TEM mode. To complete the circuit analogy, we now define the characteristic impedance Z_c of a transmission-line mode as the ratio of the voltage to current for a forward propagating wave, $Z_c = [L_e/C_e]^{1/2}$. The voltage and current waves in the presence of both forward and backward waves can then be cast in the most general form,

$$\begin{aligned} V(z) &= V_m^+ e^{-j\beta z} + V_m^- e^{+j\beta z}, \\ I(z) &= \frac{1}{Z_c}\{V_m^+ e^{-j\beta z} - V_m^- e^{+j\beta z}\}, \end{aligned} \tag{63}$$

where $V_m^\pm$ are the amplitudes of the forward- and backward-traveling waves. In most applications, the design of a transmission-line circuit can be carried out on the basis of the voltage and current waves, without referring back to the underlying electric and magnetic field distributions. It is also of interest to note that the governing equations (63) resemble those of a plane wave. Thus it is not surprising that many of the techniques we used to analyze plane-wave propagation in a multilayer problem are equally applicable here.

7.2 Quasi-TEM–Mode Transmission Lines

Microstrip line is one of the most common forms of transmission line in microwave integrated circuits because of its broadband nature, and because it is easy to fabricate with

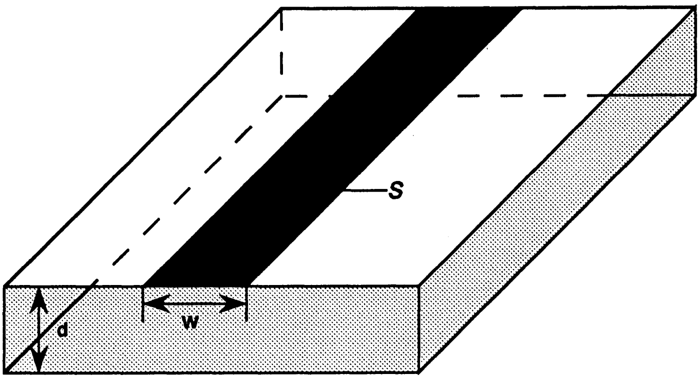

FIG. 16. A microstrip transmission-line structure.

modern integrated- or printed-circuit technology (Hoffmann, 1987). The cross section of such a line is shown in Fig. 16. Basically it consists of a thin metal strip of finite width on a dielectric substrate on a ground plane. The transmission line formed by the strip and its image is of the same type as the two-wire transmission line, and thus would support a TEM mode if the dielectric substrate were replaced by air. However, in the presence of a substrate, a pure TEM mode can no longer exist: It becomes impossible to satisfy the boundary conditions at the air-dielectric interface. However, if both the strip width and substrate thickness are very small compared with a wavelength, a quasi-TEM mode will still exist, whose E_z and H_z are small compared to their transverse counterparts, which are found (at least approximately) from quasistatic solutions in the cross-sectional plane in a manner similar to that for TEM modes.

As for the case of TEM modes, the transverse electric field (which is a static field in x and y) of a quasi-TEM mode can be associated with a capacitance C_e per unit length, and the transverse magnetic field with an inductance L_e per unit length. As these two static fields are completely decoupled, the capacitance depends on the spatial distribution of ϵ, but not of μ; and conversely for the inductance, which is affected by μ and not ϵ. The importance of this observation is that relations (62) do not hold, and therefore $L_eC_e \neq \mu\epsilon$, if $\mu\epsilon$ is not independent of x and y. Nevertheless, within the quasi-TEM approximation, we still have

$$\gamma = j\beta = j\omega(L_eC_e)^{1/2} \text{ and } Z_c = [L_e/C_e]^{1/2}, \quad (64)$$

and thus such transmission lines can still be treated by much the same methods as are used for true TEM lines.

In addition to microstrip, other quasi-TEM structures such as suspended microstrip, slotline, coplanar waveguide, finline, etc., also submit to the same treatment. Figure 17 shows the geometry of some of these structures. Each has its own practical advantages and disadvantages which make it suitable for certain types of application.

GLOSSARY

Brewster Angle: Angle of incidence at which a perpendicularly polarized electromagnetic plane wave will be transmitted through a plane dielectric interface without reflection.

Chiral Medium: A medium in which **D** is proportional to a linear combination of **E** and $\nabla \times \mathbf{E}$, and similarly for **B** and **H**.

Critical Angle: Angle of incidence at which an electromagnetic plane wave will be reflected at a plane dielectric interface without any transmission of power through the interface.

Dispersion: Distortion of a pulsed wave due to a dependence of wave speed on frequency.

Group Velocity: Velocity of the envelope of a modulated wave.

Phase Velocity: Velocity of the phase of the carrier of a modulated plane wave.

Skin Depth: Depth at which a plane wave has decayed in amplitude to e^{-1} of its original value in a lossy medium.

Surface Wave: A wave which is confined close to a surface or surfaces of a waveguiding structure.

Wavelength: Distance between points of a traveling wave whose phases differ by 2π.

INTRODUCTION

In atomic spectroscopy the application of external perturbations such as electric and magnetic fields provides considerable insight into the properties of atoms. In the study of the properties of matter in the solid state of aggregation, spectroscopic techniques have also been crucial in the elucidation of the properties of such systems. In this area we have at our disposal, in addition to the external perturbations mentioned above, a perturbation unique to crystals, namely, the use of uniaxial stresses which alter the symmetry of the environment of the individual atoms in the solid. Furthermore, the presence of microscopic, nonuniform distributions of electric charge and magnetic moments modifies the electronic states of the atoms within the solid.

Free atoms or ions possess the complete rotation-inversion symmetry described by the three-dimensional orthogonal group O(3) (see Koster *et al.*, 1966). This symmetry is reduced by the application of external perturbations or by the electric and magnetic fields present in the solid phase. This article is devoted to a study of the excitation spectra of atoms due to the reduction of their symmetry as mentioned above. In Sec. 1 we deal with the properties of free ions. The paramagnetism of ions with incomplete shells, ordinarily present in the form of compounds, is discussed in Sec. 2. Section 3 is devoted to the effect of the crystal field on the energy-level spectra of atoms, while Sec. 4 deals with the effect of uniaxial stress on shallow impurities in semiconductors. Topics such as the Jahn-Teller effect are outside the scope of this article. Throughout we give a general discussion of the subject with a few illustrative examples. There is a large literature in this field, for the details of which the reader is referred to treatises like those by Abragam and Bleaney (1970) and by

1. QUANTUM MECHANICS OF COMPLEX ATOMS AND IONS

1.1 General Considerations: The Central-Field Approximation

The dynamical properties of an ion containing N electrons in the field of a heavy nucleus of charge Ze are described, in a first approximation, by the nonrelativistic Hamiltonian operator

$$H=\sum_{i=1}^{N}\frac{p_i^2}{2m}-\sum_{i=1}^{N}\frac{Ze^2}{4\pi\epsilon_0 r_i}+\sum_{i<j}\frac{e^2}{4\pi\epsilon_0 r_{ij}}, \quad (1)$$

where r_{ij} is the distance between the ith and jth electrons, r_i is the distance between the ith electron and the nucleus, $-e$ and m are the electric charge and mass of the electron, and ϵ_0 is the permittivity of free space. In this approximation the nucleus is assumed so massive that it can be regarded as at rest.

We note that **L**, the total orbital angular momentum, commutes with H, the latter being invariant under the operations of the rotation-inversion group (see SYMMETRIES AND CONSERVATION LAWS). In addition, since the spin operators of the electrons are absent from H, the total intrinsic spin **S** is, like **L**, a constant of the motion. Thus, H, L^2, S^2, L_z, and S_z, where the latter two are projections of **L** and **S** on an arbitrary axis, $\hat{\mathbf{z}}$, can be simultaneously diagonalized. The energy spectrum of the Hamiltonian (1) cannot be obtained by separation of variables because of the Coulomb interaction between the electrons. We can, however, take their effect into account as a perturbation by introducing an average central potential $V(r)$ and express the Hamiltonian operator as the sum of two terms, H_0 and H_1, where H_0 includes the kinetic energy of the electrons, the Coulomb attraction of the central nucleus, and the central potential $\Sigma_{i=1}^{N}V(r_i)$ for the electrons, and H_1, the effect of the residual Coulomb repulsion between the electrons. The Schrödinger equation for H_0 can now be solved by separation of variables. The one-electron wave functions are of the form

$$\Psi_i(nlm_lm_s)=R_{nl}(r_i)Y_l^{m_l}(\theta_i,\phi_i)\chi_{m_s}^{(i)},$$

where n and l are the principal and angular momentum quantum numbers ($n=1,2,3,\ldots$; $l=0,1,2,\ldots,n-1$); m_l and m_s are the eigenvalues of the projection on $\hat{\mathbf{z}}$ of the orbital and spin angular momenta ($m_l=-l, -l+1, \ldots, l-1, l$; $m_s=\pm 1/2$); r_i, θ_i, and ϕ_i are the polar coordinates of the ith electron, $Y_l^m(\theta,\phi)$ is a spherical harmonic, and $\chi_{m_s}^{(i)}$ is a spin function. The states $|nlm_lm_s\rangle$ are filled in order of increasing energy E_{nl} to form the lowest-energy state of the atom or ion. Often the semiempirical rule stating that the energy eigenvalues occur in the order of increasing $n+l$ is applied. The disposition of the electrons in the one-electron states is called a *configuration.*

We have seen that the eigenstates of the Hamiltonian (1) can be selected so that H, L^2, S^2, L_z, and S_z are simultaneously diagonal so that its levels are labeled by the values of L and S which represent the eigenvalues of the operators **L·L** and **S·S**, namely, $L(L+1)$ and $S(S+1)$, respectively. The states $|nLSM_LM_S\rangle$ have a degeneracy of order $(2L+1)(2S+1)$. These levels are designated by the notations $S,P,D,F,G,H,I,K,L,M,N,\ldots$ corresponding to $L=0,1,2,3,\ldots,10,\ldots$. The multiplicity $2S+1$ is placed as a superindex on the left of this symbol. Thus, a ^2P level corresponds to $L=1$, $S=1/2$. These levels are called *terms.* Group theory cannot tell us what is the order of the terms. An analysis of the configurations on the basis of the central-field approximation complying with the requirement of antisymmetry under exchange of identical particles is necessary.

1.2 The Ground State of Free Ions: Hund's Rules

We consider the nature of the lowest term arising from a given configuration. For example, the configuration of Ne is $(1s)^2(2s)^2(2p)^6$ in its lowest state. We can form only one antisymmetric wave function with this configuration, i.e., only one Slater determinant with the ten orbitals in the configuration. On the other hand, the Si atom has the configuration $(1s)^2(2s)^2(2p)^6(3s)^2(3p)^2$. Including the spin degeneracy, there are six $3p$ orbitals with which one can form 15 Slater determinants constructed with linear combinations of states $(m_{1l},m_{2l},m_{1s},m_{2s})$. They are classified as ^1S, ^3P, and ^1D, showing that the configuration of

Si splits into three *terms* which are onefold, ninefold, and fivefold degenerate, respectively.

We can derive the same result as follows using the irreducible representations $D^{(J)}$ of the group SO(3) (see GROUP THEORY). The combination of the orbital angular momenta gives $D^{(1)} \times D^{(1)} = D^{(0)} \oplus D^{(1)} \oplus D^{(2)}$ while that of the spin states corresponds to $D^{(1/2)} \times D^{(1/2)} = D^{(0)} \oplus D^{(1)}$. The state $L=2$, $M_L=2$ has two electrons in the $m_l=1$ state. Thus, its spin state must be antisymmetric, i.e., it belongs to $D^{(0)}$. Successive application of $L_- = L_x - iL_y$ gives the five states $|L,S,M_L,M_S\rangle$ with $L=2$, $S=0$, $M_L=2,1,0,-1,-2$, and $M_S=0$, forming the ^1D term with symmetric orbitals and antisymmetric spin states. The orbital part of the P states ($L=1$) is orthogonal to the D states with $M_L=1$. Both are linear combinations of $|1,0\rangle = |m_{l1}=1, m_{l2}=0\rangle$ and $|0,1\rangle = |m_{l1}=0, m_{l2}=1\rangle$, namely, $(|1,0\rangle + |0,1\rangle)2^{-1/2}$ and $(|1,0\rangle - |0,1\rangle)2^{-1/2}$. The first, being symmetric, is part of the ^1D term. The second can only be combined with the symmetric spin triplet, giving rise to nine states in a ^3P term. There remains the $L=S=0$ term ^1S.

Two $3d$ electrons $[(3d)^2]$ can be combined in the same way:

$$D^{(2)} \times D^{(2)} = D^{(0)} \oplus D^{(1)} \oplus D^{(2)} \oplus D^{(3)} \oplus D^{(4)}$$

and

$$D^{(1/2)} \times D^{(1/2)} = D^{(0)} \oplus D^{(1)}.$$

This yields the terms ^1S, ^3P, ^1D, ^3F, ^1G. The next task is to find the order of the terms. Their energies are split by the Coulomb repulsion; their order is established using a method due to Slater (1929) which makes use of the invariance of the trace of an operator under unitary transformations. The lowest state obtained by that method can be determined by the following rules known as Hund's rules:

1. The ground-state term has the highest spin multiplicity consistent with the Pauli principle. This rule is a consequence of the Pauli principle because electrons with parallel spins avoid one another.
2. The ground term has the largest possible value of L consistent with 1 and with the Pauli principle.

After the terms (L,S) have been obtained we introduce relativistic corrections to the Hamiltonian. The most important is the spin-orbit interaction; an accurate approximation has the form

$$H_2 = \sum_i \zeta(r_i)\mathbf{l}_i \cdot \mathbf{s}_i, \tag{2}$$

where $\zeta(r_i)$ is a function of the distance of the ith electron from the nucleus. We assume here that $H_2 \ll H_1$, the so-called *L-S* or Russell-Saunders coupling. If $H_2 \gg H_1$, we must form $\mathbf{j}_i = \mathbf{l}_i + \mathbf{s}_i$ and then combine the total angular momenta of the individual electrons (*j-j* coupling). This, and the intermediate case, are important in heavy elements but we shall not deal with them here.

The Hamiltonian $H = H_0 + H_1 + H_2$ is invariant under rotations so that $[H,\mathbf{J}]=0$ where $\mathbf{J} = \mathbf{L} + \mathbf{S} = \Sigma_i(\mathbf{l}_i + \mathbf{s}_i)$ is the *total* angular momentum of the system.

To proceed further we recall the Wigner-Eckart theorem which simplifies the calculation of matrix elements of tensor operators. We express the components of a tensor in such a way that, under rotations, they transform in the same manner as spherical harmonics. A tensor of rank k has components $T_\kappa^{(k)}$ where $\kappa = -k, -k+1, \ldots, k-1, k$. When the components of a tensor are given in this form they are said to be in irreducible form because they generate the irreducible representation $D^{(k)}$ of SO(3). The Wigner-Eckart theorem is applicable to expressions of the matrix elements of irreducible tensor components between states $|njm\rangle$ of J^2 and J_z, where $\mathbf{J}$ is the total angular momentum of the system. The index n collects, in a single symbol, all the other quantum numbers necessary to specify the states. The theorem states that

$$\begin{aligned}\langle n'j'm' | T_\kappa^{(k)} | njm\rangle &= (-1)^{2k}(2j'+1)^{-1/2}\langle n'j' \| T^{(k)} \| nj\rangle \\ &\quad \times \langle jk;j'm' | jk;m\kappa\rangle,\end{aligned} \tag{3}$$

where $\langle jk;j'm' | jk;m\kappa\rangle$ is a Clebsch-Gordan coefficient. The quantity $\langle n'j' \| T^{(k)} \| nj\rangle$ is a number depending only on $n'j'nj$ and k and not on the "angular" variables m', m, and κ. All angular dependence is thus contained in the Clebsch-Gordan coefficient which vanishes if $m' \neq m + \kappa$. For states with $j'=j$, the following special case is a consequence of the Wigner-Eckart theorem:

$$\langle n'jm'|V_\kappa|njm\rangle=\frac{\langle n'jm|\mathbf{V}\cdot\mathbf{J}|njm\rangle}{j(j+1)}\langle njm'|J_\kappa|njm\rangle. \tag{4}$$

Since **V·J** is a scalar, $\langle n'jm|\mathbf{V}\cdot\mathbf{J}|njm\rangle$ is independent of m. This shows that the matrix elements of any vector operator **V** between states $|jm'\rangle$ and $|jm\rangle$ (with all other quantum numbers the same) are proportional to those of **J**. We consider now a given term (L,S) of an atom. Then

$$\begin{aligned}\langle nLSM'_LM'_S|H_2|nLSM_LM_S\rangle&=\sum_i\frac{\langle nLM_L|\zeta(r_i)\mathbf{l}_i\cdot\mathbf{L}|nLM_L\rangle\langle SM_S|\mathbf{s}_i\cdot\mathbf{S}|SM_S\rangle}{L(L+1)S(S+1)}\\&\quad\times\langle LM'_L|\mathbf{L}|LM_L\rangle\cdot\langle SM'_S|\mathbf{S}|SM_S\rangle\\&=\lambda\langle nLSM'_LM'_S|\mathbf{L}\cdot\mathbf{S}|nLSM_LM_S\rangle,\end{aligned} \tag{5}$$

where

$$\lambda=\sum_i\frac{\langle nLM_L|\zeta(r_i)\mathbf{l}_i\cdot\mathbf{L}|nLM_L\rangle\langle SM_S|\mathbf{s}_i\cdot\mathbf{S}|SM_S\rangle}{L(L+1)S(S+1)}. \tag{6}$$

This means that if we consider only one term, H_2 can be replaced by

$$H_2=\lambda\mathbf{L}\cdot\mathbf{S}. \tag{7}$$

The function $\zeta(r)$ is positive for attractive potentials. For a particular choice of configuration, electrons with given values of n and l can be described by the parameter $\zeta(n,l)$ when dealing with the spin-orbit interaction, this parameter being defined by

$$\zeta(n,l)=\int_0^\infty\zeta(r)R^2_{nl}(r)r^2\,dr. \tag{8}$$

Taking $M'_L=M_L$ and $M'_S=M_S$, we have

$$\begin{aligned}&\left\langle nLSM_LM_S\middle|\sum_i\zeta(r_i)\mathbf{l}_i\cdot\mathbf{s}_i\middle|nLSM_LM_S\right\rangle\\&\quad=\langle nLSM_LM_S|\lambda\mathbf{L}\cdot\mathbf{S}|nLSM_LM_S\rangle\\&\quad=\lambda M_LM_S.\end{aligned}$$

We take for $|nLSM_LM_S\rangle$ the single Slater determinant with $M_S=S$. Then

$$\lambda M_LS=\zeta(n,l)\sum_i m_{li}m_{si}.$$

If the shell is less than half-filled, all m_{si} are the same, say, $m_{si}=1/2$ for $M_S=S$, and

$$\lambda=\frac{\zeta(n,l)}{M_LS}\frac{1}{2}\sum_i m_{li}=\frac{\zeta(n,l)}{2S}>0, \tag{9}$$

and the lowest state in the term corresponds to **L·S** negative and having the largest absolute value. When the shell is more than half-filled some of the spins must be reversed so that

$$\begin{aligned}\lambda&=\frac{\zeta(n,l)}{M_LS}\left(\frac{1}{2}\sum_{m_{li}=-l}^{l}m_{li}-\frac{1}{2}M_L\right)\\&=-\frac{\zeta(n,l)}{2S}<0.\end{aligned} \tag{10}$$

This leads to the third Hund rule:

3. The lowest level in a term of an atom is that for which $J=|L-S|$ if the incomplete shell is less than half-full and $J=L+S$ if the shell is more than half-full. Of course, if the shell is exactly half-filled $J=S$.

Once the lowest term has been found, the spin-orbit interaction H_2 splits the $(2L+1)(2S+1)$ degeneracy into states with $J=|L-S|,|L-S|+1,\ldots,L+S-1,L+S$. The additional energies are given by

$$\begin{aligned}E_J&=\langle nLSJM_J|\lambda\mathbf{L}\cdot\mathbf{S}|nLSJM_J\rangle\\&=\frac{\lambda}{2}[J(J+1)-L(L+1)-S(S+1)],\end{aligned} \tag{11}$$

which are, of course, independent of M_J. The separation of these levels is $E_J-E_{J-1}=\lambda J$, a result known as the Landé interval rule.

The Zeeman interaction in a magnetic field **B** is

$$H_Z=\mu_B\mathbf{B}\cdot(\mathbf{L}+g_e\mathbf{S}), \tag{12}$$

where $g_e \approx 2$. By virtue of the Wigner-Eckart theorem in the form given by Eq. (4), the matrix elements of H_Z for states in an atomic level characterized by $|nLSJM_J\rangle$ are

$$\langle nLSJM'_J|H_Z|nLSJM_J\rangle$$
$$=g\mu_B\mathbf{B}\cdot\langle nLSJM'_J|\mathbf{J}|nLSJM_J\rangle, \tag{13}$$

where g, the so-called Landé g factor, depends on the particular level, i.e., on L, S, and J, and is equal to

$$g=\frac{1}{2}(g_e+1)-\frac{1}{2}(g_e-1)\frac{L(L+1)-S(S+1)}{J(J+1)}. \tag{14}$$

For more details on the spectroscopy of atoms, the reader is referred to Condon and Shortley (1953) and to Heckmann and Träbert (1989); see also ATOMIC SPECTROSCOPY.

2. MAGNETIC PROPERTIES OF FREE IONS

2.1 Magnetic Susceptibilities of Free Ions: Theories of Langevin and Brillouin

In the previous section we have described the energy levels of free atoms and ions. In the presence of a magnetic field **B**, each J multiplet is split into $2J+1$ levels with additional energies $g\mu_B BM_J$ ($M_J=-J, -J+1,..., J-1,J$) where g is given by Eq. (14). These energy separations are observed, e.g., in magnetoabsorption experiments (Zeeman effect) and manifest themselves in the phenomenon of paramagnetism. If the energy separation between the lowest and the excited J multiplets is large compared to the Zeeman and thermal energies, the magnetization of an ensemble of N atoms or ions per unit volume is

$$M=Ng\mu_B JB_J\left(\frac{g\mu_B JB}{k_BT}\right), \tag{15}$$

where

$$B_J(x)=\frac{2J+1}{2J}\coth\left(\frac{2J+1}{2J}x\right)-\frac{1}{2J}\coth\left(\frac{x}{2J}\right) \tag{16}$$

is called the Brillouin function. Here J is the quantum number of the total angular momentum in the ground state of the ion and k_B is the Boltzmann constant. At ordinary temperatures and magnetic fields, $g\mu_B JB \ll k_BT$, and the magnetic susceptibility is

$$\chi=N(p\mu_B)^2/3k_BT, \tag{17}$$

where $p=g[J(J+1)]^{1/2}$ is called the effective number of Bohr magnetons. Table 1 gives a set of experimental and calculated values for

Table 1. Rare-earth ions, their ground-state levels, g factors, and calculated and experimental numbers of Bohr magnetons p (after Refs. 7 and 8).

representative rare-earth ions (having incomplete $4f$ shells) obtained at room temperature in several salts of these elements. These are collected from several references [see Van Vleck (1932) and Kittel (1986)]. Table 2 gives similar results for the transition-metal elements of the iron group. In this table values of p calculated with $g\sqrt{J(J+1)}$ and with $2\sqrt{S(S+1)}$ are listed. We note the following trends:

1. For the rare-earth salts there is good agreement between the theoretical and measured values of the susceptibility expressed in terms of p, the effective number of Bohr magnetons, except for Eu and Sm.
2. In the case of transition-metal ions we note that the agreement between the theoretical and experimental numbers of Bohr magnetons is unsatisfactory but there is improved agreement if, instead of using $p=g\sqrt{J(J+1)}$, we use $p=2\sqrt{S(S+1)}$. This suggests that the orbital contribution to the magnetic moment is zero or, as we usually say, that the orbital contribution to the magnetic moment is *quenched.*
3. There is a significant deviation between $p = 2\sqrt{S(S+1)}$ and the experimental value of p for Fe^{2+}, Co^{2+}, Ni^{2+}, and Cu^{2+}. This seems to indicate that there is some contribution to p due to the orbital motion of the electrons in the $3d$ shell.

Item **1** can be understood in terms of the properties of free ions. Items **2** and **3** require for their analysis a study of the effect of the crystal environment on the magnetic atoms. This will be discussed in Sec. 3. In the remainder of this section we discuss the "anomalous" behavior of europium and samarium.

2.2 Van Vleck Paramagnetism: The Behavior of Europium and Samarium

The magnetic properties of Eu^{3+} and Sm^{3+} are understood if we recognize that the splitting of the lowest term by the spin-orbit coupling is small. Consider, for example, Eu^{3+} which has a ^7F ground term. Since the $4f$ shell is less than half-filled the lowest level is $^7F_0$ corresponding to $J=0$. According to the simple theory, Eu^{3+} should be diamagnetic. But measurement of the magnetic susceptibility at room temperature shows that p, the number of effective Bohr magnetons, is 3.5. The ^7F term splits into the levels $^7F_0$, $^7F_1$,...,$^7F_6$ by the spin-orbit interaction $\lambda\mathbf{L}\cdot\mathbf{S}$. All levels, except the lowest, have $g=3/2$ and $\lambda\approx 255$ cm^{-1}.

If we denote the energy states of the atoms by $|n\rangle$ and the probability that the state $|n\rangle$ be occupied at temperature T by p_n (in the absence of an external magnetic field), the linear magnetic susceptibility is

$$\chi=\frac{N\mu_B^2}{k_BT}\left[\sum_n p_n|\langle n|L_z+2S_z|n\rangle|^2 -\left(\sum_n p_n\langle n|L_z+2S_z|n\rangle\right)^2\right]$$

Table 2. Transition-metal ions of the iron group, their ground-state levels, g factors, and calculated and experimental numbers of Bohr magnetons, p (after Refs. 7 and 8).

$$+N\mu_{\mathrm{B}}^{2}\sum_{n\neq n'}\frac{p_{n}-p_{n'}}{E_{n'0}-E_{n0}}|\langle n'|L_{z}+2S_{z}|n\rangle|^{2}$$

$$-\frac{Ne^{2}}{4mc^{2}}\sum_{n}p_{n}\left\langle n\left|\sum_{i}(x_{i}^{2}+y_{i}^{2})\right|n\right\rangle. \quad (18)$$

Here E_{n0} is the energy eigenvalue of the $|n\rangle$ eigenstate in the absence of the Zeeman interaction. The first term in Eq. (18) is the ordinary, temperature-dependent paramagnetic susceptibility; the second, which becomes important at low temperatures, owes its origin to mixing of states by the Zeeman interaction. It is particularly important in ions like Eu^{3+} whose lowest level has zero total angular momentum; at the lowest temperatures it leads to a temperature-independent paramagnetic susceptibility known as Van Vleck paramagnetism. The third term in Eq. (18) is the diamagnetic contribution to the susceptibility. It will be neglected from now on. Another expression for χ, equivalent to Eq. (18), is

$$\chi=\frac{N}{k_{\mathrm{B}}T}\left[\left\langle\left(\frac{\partial E_{n}}{\partial B}\right)^{2}_{B=0}\right\rangle-\left(\left\langle\frac{\partial E_{n}}{\partial B}\right\rangle_{B=0}\right)^{2}\right]$$

$$-N\left\langle\left(\frac{\partial^{2}E_{n}}{\partial B^{2}}\right)_{B=0}\right\rangle, \quad (19)$$

where $E_{n}=E_{n}(B)$ is the energy of the n quantum-mechanical state as a function of the magnetic induction B; the averages are taken over the statistical distribution in zero magnetic field. The term $-N(\partial^{2}E_{n}/\partial B^{2})_{B=0}$ gives the Van Vleck paramagnetism. The results of the calculation of $E_{n}(B)$ to second order in B for Eu^{3+} are given in Table 3 for the three lowest J multiplets. We find

$$\chi=N\mu_{\mathrm{B}}^{2}\left[\frac{8}{\Delta}+\left(\frac{9}{2k_{\mathrm{B}}T}-\frac{1}{2\Delta}\right)e^{-\Delta/k_{\mathrm{B}}T}\right.$$

$$\left.+\left(\frac{45}{2k_{\mathrm{B}}T}-\frac{5}{6\Delta}\right)e^{-3\Delta/k_{\mathrm{B}}T}+\cdots\right]$$

$$\times[1+3e^{-\Delta/k_{\mathrm{B}}T}+5e^{-3\Delta/k_{\mathrm{B}}T}+\cdots]^{-1}, \quad (20)$$

where Δ is the energy separation between the $^{7}F_{1}$ and $^{7}F_{0}$ levels, i.e., $\Delta=\lambda$. Using the experimental value of the spin-orbit interaction, we find $p\approx3.5$ at $T=293$ K, in good agreement with the measurements of the susceptibility. We note that, as the temperature is lowered toward zero, χ approaches $8N\mu_{\mathrm{B}}^{2}/\Delta$.

Table 3. Energies of the low-lying states of Eu^{3+} in an external magnetic field.

J	M_J	Energy
0	0	$-4(\mu_{\mathrm{B}}B)^{2}/\Delta$
1	-1	$\Delta-(3/2)\mu_{\mathrm{B}}B-9(\mu_{\mathrm{B}}B)^{2}/8\Delta$
	0	$\Delta+5(\mu_{\mathrm{B}}B)^{2}/2\Delta$
	1	$\Delta+(3/2)\mu_{\mathrm{B}}B-9(\mu_{\mathrm{B}}B)^{2}/\Delta$
2	-2	$3\Delta-3\mu_{\mathrm{B}}B-10(\mu_{\mathrm{B}}B)^{2}/21\Delta$
	-1	$3\Delta-(3/2)\mu_{\mathrm{B}}B+61(\mu_{\mathrm{B}}B)^{2}/168\Delta$
	0	$3\Delta+9(\mu_{\mathrm{B}}B)^{2}/14\Delta$
	1	$3\Delta+(3/2)\mu_{\mathrm{B}}B+61(\mu_{\mathrm{B}}B)^{2}/168\Delta$
	2	$3\Delta+3\mu_{\mathrm{B}}B-10(\mu_{\mathrm{B}}B)^{2}/21\Delta$

Samarium exhibits a similar anomaly. The ground state of Sm^{3+} is $^{6}H_{5/2}$, which is separated from the next level, $^{6}H_{7/2}$, by $\Delta=(7\lambda/2)=932\ \mathrm{cm}^{-1}$. A calculation for Sm^{3+} similar to that for Eu^{3+} makes use of the energy levels given in Table 4. The magnetic susceptibility is

$$\chi=N\mu_{\mathrm{B}}^{2}\left[\frac{5}{7k_{\mathrm{B}}T}+\frac{60}{7\Delta}+\left(\frac{2704}{189k_{\mathrm{B}}T}\right.\right.$$

$$\left.\left.+\frac{3256}{1701\Delta}\right)e^{-\Delta/k_{\mathrm{B}}T}+\cdots\right]$$

$$\times[3+4e^{-\Delta/k_{\mathrm{B}}T}+\cdots]^{-1}. \quad (21)$$

At $T=293$ K we find $p=1.6$ which compares favorably with the experimental value of 1.5.

3. THE EFFECT OF THE CRYSTAL FIELD ON MAGNETIC ATOMS

3.1 The Crystal Field

We consider an atom or ion in a crystal field. The outer electrons usually form covalent bonds with those of the neighboring atoms and, hence, produce no magnetic effects other than the ubiquitous diamagnetism. However, if the atom has incomplete d or f shells, the electrostatic field produced by the total charge distribution around the ion has significant influence on its magnetic properties. This field, $\Phi(\mathbf{x})$, must satisfy Laplace's equation, and, having no singularities in the region of the ion itself, it is a linear combination of functions of the form $r^{l}Y_{l}^{m}(\theta,\phi)$ where $r=|\mathbf{x}|$ is measured from the center of the ion, and θ, ϕ are the polar angles with respect to a

Table 4. Energies of the low-lying states of Sm^{3+} in an external magnetic field.

J	M_J	Energy
5/2	−5/2	$-(5/7)\mu_B B-45(\mu_B B)^2/49\Delta$
	−3/2	$-(3/7)\mu_B B-75(\mu_B B)^2/49\Delta$
	−1/2	$-(1/7)\mu_B B-90(\mu_B B)^2/49\Delta$
	1/2	$(1/7)\mu_B B-90(\mu_B B)^2/49\Delta$
	3/2	$(3/7)\mu_B B-75(\mu_B B)^2/49\Delta$
	5/2	$(5/7)\mu_B B-45(\mu_B B)^2/49\Delta$
7/2	−7/2	$\Delta-(26/9)\mu_B B-2548(\mu_B B)^2/3645\Delta$
	−5/2	$\Delta-(130/63)\mu_B B-54\,466(\mu_B B)^2/178\,605\Delta$
	−3/2	$\Delta-(26/21)\mu_B B-838(\mu_B B)^2/19\,845\Delta$
	−1/2	$\Delta-(26/63)\mu_B B+3184(\mu_B B)^2/35\,721\Delta$
	1/2	$\Delta+(26/63)\mu_B B+3184(\mu_B B)^2/35\,721\Delta$
	3/2	$\Delta+(26/21)\mu_B B-838(\mu_B B)^2/19\,845\Delta$
	5/2	$\Delta+(130/63)\mu_B B-54\,466(\mu_B B)^2/178\,605\Delta$
	7/2	$\Delta+(26/9)\mu_B B-2548(\mu_B B)^2/3645\Delta$

suitably chosen coordinate system. The Hamiltonian of the ion in question becomes

$$H=H_0+H_1+H_2+H', \tag{22}$$

where

$$H'=-e\sum_i \Phi(\mathbf{x}_i)$$
$$=\sum_i \sum_{l=0}^{\infty} \sum_{m=-l}^{l} A_l^m r_i^l Y_l^m(\theta_i,\phi_i) \tag{23}$$

and H_0, H_1, and H_2 are the central-field approximation Hamiltonian, the Coulomb repulsion between the electrons, and the spin-orbit interaction, respectively. The sum over i extends over all electrons in the atom.

Restrictions on the coefficients A_l^m are imposed by the requirements that H' be real and that it remain invariant under the symmetry operations leaving the site of the ion unchanged. In order for H' to be real, we must have

$$A_l^{-m}=(-1)^m A_l^{m*}. \tag{24}$$

If $\mathbf{x}=0$ is a center of inversion, $\Phi(\mathbf{x})$ must be even in x, y, and z so that only even-l terms appear in its expansion. If the (x,y) plane is a mirror plane, σ_h, then, since $\Phi(\mathbf{x})$ must be invariant under the transformation $z\to z'=-z$ (or $\theta\to\theta'=\pi-\theta$), $A_l^m=0$ unless $l+m$ is even. If the z axis is an n-fold axis of rotational symmetry, then m must be a multiple of n. If the xz plane is a vertical mirror plane, σ_v, since $\Phi(\mathbf{x})$ is invariant under $\theta\to\theta'=\theta$, $\phi\to\phi'=2\pi-\phi$, then $A_l^{-m}=(-1)^m A_l^m$ and A_l^m is real.

The effect of the crystal field on the energy levels depends on the relative importance of H' compared to the remaining terms in the Hamiltonian of the ion. We consider three possible situations:

1. Weak field: $H_1 \gg H_2 \gg H'$. Here H' causes a small splitting of the J multiplets of the ion. The magnetic properties of ions for which this approximation holds are similar to those of the free ions except when $k_B T \lesssim H'$. Many salts of the rare earths behave in this way. These salts contain atoms with incomplete nf shells. The $(n+1)s$ and $(n+1)p$ shells are filled so that the f-shell electrons are partially screened from the outside electrostatic field by the eight electrons in the s and p shells above the incomplete f shell.
2. Intermediate field: $H_1 \gg H' \gg H_2$. In this case H' splits the Russell-Saunders terms. We note that, since H' is independent of the spin, if we disregard H_2, the spin is a constant of the motion. In this case, if the lowest level is nondegenerate, there is no orbital contribution to the magnetic moment of the ion and the material behaves, in a first approximation, as a collection of spins with angular momentum $\mathbf{S}$. This situation often occurs in compounds of the iron group elements which have an incomplete $3d$ shell. The outer $(4s)^2$ electrons participate in the binding of the system, and do not contribute significantly to the screening of the $3d$ shell. This is the reason why H' is usually stronger than the spin-orbit interaction H_2. We say that the orbital

angular momentum **L** is quenched. This result is proved as follows. In the absence of an external magnetic field $[H,T]=0$ where T is the time-reversal operator. If $H\Psi_0 = E_0\Psi_0$ where Ψ_0 is nondegenerate, then $T\Psi_0 = c\Psi_0$ where $|c|=1$. Now

$$\langle T\Psi_0|\mathbf{L}|T\Psi_0\rangle = -\langle\Psi_0|\mathbf{L}|\Psi_0\rangle.$$

But

$$\langle T\Psi_0|\mathbf{L}|T\Psi_0\rangle = c^*c\langle\Psi_0|\mathbf{L}|\Psi_0\rangle = \langle\Psi_0|\mathbf{L}|\Psi_0\rangle$$

so that $\langle\Psi_0|\mathbf{L}|\Psi_0\rangle=0$.

3. Strong field: $H' \gg H_1 \gg H_2$. In this case H' is so strong that the description of the electrons in terms of the central-field approximation breaks down. In a first approximation the electron states are described by quantum numbers appropriate to the crystal potential alone and H_1 and H_2 are treated as perturbations. This situation occurs in the cyanides of elements of the iron group, in many compounds of elements of the palladium and platinum groups, and in some salts of the trans-uranic elements.

3.2 Weak Crystal Field: Salts of the Rare-Earth Elements

We study first case **1**. The ground term of the ion is characterized by L and S and is split by H_2 into several J multiplets with $J=|L-S|,|L-S|+1,\ldots,L+S-1,L+S$. The states corresponding to J generate one of the irreducible representations $D_{\pm}^{(J)}$ of O(3). The group of H' is, in general, a finite subgroup of O(3). The new level scheme is, therefore, obtained by reducing the representation of the group of H' generated by the $2J+1$ states $|JM_J\rangle$.

For example, the symmetry of the Ce^{3+} ion in cerium ethyl sulfate, $Ce(C_2H_5SO_4)_3\cdot 9H_2O$, is $C_{3h}=\bar{6}$. The symmetry elements of this group are

$$C_{3h}=\{E,C_3,C_3^{-1},\sigma_h,\sigma_hC_3,\sigma_hC_3^{-1}\}.$$

It is an Abelian group so that the double group $\bar{C}_{3h}$ has 12 elements and 12 irreducible representations. Since Ce^{3+} contains a single $4f$ electron its levels are classified according to the double-valued representations of $\bar{C}_{3h}$. The reduction of the $D_{-}^{(5/2)}$ representation is $D_{-}^{(5/2)}=\Gamma_7\oplus\Gamma_8\oplus\Gamma_9\oplus\Gamma_{10}\oplus\Gamma_{11}\oplus\Gamma_{12}$. Thus, since the ground state of Ce^{3+} is $^2F_{5/2}$ its ground state splits into three doublets: $\Gamma_7+\Gamma_8$, $\Gamma_9+\Gamma_{10}$, and $\Gamma_{11}+\Gamma_{12}$ corresponding to $M_J=\pm 1/2,\pm 3/2,\pm 5/2$, respectively. We recall that time-reversal invariance requires the double degeneracies of the Kramers doublets $\Gamma_7+\Gamma_8$, $\Gamma_9+\Gamma_{10}$, $\Gamma_{11}+\Gamma_{12}$. To obtain numerical results we must go beyond group theory and make use of perturbation theory. The potential H' can be written as

$$H'=\sum_{l=0}^{\infty}\sum_{m=-l}^{l}A_l^mT_m^{(l)}, \tag{25}$$

where

$$T_m^{(l)}=\sum_i r_i^lY_l^m(\theta_i,\phi_i). \tag{26}$$

The operators $T_m^{(l)}$ for $m=-l,-l+1,\ldots,l-1,l$ are the irreducible components of a tensor operator of rank l. Thus, by virtue of the Wigner-Eckart theorem

$$\langle J'M_J'|T_m^{(l)}|JM_J\rangle=(2J'+1)^{-1/2}\langle J'\|T^{(l)}\|J\rangle \times\langle J,l;J'M_{J'}'|J,l;M_Jm\rangle. \tag{27}$$

But the Clebsch-Gordan coefficient vanishes unless $M_{J'}'=M_J+m$, and l is restricted to the range $|J'-J|,|J'-J|+1,\ldots,J'+J-1,J'+J$. Hence

$$\langle J'M_{J'}'|H'|JM_J\rangle = \sum_{l=|J'-J|}^{J'+J}A_l^{M_{J'}'-M_J}\frac{\langle J'\|T^{(l)}\|J\rangle}{(2J'+1)^{1/2}} \times\langle J,l;J'M_{J'}'|J,l;M_J,M_{J'}'-M_J\rangle. \tag{28}$$

We return now to the example of Ce^{3+} whose lower term is split into $^2F_{5/2}$ and $^2F_{7/2}$ by the spin-orbit interaction. To determine the number of parameters required in the expansion of the potential we recall that m must be a multiple of 3 and that $l+m$ must be even. Thus, we need $A_2^0,A_3^0,A_3^{\pm 3},A_4^0,A_5^{\pm 3},A_6^0,A_6^{\pm 6},\ldots$. Since only terms with l between 1 and 6 appear in the matrix elements we can stop after the list above. If we consider only the lowest term, i.e., if we neglect hybridization with terms above ^2F, there is an additional simplification. In fact, the relevant matrix elements of $T_m^{(l)}$ are between $4f$ states which have negative parity. Thus, only terms with l

even yield nonvanishing matrix elements. Further, $A_l^{-m}=(-1)^m A_l^{m*}$. By taking the $\Phi=0$ fiducial line in a suitable way we can require $A_6^6 = A_6^{-6}$ to be real. Thus

$$\begin{aligned}\Phi(\mathbf{x}) &= A_2^0 r^2 Y_2^0(\theta,\phi) + A_4^0 r^4 Y_4^0(\theta,\phi)\\ &\quad + A_6^0 r^6 Y_6^0(\theta,\phi)\\ &\quad + A_6^6 r^6 [Y_6^6(\theta,\phi) + Y_6^{-6}(\theta,\phi)] + \cdots, \qquad (29)\end{aligned}$$

where the additional terms give zero contributions to the matrix elements of H'. Experimentally, it is known that the separation of $^2F_{7/2}$ from $^2F_{5/2}$ is of order 2000 cm^{-1} while the effect of H' is about 200 cm^{-1}. Thus, in a first approximation we will consider only $J'=J$ matrix elements. Since $2J=5$, we can disregard the A_6^0 and A_6^6 contributions to $\Phi(\mathbf{x})$. Thus we use

$$\Phi(\mathbf{x}) = B_2^0(3z^2-r^2) + B_4^0(35z^4-30r^2z^2+3r^4) + \cdots \qquad (30)$$

with

$$B_2^0 = A_2^0(5/16\pi)^{1/2}, \quad B_4^0 = A_4^0(3/16\sqrt{\pi}). \qquad (31)$$

Since we are dealing here with a single $4f$ electron it is possible to calculate in a simple way the matrix elements of Φ between the $4f$ states. We can describe the states of the ion by Slater determinants with all levels filled. The several states differ only in the particular $4f$ eigenfunction that appears in each. In the diagonal matrix elements the contributions of the filled shells give zero so that we finally have an integral over the position of the $4f$ electron. But this procedure becomes more complicated with the configurations $(4f)^n$ for $n=2,3,\ldots$ so that we use a more powerful approach developed by Stevens (1952) and reviewed by Hutchings (1964) called the method of "operator equivalents." This method is based on the Wigner-Eckart theorem already stated in Eq. (3).

3.3 The Method of Operator Equivalents

The matrix element of $T_\kappa^{(k)}$, the κ-irreducible component of a tensor of rank k, between two states $|njm\rangle$ and $|njm'\rangle$ having the same angular momentum j is given in Eq. (3) with $n'=n$ and $j'=j$. Suppose now that a second irreducible component of a tensor of rank k, $O_\kappa^{(k)}$, has matrix elements which are easier to calculate than those of $T^{(k)}$. Those are again proportional to the same Clebsch-Gordan coefficient as for $T_\kappa^{(k)}$. Thus, the matrix elements of $T_\kappa^{(k)}$ are simply proportional to those of $O_\kappa^{(k)}$, the constant of proportionality being independent of m, m', and κ. We form operators $O_\kappa^{(k)}$ by taking combinations of powers of degree k of components of $\mathbf{J}$ with zero trace. The operator equivalent of $3z^2-r^2=2z^2-x^2-y^2$ is, clearly, $3J_z^2 - \mathbf{J}\cdot\mathbf{J} = 2J_z^2 - J_x^2 - J_y^2$. For more complicated operators we must write the powers of J_x, J_y, J_z in a completely symmetrical fashion. For example, the operator equivalent to

$$\sum_i (35z_i^4 - 30z_i^2r_i^2 + 3r_i^4)$$

is obtained by writing

$$\begin{aligned}35z^4-30z^2r^2+3r^4 &= 35z^4-30z^2(x^2+y^2+z^2)\\ &\quad +3(x^4+y^4+z^4+2y^2z^2\\ &\quad +2z^2x^2+2x^2y^2).\end{aligned}$$

The operator equivalents to x^4, y^4, and z^4 are, simply, J_x^4, J_y^4, and J_z^4, respectively. The operator equivalent of x^2y^2 is

$$\begin{aligned}&\tfrac{1}{6}(J_x^2J_y^2 + J_y^2J_x^2 + J_xJ_yJ_xJ_y + J_yJ_xJ_yJ_x + J_xJ_y^2J_x\\ &\quad + J_yJ_x^2J_y) = \tfrac{1}{6}(3J_x^2J_y^2 + 3J_y^2J_x^2 - 2\mathbf{J}\cdot\mathbf{J} + 5J_z^2).\end{aligned}$$

From these results we conclude that

$$\begin{aligned}O_0^{(4)} &= 35J_z^4 - 30J(J+1)J_z^2 + 25J_z^2 - 6J(J+1)\\ &\quad + 3J^2(J+1)^2. \qquad (32)\end{aligned}$$

Therefore,

$$\begin{aligned}&\left\langle JM_J' \middle| \sum_i (3z_i^2 - r_i^2) \middle| JM_J \right\rangle\\ &\quad = a\langle JM_J' | 3J_z^2 - \mathbf{J}\cdot\mathbf{J} | JM_J\rangle\\ &\quad = a[3M_J^2 - J(J+1)]\delta_{M_JM_J'} \qquad (33)\end{aligned}$$

and

$$\begin{aligned}&\left\langle JM_J' \middle| \sum_i (35z_i^4 - 30z_i^2r_i^2 + 3r_i^4) \middle| JM_J \right\rangle\\ &\quad = b\langle JM_J' | O_0^{(4)} | JM_J\rangle\\ &\quad = b[35M_J^4 - 30J(J+1)M_J^2 + 25M_J^2\\ &\qquad - 6J(J+1) + 3J^2(J+1)^2]\delta_{M_JM_J'}, \qquad (34)\end{aligned}$$

where a and b are appropriate numerical coefficients. In this approximation, the shifts in the energy levels are

$$\begin{aligned} \Delta E_{\pm 1/2} &= -8aB_2^0 + 120bB_4^0, \\ \Delta E_{\pm 3/2} &= -2aB_2^0 - 180bB_4^0, \\ \Delta E_{\pm 5/2} &= 10aB_2^0 + 60bB_4^0. \end{aligned} \tag{35}$$

The coefficients B_2^0 and B_4^0 are simply related to A_2^0 and A_4^0. The latter can be calculated accurately for ionic crystals and for crystals in which the electron density is known as a function of position. The parameters a and b are determined using the radial wave function $R(r)$ of the $4f$ electron. We find

$$a = -\tfrac{2}{35}\,\overline{r^2}, \quad \overline{r^2} = \int_0^\infty R^2(r) r^4 \, dr, \tag{36}$$

and

$$b = \tfrac{1}{60}\,\tfrac{8}{21}\,\overline{r^4}, \quad \overline{r^4} = \int_0^\infty R^2(r) r^6 \, dr. \tag{37}$$

3.4 Crystal Field of Intermediate Strength: The Spin-Hamiltonian Formalism

The study of case **2** requires the introduction of the so-called *spin-Hamiltonian* formalism (Pryce, 1950; Abragam and Pryce, 1951). It is applicable when $H_1 \gg H' \gg H_2$. We suppose that we have obtained the solution of the Schrödinger equation of the ion in the crystal field without spin-orbit interaction, i.e.,

$$(H_0 + H_1 + H') \, |nr\rangle = E_n \, |nr\rangle. \tag{38}$$

The label n denotes the orbital levels and $r = 1,2,\ldots,l_n$, the different orthonormal states with energy E_n. We note that, since $H_0 + H_1 + H'$ does not contain the spin operator, $\mathbf{S}$ is a constant of the motion. Taking account of the spin, the states are $|nrM_S\rangle$ having degeneracy $l_n(2S+1)$. The ground state is denoted by $n=0$. We introduce now the spin-orbit interaction H_2 in the form $\lambda\mathbf{L}\cdot\mathbf{S}$ appropriate to the case in which a single term is taken into account. For additional generality we assume that a magnetic field of induction $\mathbf{B}$ has been applied. Thus the perturbation on the level E_n characterized by the multiplet $\{|nrM_S\rangle\}$ is

$$H'' = \lambda\mathbf{L}\cdot\mathbf{S} + \mu_B \mathbf{B}\cdot(\mathbf{L} + 2\mathbf{S}). \tag{39}$$

The splittings are obtained to second order in H'' by diagonalizing a matrix whose elements are

$$\begin{aligned} \langle r'M'_S|H_S|rM_S\rangle &= \lambda\langle nr'|\mathbf{L}|nr\rangle\cdot\langle M'_S|\mathbf{S}|M_S\rangle + \mu_B\mathbf{B}\cdot(\delta_{M'_S M_S}\langle nr'|\mathbf{L}|nr\rangle + 2\delta_{r'r}\langle M'_S|\mathbf{S}|M_S\rangle) \\ &\quad + \sum_{n'r''M''_s}{}' \frac{\langle nr'M'_S|H''|n'r''M''_S\rangle\langle n'r''M''_S|H''|nrM_S\rangle}{E_n - E_{n'}} + \cdots. \end{aligned} \tag{40}$$

Here the prime means that the sum extends over all n' except $n'=n$. The matrix elements of H'' are of the form

$$\begin{aligned} &\langle n'r''M''_S|H''|nrM_S\rangle \\ &\quad = \lambda\langle n'r''|\mathbf{L}|nr\rangle\cdot\langle M''_S|\mathbf{S}|M_S\rangle + \mu_B\mathbf{B}\cdot\langle n'r''|\mathbf{L}|nr\rangle\delta_{M''_S M_S}. \end{aligned} \tag{41}$$

The term in $\mathbf{S}$ drops out because of the orthogonality of $|nr\rangle$ and $|n'r''\rangle$ for $n' \neq n$. The second-order contribution to $\langle r'M'_S|H_S|rM_S\rangle$ is $(i,j = x,y,z)$

$$\begin{aligned} &\sum_{ij}\sum_{n'}{}' \frac{1}{E_n - E_{n'}} \sum_{r''M''_S} (\lambda\langle nr'|L_i|n'r''\rangle\langle M'_S|S_i|M''_S\rangle \\ &\quad + \mu_B B_i\langle nr'|L_i|n'r''\rangle\delta_{M'_S M''_S})(\lambda\langle n'r''|L_j|nr\rangle\langle M''_S|S_j|M_S\rangle + \mu_B B_j\langle n'r''|L_j|nr\rangle\delta_{M''_S M_S}). \end{aligned} \tag{42}$$

We note that the sum over M''_S can be carried out:

$$\sum_{M''_S} \langle M'_S|S_i|M''_S\rangle\langle M''_S|S_j|M_S\rangle = \langle M'_S|S_iS_j|M_S\rangle. \tag{43}$$

For each orbital level we define a matrix of dimension l_n by means of the equation

$$\langle r'|D_{ij}^{(n)}|r\rangle=\lambda^2 \sum_{n'}{}' \sum_{r''} \frac{\langle nr'|L_i|n'r''\rangle\langle n'r''|L_j|nr\rangle}{E_n-E_{n'}}. \tag{44}$$

The second-order contribution to H_S is, therefore,

$$\begin{aligned}&\langle r'M'_S|H_S|rM_S\rangle_2\\ &=\sum_{ij}\langle r'|D_{ij}^{(n)}|r\rangle(\langle M'_S|S_iS_j|M_S\rangle\\ &\quad+(\mu_B/\lambda)\langle M'_S|S_iB_j+S_jB_i|M_S\rangle\\ &\quad+(\mu_B/\lambda)^2B_iB_j\delta_{M'_SM_S}).\end{aligned} \tag{45}$$

Then, if we denote the matrix $D_{ij}^{(n)}$ simply by this symbol and $\langle nr'|\mathbf{L}|nr\rangle$ by $\mathbf{M}$ we can write

$$\begin{aligned}H_S=&\lambda\mathbf{M}\cdot\mathbf{S}+\mu_B\mathbf{B}\cdot(\mathbf{M}+2\mathbf{S})+\sum_{ij}D_{ij}^{(n)}S_iS_j\\ &+(\mu_B/\lambda)\sum_{ij}(D_{ij}^{(n)}+D_{ji}^{(n)})S_iB_j\\ &+(\mu_B/\lambda)^2\sum_{ij}D_{ij}^{(n)}B_iB_j.\end{aligned} \tag{46}$$

The last term is understood as the direct product of $D_{ij}^{(n)}$ by the unit matrix of dimension $(2S+1)$. For an orbital nondegenerate level, $\mathbf{M}=0$ so that

$$\begin{aligned}H_S=&2\mu_B\mathbf{B}\cdot\mathbf{S}+\sum_{ij}D_{ij}S_iS_j\\ &+(\mu_B/\lambda)\sum_{ij}(D_{ij}+D_{ji})S_iB_j\\ &+(\mu_B/\lambda)^2\sum_{ij}D_{ij}B_iB_j,\end{aligned} \tag{47}$$

where

$$D_{ij}=\lambda^2\sum_{n',r'}{}'\frac{\langle n|L_i|n'r'\rangle\langle n'r'|L_j|n\rangle}{E_n-E_{n'}} \tag{48}$$

is a number for each set of indices i, j. The spin Hamiltonian is often written as

$$\begin{aligned}H_S=&\sum_{ij}D_{ij}S_iS_j+\mu_B\sum_{ij}g_{ij}S_iB_j\\ &+(\mu_B/\lambda)^2\sum_{ij}D_{ij}B_iB_j,\end{aligned} \tag{49}$$

where

$$g_{ij}=2\delta_{ij}+(D_{ij}+D_{ji})/\lambda. \tag{50}$$

3.5 $\mathbf{Fe^{2+}}$ in a Tetrahedral Environment

We consider, as an example, the energy-level splitting of the ^5D term of Fe^{2+} in a crystal environment of symmetry T_d. These results were first obtained by Slack *et al.* (1969) using a procedure different from that given here following the method of Villeret *et al.* (1990a,b). The lowest configuration of Fe^{2+} is $(3d)^6$. The ion has, therefore, an even number of electrons so that its energy levels are classified according to the single-valued representations of $\overline{T}_d$. The crystal potential H' is of the form

$$\begin{aligned}H'=&A_3\sum_i x_iy_iz_i\\ &-A_4\sum_i(x_i^4+y_i^4+z_i^4-\tfrac{3}{5}r_i^4)+\cdots.\end{aligned} \tag{51}$$

A constant term has been omitted since it shifts all the energy levels by the same amount. The term in xyz gives zero matrix elements between the even $3d$ states. There remains the contribution containing fourth powers of the coordinates. Its operator equivalent is

$$\begin{aligned}O^{(4)}=&\tfrac{1}{8}(L_+^2+L_-^2)^2+\tfrac{3}{2}L_z^4-L(L+1)L_z^2\\ &-\tfrac{1}{10}L^2(L+1)^2+\tfrac{1}{5}L(L+1).\end{aligned} \tag{52}$$

The constant before the potential we denote by $\pm a$ $(a>0)$. If the configuration $(3d)^n$ is more than half-full $(n>5)$

$$H'=\pm aO^{(4)}, \tag{53}$$

and we take the positive sign for n odd and the negative sign for n even. For $n<5$ the opposite choice must be made. Thus for Fe^{2+}: $(3d)^6$,

$$H'=-a[\tfrac{1}{8}(L_+^2+L_-^2)^2+\tfrac{3}{2}L_z^4-6L_z^2-\tfrac{12}{5}]. \tag{54}$$

The states of H_0+H_1 which include the central-field Hamiltonian and the Coulomb repulsion between the electrons (H_1) can be characterized by $|M_L\rangle$, $M_L=2,1,0,-1,-2$, with $L_z|M_L\rangle=M_L|M_L\rangle$. These states generate the representation $D_+^{(2)}$ of O(3). The level splitting is obtained, reducing this representation when these functions generate a representation of

T_d. We obtain $D_+^{(2)} = \Gamma_3 + \Gamma_5$. This result can be deduced directly because the states $|M_L\rangle$ transform under the operations of SO(3) as the spherical harmonics $Y_L^{M_L}(\theta,\phi)$ with $L=2$. The combinations of the states $|M_L\rangle$ which belong to Γ_3 and Γ_5 will be denoted by

$$\begin{aligned}\Gamma_3:&\quad u_1=|0\rangle,\quad u_2=2^{-1/2}(|2\rangle+|-2\rangle),\\ \Gamma_5:&\quad v_+=|-1\rangle,\\ &\quad v_0=2^{-1/2}(|2\rangle-|-2\rangle);\quad v_-=-|1\rangle.\end{aligned}\tag{55}$$

We find the splitting between the Γ_3 and Γ_5 levels by taking the expectation value of H' for one state from each irreducible representation. They are $-18a/5$ for Γ_3 and $12a/5$ for Γ_5. Thus, the separation between the levels is $\Delta=6a$. We now obtain the spin Hamiltonian for the orbital Γ_3 level. We recall that $S=2$ so that the spin quantum number takes the values $M_S=2,1,0,-1,-2$. The orbital Γ_3 level is twofold degenerate. Thus, the spin Hamiltonian is tenfold dimensional. It is, however, preferable to write the complete 25×25 matrix which includes also the Γ_5 orbital levels. We note that the matrix elements of $\mathbf{L}$ in the states u_1 and u_2 vanish. We need to obtain the matrix elements of H'' in the 25 states ${}^5\Gamma_3+{}^5\Gamma_5$ written in the order $|u_i,M_S\rangle$, $|v_\kappa,M_S\rangle$; $i=1,2$; $\kappa=+,0,-$; $M_S=2,1,0,-1,-2$. The appropriate spin Hamiltonian is

$$H_S=\begin{pmatrix}2\mu_B\mathbf{B}\cdot\mathbf{S} & \mathbf{U}\cdot(\lambda\mathbf{S}+\mu_B\mathbf{B})\\ \mathbf{U}^\dagger\cdot(\lambda\mathbf{S}+\mu_B\mathbf{B}) & \Delta-\lambda\mathbf{I}\cdot\mathbf{S}+\mu_B\mathbf{B}\cdot(2\mathbf{S}-\mathbf{I})\end{pmatrix},\tag{56}$$

where $\mathbf{U}$ is a 2×3 matrix whose elements are those of the angular momentum operator between the states u_i and v_κ ($i=1,2$; $\kappa=+,0,-$) and $\mathbf{I}$ is the matrix whose elements are $-\langle v_{\kappa'}|\mathbf{L}|v_\kappa\rangle$. Its components are identical to the angular momentum matrices for $I=1$. The matrix $\mathbf{U}$ is

$$\mathbf{U}=\begin{pmatrix}(\frac{3}{2})^{1/2}(\hat{\mathbf{x}}-\hat{\imath}\hat{\mathbf{y}}) & 0 & -(\frac{3}{2})^{1/2}(\hat{\mathbf{x}}+\hat{\imath}\hat{\mathbf{y}})\\ 2^{-1/2}(\hat{\mathbf{x}}+\hat{\imath}\hat{\mathbf{y}}) & 2\hat{\mathbf{z}} & -2^{-1/2}(\hat{\mathbf{x}}-i\,\hat{\mathbf{y}})\end{pmatrix}.\tag{57}$$

Thus the Hamiltonian is a supermatrix with diagonal blocks of dimensions 10 and 15 and off-diagonal rectangular matrices.

The Schrödinger equation

$$H_S\begin{pmatrix}\psi_3\\ \psi_5\end{pmatrix}=E\begin{pmatrix}\psi_3\\ \psi_5\end{pmatrix},\tag{58}$$

where ψ_3 and ψ_5 have 10 and 15 components, respectively, is equivalent to the coupled relations

$$2\mu_B\mathbf{B}\cdot\mathbf{S}\psi_3+\mathbf{U}\cdot(\lambda\mathbf{S}+\mu_B\mathbf{B})\psi_5=E\psi_3\tag{59}$$

and

$$\mathbf{U}^\dagger\cdot(\lambda\mathbf{S}+\mu_B\mathbf{B})\psi_3+[\Delta+2\mu_B\mathbf{B}\cdot\mathbf{S}-\mathbf{I}\cdot(\lambda\mathbf{S}+\mu_B\mathbf{B})]\psi_5=E\psi_5.\tag{60}$$

Eliminating ψ_5, we find

$$\begin{aligned}&[2\mu_B\mathbf{B}\cdot\mathbf{S}-(\lambda\mathbf{S}+\mu_B\mathbf{B})\cdot\mathbf{U}\\ &\times\{\Delta-E+2\mu_B\mathbf{B}\cdot\mathbf{S}-\mathbf{I}\cdot(\lambda\mathbf{S}+\mu_B\mathbf{B})\}^{-1}\mathbf{U}^\dagger\cdot(\lambda\mathbf{S}\\ &+\mu_B\mathbf{B})]\psi_3=E\psi_3.\end{aligned}\tag{61}$$

We now solve this equation by iteration assuming $\Delta \gg \overline{H''}$. We obtain

$$\begin{aligned}&\Big(-\frac{\lambda^2}{\Delta}\mathbf{S}\cdot\mathbf{U}\mathbf{U}^\dagger\cdot\mathbf{S}+2\mu_B\mathbf{B}\cdot\mathbf{S}\\ &-\frac{\lambda\mu_B}{\Delta}(\mathbf{S}\cdot\mathbf{U}\mathbf{U}^\dagger\cdot\mathbf{B}+\mathbf{B}\cdot\mathbf{U}\mathbf{U}^\dagger\cdot\mathbf{S})\\ &-\frac{\mu_B^2}{\Delta}\mathbf{B}\cdot\mathbf{U}\mathbf{U}^\dagger\cdot\mathbf{B}\Big)\psi_3=E\psi_3.\end{aligned}\tag{62}$$

Consider first $H_{S,3}^{(0)}$, the term in $H_{S,3}$ independent of $\mathbf{B}$. It is

$$\begin{aligned}H_{S,3}^{(0)}&=-\frac{\lambda^2}{\Delta}\mathbf{S}\cdot\mathbf{U}\mathbf{U}^\dagger\cdot\mathbf{S}\\ &=-\frac{\lambda^2}{\Delta}\begin{pmatrix}3(\mathbf{S}\cdot\mathbf{S}-S_z^2) & \sqrt{3}(S_x^2-S_y^2)\\ \sqrt{3}(S_x^2-S_y^2) & \mathbf{S}\cdot\mathbf{S}+3S_z^2\end{pmatrix}.\end{aligned}\tag{63}$$

The terms linear and quadratic in $\mathbf{B}$ are

$$H_{S,3}^{(1)}=2\mu_B\begin{pmatrix}\mathbf{B}\cdot\mathbf{S}-\frac{3\lambda}{\Delta}(\mathbf{S}\cdot\mathbf{B}-S_zB_z) & -\sqrt{3}\frac{\lambda}{\Delta}(S_xB_x-S_yB_y)\\ -\sqrt{3}\,\frac{\lambda}{\Delta}(S_xB_x-S_yB_y) & \mathbf{B}\cdot\mathbf{S}-\frac{\lambda}{\Delta}(\mathbf{S}\cdot\mathbf{B}+3S_zB_z)\end{pmatrix}\tag{64}$$

and

$$H_{S,3}^{(2)}=-\frac{\mu_B^2}{\Delta}\begin{pmatrix} 3(B^2-B_z^2) & \sqrt{3}(B_x^2-B_y^2) \\ \sqrt{3}(B_x^2-B_y^2) & B^2+3B_z^2 \end{pmatrix}, \qquad (65)$$

respectively. The operator $H_{S,3}^{(0)}$ can be rewritten in the form

$$H_{S,3}^{(0)}=-\frac{2\lambda^2}{\Delta}S(S+1)-\frac{\lambda^2}{\Delta}\Omega, \qquad (66)$$

where

$$\Omega=(\mathbf{S}\cdot\mathbf{S}-3S_z^2)\sigma_z+\tfrac{1}{2}\sqrt{3}(S_+^2+S_-^2)\sigma_x. \qquad (67)$$

We denote the states $|u_1,M_S\rangle$ by $|M_S^+\rangle$ and $|u_2,M_S\rangle$ by $|M_S^-\rangle$ and $\sigma_z u_1 = u_1$, $\sigma_z u_2 = -u_2$, $\sigma_x u_1 = u_2$, $\sigma_x u_2 = u_1$. This means that the state $|2^+\rangle$ has nonvanishing matrix elements only with itself and with $|0^-\rangle$. But $|0^-\rangle$ is connected by Ω with itself and with $|-2^+\rangle$. Thus, after similar considerations, the matrix of Ω can be written in block form with two submatrices of dimension three and two of dimension two. The diagonalization of Ω is a trivial exercise. The eigenvectors and eigenvalues of $H_{S,3}^{(0)}$ are

$$-\frac{24\lambda^2}{\Delta}:\quad \frac{1}{2}(|2^-\rangle+\sqrt{2}|0^+\rangle+|-2^-\rangle) \quad (\Gamma_1),$$

$$-\frac{18\lambda^2}{\Delta}:\quad \begin{cases} \frac{1}{\sqrt{2}}(|2^-\rangle-|-2^-\rangle) \\ \frac{1}{2}(\sqrt{3}|1^+\rangle+|-1^-\rangle) \quad (\Gamma_4), \\ \frac{1}{2}(|1^-\rangle+\sqrt{3}|-1^+\rangle) \end{cases}$$

$$-\frac{12\lambda^2}{\Delta}:\quad \begin{cases} \frac{1}{2}(|2^+\rangle+\sqrt{2}|0^-\rangle+|-2^+\rangle) \\ \frac{1}{2}(|2^-\rangle-\sqrt{2}|0^+\rangle+|-2^-\rangle) \end{cases} \quad (\Gamma_3),$$

$$-\frac{6\lambda^2}{\Delta}:\quad \begin{cases} \frac{1}{\sqrt{2}}(|2^+\rangle-|-2^+\rangle) \\ \frac{1}{2}(|1^+\rangle-\sqrt{3}|-1^-\rangle) \quad (\Gamma_5), \\ \frac{1}{2}(\sqrt{3}|1^-\rangle-|-1^+\rangle) \end{cases}$$

$$0:\quad \frac{1}{2}(|2^+\rangle-\sqrt{2}|0^-\rangle+|-2^+\rangle) \quad (\Gamma_2).$$

These ten states belong to $\Gamma_3\times(\Gamma_3\oplus\Gamma_5) = \Gamma_1\oplus\Gamma_2\oplus\Gamma_3\oplus\Gamma_4\oplus\Gamma_5$ since the states $|M_S\rangle$ belong to $D_+^{(2)} \to \Gamma_3\oplus\Gamma_5$.

Using these wave functions, assuming that $6\lambda^2/\Delta \gg \mu_B B$, we regard $H_{S,3}^{(1)}$ and $H_{S,3}^{(2)}$ as perturbations. We obtain, in this way, the different energy eigenvalues. We quote here only the value for the lowest level, Γ_1:

$$E_{\Gamma_1}=-\frac{24\lambda^2}{\Delta}-\frac{4\Delta(\mu_B B)^2}{3\lambda^2}-\frac{2(\mu_B B)^2}{\Delta}.$$

The remaining eigenvalues are obtained in a straightforward way. Thus, at 0 K, the magnetic susceptibility is

$$\chi\cong\frac{N\mu_B^2}{3}\frac{8\Delta}{\lambda^2}. \qquad (68)$$

For Fe^{2+} in CdTe, this is equivalent to $\chi = N\mu_B^2/3k_B T_{\text{eff}}$ with $T_{\text{eff}}=0.6$ K. A more accurate calculation gives

$$\chi=\frac{N\mu_B^2}{3}\frac{8\Delta}{\lambda^2}\left(1+\frac{13|\lambda|}{\Delta}+100\frac{\lambda^2}{\Delta^2}+\cdots\right). \qquad (69)$$

3.6 Co^{2+} in a Tetrahedral Field

As a second example we consider Co^{2+} in a T_d environment. The ground-state configuration is $(3d)^7$ so that, according to Hund's rules, the lowest term is ^4F. An orbital F state generates the representation $D_+^{(3)}$ of SO(3) which reduces to $\Gamma_2\oplus\Gamma_4\oplus\Gamma_5$ of T_d. The crystal potential is

$$H'=a[\tfrac{1}{8}(L_+^2+L_-^2)^2+\tfrac{3}{2}L_z^4-12L_z^2-12] \qquad (70)$$

with $a>0$. The reduction of $D_+^{(3)}$ can be carried out in a variety of ways. The most convenient one for our purposes is to note that the states $|M_L\rangle$ with $M_L=3,2,1,0,-1,-2,-3$ transform according to the representation $D_+^{(3)}$ of O(3). Thus, they transform as the f levels of a single electron except that the parity of $|M_L\rangle$ is positive since they are formed by combinations of $3d$ states.

The reduction of $D_+^{(3)}$ is given by the following states:

$$\beta=2^{-1/2}(|2\rangle-|-2\rangle),\quad \Gamma_2$$

$$\left.\begin{array}{l}\epsilon_+=(\tfrac{5}{8})^{1/2}|-1\rangle-(\tfrac{3}{8})^{1/2}|3\rangle,\\ \epsilon_0=2^{-1/2}(|2\rangle+|-2\rangle),\\ \epsilon_-=(\tfrac{5}{8})^{1/2}|1\rangle-(\tfrac{3}{8})^{1/2}|-3\rangle,\end{array}\right\}\Gamma_5$$

$$\left.\begin{array}{l}\delta_+=-(\tfrac{3}{8})^{1/2}|1-(\tfrac{5}{8})^{1/2}|-3,\\ \delta_0=|0,\\ \delta_-=-(\tfrac{3}{8})^{1/2}|-1-(\tfrac{5}{8})^{1/2}|3;\end{array}\right\}\Gamma_4$$

The energy eigenvalues can now be calculated using these wave functions and the expression for H'. We find

$$E_{\Gamma_5}-E_{\Gamma_2}=\Delta=30a, \tag{71}$$

and

$$E_{\Gamma_4}-E_{\Gamma_2}=9\Delta/5=54a. \tag{72}$$

Since here the orbital ground state is nondegenerate, the spin Hamiltonian for the lowest state $\Gamma_2\times\Gamma_8=\Gamma_8$ is simply given by Eqs. (49) and (50) with

$$D_{ij}=\lambda^2\sum_{nr}{}' \frac{\langle 0|L_i|nr\rangle\langle nr|L_j|0\rangle}{E_0-E_n}. \tag{73}$$

The sum over nr is over all states other than $|0\rangle$ including all degenerate orbital states. But D_{ij} is a second-rank tensor with symmetry T_d so that $D_{xx}=D_{yy}=D_{zz}=D$, and $D_{ij}=0$ if $i\neq j$. Thus

$$D=\lambda^2\sum_{nr}{}' \frac{|\langle nr|L_z|0\rangle|^2}{E_0-E_n}. \tag{74}$$

The ground (orbital) state is β and $L_z|\beta\rangle=2\epsilon_0$ so that $\langle\epsilon_0|L_z|\beta\rangle=2$ and, neglecting higher terms,

$$D=-4\lambda^2/\Delta. \tag{75}$$

Thus

$$H_S=-\frac{15\lambda^2}{\Delta}+g\mu_B\mathbf{B}\cdot\mathbf{S}-\frac{4\mu_B^2}{\Delta}B^2 \tag{76}$$

with

$$g=2-8\lambda/\Delta. \tag{77}$$

These examples suffice to explain the procedures for the calculation of the energy eigenvalues and g factors of the low-lying levels of magnetic ions in crystals. The analysis is often simplified by introducing the operator

$$\mathbf{F}=\mathbf{M}+\mathbf{S}, \tag{78}$$

where $\mathbf{M}$ is defined in Eq. (46). The operator $\mathbf{M}$ has the same commutation rules as any angular momentum operator and the common eigenvectors of $\mathbf{F}\cdot\mathbf{F}$ and F_z are found by the usual rules of composition of angular momenta.

4. ENERGY-LEVEL SPLITTINGS IN CRYSTALS UNDER EXTERNAL STRESS

4.1 Deformation Potentials of Band Extrema in Semiconductors

We consider the energy shifts under stress of orbitally nondegenerate states of tetrahedrally coordinated elemental and compound semiconductors. These considerations are applicable to a large number of similar materials. We recall that, by virtue of Kramers's theorem, the Bloch states of electrons in a crystal always possess an evenfold degeneracy. The main consequence of this theorem is that a state at wave vector **k** is degenerate with one at $-\mathbf{k}$, their spin states being orthogonal. However, if the crystal has a center of inversion there is a spin degeneracy for each value of **k**. Thus, in Si and Ge the Bloch states have twofold and fourfold degeneracies at each point in the Brillouin zone. Application of stress cannot remove the twofold degeneracy but will, in general, split the quadruplet levels into two doublets.

We first discuss the energy shifts of the electronic levels at the extrema of the conduction band of the elemental group-IV semiconductors. The absolute minima of the conduction band occur along Δ in Si and at the L point in Ge, i.e., along the ⟨100⟩ and ⟨111⟩ directions. The minimum of the conduction band of Ge is at the Brillouin zone edge along ⟨111⟩. There are local minima at $\Gamma(\mathbf{k}=0)$ whose classification is Γ_6^- in Si and Γ_7^- in Ge. In both cases we rewrite the deformation potential in the form

$$\begin{aligned}\sum_{ij} D_{ij}\epsilon_{ij}=\frac{1}{3}\Big(\sum_{i} D_{ii}\Big)\Big(\sum_{j} \epsilon_{jj}\Big)+\frac{1}{6}[(2D_{zz}&\\ -D_{xx}-D_{yy})(2\epsilon_{zz}-\epsilon_{xx}-\epsilon_{yy})&\\ +3(D_{xx}-D_{yy})(\epsilon_{xx}-\epsilon_{yy})]&\\ +2\sum_{i<j} D_{ij}\epsilon_{ij},& \qquad (79)\end{aligned}$$

where x, y, z denote the cubic axes. The quantity $\Sigma_i D_{ii}$ belongs to the totally symmetric representation Γ_1^+ of O_h, $2D_{zz}-D_{xx}-D_{yy}$, and $\sqrt{3}(D_{xx}-D_{yy})$ generate Γ_3^+ and D_{yz}, D_{zx}, D_{xy} generate Γ_5^+. Using results from the theory of groups, the Γ_6^- and Γ_7^- levels shift by

$$\Delta E(\Gamma_{6,7})=\tfrac{1}{3}\Big\langle\Gamma_{6,7}\Big|\sum_{i} D_{ii}\Big|\Gamma_{6,7}\Big\rangle\sum_{j}\epsilon_{jj}, \qquad (80)$$

i.e., proportionally to the dilatation.

The conduction-band edge of Si is a Δ_1 state. The group of Δ, often designated by this symbol, is C_{4v} and the decomposition of the deformation potential operator appropriate for this case is

$$\begin{aligned}\sum_{ij} D_{ij}\epsilon_{ij}=\tfrac{1}{2}(D_{xx}+D_{yy})(\epsilon_{xx}+\epsilon_{yy})+D_{zz}\epsilon_{zz}&\\ +\tfrac{1}{2}(D_{xx}-D_{yy})(\epsilon_{xx}-\epsilon_{yy})&\\ +2D_{yz}\epsilon_{yz}+2D_{zx}\epsilon_{zx}+2D_{xy}\epsilon_{xy}.& \qquad (81)\end{aligned}$$

Here $D_{xx}+D_{yy}$ and D_{zz} belong to Δ_1, D_{xy} to Δ_2, $D_{xx}-D_{yy}$ to Δ_2', and D_{yz} and D_{zx} to Δ_5. [Note that Δ_1, Δ_1', Δ_2, Δ_2', and Δ_5 correspond to Γ_1, Γ_2, Γ_4, Γ_3, and Γ_5, respectively, in the notation of Koster *et al.* (1966)]. We immediately conclude that the energy shift of a specific Δ_1 is given by

$$\begin{aligned}\Delta E=\Big\langle\Delta_1\Big|\sum_{ij} D_{ij}\epsilon_{ij}\Big|\Delta_1\Big\rangle&\\ =\Xi_d(\epsilon_{xx}+\epsilon_{yy})+(\Xi_d+\Xi_u)\epsilon_{zz},& \qquad (82)\end{aligned}$$

where

$$\Xi_d=\tfrac{1}{2}\langle\Delta_1|D_{xx}+D_{yy}|\Delta_1\rangle \qquad (83)$$

and

$$\Xi_u=\tfrac{1}{2}\langle\Delta_1|2D_{zz}-D_{xx}-D_{yy}|\Delta_1\rangle \qquad (84)$$

are called the dilatational and shear deformation potential constants, respectively.

A similar treatment can be given for the $L_6^+(\Gamma_4^+)$ minimum of the lowest conduction band of germanium. Here, the deformation potential is best expressed in terms of invariants in which the $\hat{\zeta}$ axis is the axis of highest rotational symmetry of the group of L, namely [111]. It is sometimes convenient, as we do here, to select $\hat{\xi}$ and $\hat{\eta}$ parallel to [11$\bar{2}$] and [$\bar{1}$10], respectively. Then

$$\begin{aligned}\sum_{ij} D_{ij}\epsilon_{ij}=\tfrac{1}{2}(D_{\xi\xi}+D_{\eta\eta})(\epsilon_{\xi\xi}+\epsilon_{\eta\eta})+D_{\zeta\zeta}\epsilon_{\zeta\zeta}&\\ +\tfrac{1}{2}(D_{\xi\xi}-D_{\eta\eta})(\epsilon_{\xi\xi}-\epsilon_{\eta\eta})&\\ +2D_{\xi\eta}\epsilon_{\xi\eta}&\\ +2D_{\zeta\xi}\epsilon_{\zeta\xi}+2D_{\zeta\eta}\epsilon_{\zeta\eta}.& \qquad (85)\end{aligned}$$

Now $D_{\xi\xi}+D_{\eta\eta}$ and $D_{\zeta\zeta}$ belong to L_1 while the pairs $(D_{\xi\xi}-D_{\eta\eta}, D_{\xi\eta})$ and $(D_{\zeta\xi}, D_{\zeta\eta})$ generate L_3. Using the orthogonality theorem of the theory of group representations and time-reversal symmetry, we find

$$\begin{aligned}\Big\langle L_6^+\Big|\sum_{ij} D_{ij}\epsilon_{ij}\Big|L_6^+\Big\rangle&\\ =\Xi_d(\epsilon_{\xi\xi}+\epsilon_{\eta\eta})+(\Xi_d+\Xi_u)\epsilon_{\zeta\zeta}&\\ =(\Xi_d+\tfrac{1}{3}\Xi_u)(\epsilon_{xx}+\epsilon_{yy}+\epsilon_{zz})&\\ +\tfrac{2}{3}\Xi_u(\epsilon_{yz}+\epsilon_{zx}+\epsilon_{xy}).& \qquad (86)\end{aligned}$$

Here

$$\Xi_d=\tfrac{1}{2}\langle L_6^+|D_{\xi\xi}+D_{\eta\eta}|L_6^+\rangle \qquad (87)$$

and

$$\Xi_u=\tfrac{1}{2}\langle L_6^+|2D_{\zeta\zeta}-D_{\xi\xi}-D_{\eta\eta}|D_6^+\rangle. \qquad (88)$$

As an example in which the levels are orbitally degenerate, we consider here the deformation potential theory for the Γ_5^+ (Γ_{25}') states at the top of the valence band of elemental semiconductors having the diamond structure. We disregard the spin of the electron for the time being and designate the three degenerate states associated with the top of the valence band by the symbols ϵ_1, ϵ_2, ϵ_3. They transform under the operations of O_h as yz, zx, and xy where x, y, z are the components of a vector referred to the cubic axes. The changes in energy upon deformation are obtained diagonalizing the 3×3 matrix

$$\sum_{ij}\epsilon_{ij}\langle\epsilon_\mu|D_{ij}|\epsilon_\nu\rangle,$$

$\mu,\nu=1,2,3$. We can rewrite the quantity $\Sigma_{ij}\,\epsilon_{ij}D_{ij}$ as a linear combination of

$$(\epsilon_{xx}+\epsilon_{yy}+\epsilon_{zz})(D_{xx}+D_{yy}+D_{zz}),$$

$$(2\epsilon_{zz}-\epsilon_{xx}-\epsilon_{yy})(2D_{zz}-D_{xx}-D_{yy})$$
$$+3(\epsilon_{xx}-\epsilon_{yy})(D_{xx}-D_{yy}),$$

and

$$\epsilon_{yz}D_{yz}+\epsilon_{zx}D_{zx}+\epsilon_{xy}D_{xy}.$$

We recall that $D_{xx}+D_{yy}+D_{zz}$ belongs to the totally symmetric representation Γ_1^+ of the cubic group O_h, that $2D_{zz}-D_{xx}-D_{yy}$ and $\sqrt{3}\,(D_{xx}-D_{yy})$ belong to $\Gamma_3^+\,(\Gamma_{12})$, and D_{yz}, D_{zx}, D_{xy} to $\Gamma_5^+\,(\Gamma_{25}')$. $D_{xx}+D_{yy}+D_{zz}$ has only diagonal matrix elements in the basis $\{\epsilon_\mu\}$ $(\mu=1,2,3)$ and all its elements are equal. The matrices associated with $2D_{zz}-D_{xx}-D_{yy}$ and $\sqrt{3}\,(D_{xx}-D_{yy})$ are proportional to $2I_z^2-I_x^2-I_y^2$ and $\sqrt{3}(I_x^2-I_y^2)$, respectively, where

$$I_x=\begin{pmatrix}0&0&0\\0&0&-i\\0&i&0\end{pmatrix},\quad I_y=\begin{pmatrix}0&0&i\\0&0&0\\-i&0&0\end{pmatrix},$$

$$I_z=\begin{pmatrix}0&-i&0\\i&0&0\\0&0&0\end{pmatrix}$$

are the components of the angular momentum operator for $I=1$ on the cubic axes. In the same way the matrix elements of D_{yz}, D_{zx}, and D_{xy} in the same basis are proportional to $\{I_y,I_z\}$, $\{I_z,I_x\}$, and $\{I_x,I_y\}$, respectively. Thus, the operator $\Sigma_{ij}\,\epsilon_{ij}D_{ij}$ in the basis generating the $\Gamma_5^+\,(\Gamma_{25}')$ states has the form of the matrix

$$-a\sum_i\epsilon_{ii}-3b\sum_i\epsilon_{ii}(I_i^2-\tfrac{1}{3}I^2)$$
$$-\sqrt{3}d\sum_{i<j}\epsilon_{ij}\{I_i,I_j\}. \tag{89}$$

We consider now the effect of the spin-orbit interaction. The deformation potentials D_{ij} depend, of course, on the spin of the electron. However, in most circumstances this correction is negligible so that we can take as the deformation potential contribution to the effective second-order Hamiltonian the matrix (89) multiplied (in the sense of the direct product of matrices) by the unit 2×2 matrix. However, the spin-orbit coupling splits the sixfold degeneracy of the $\epsilon_\mu\alpha$, $\epsilon_\mu\beta$ states $(\mu=1,2,3)$ into a Γ_8^+ quadruplet and a Γ_7^+ doublet (α, β designate the two orthogonal spin states, taken, to fix the ideas, so that σ_z is diagonal, $\hat{\mathbf{z}}$ being one of the cubic axes).

The matrix elements of the spin-orbit interaction in the representation $\epsilon_\mu\chi_\pm$ $(\mu=1,2,3)$ where $\chi_+=\alpha$ and $\chi_-=\beta$ are

$$\frac{\hbar}{4m^2c^2}\langle\epsilon_{\mu'}|\nabla U\times\mathbf{p}|\epsilon_\mu\rangle\cdot\langle\chi_{\sigma'}|\boldsymbol{\sigma}|\chi_\sigma\rangle,$$

where $U(\mathbf{x})$ is the crystal potential. Now the components of the pseudovector $\nabla U\times\mathbf{p}$ generate the $\Gamma_4^+\,(\Gamma_{15}')$ representation of O_h so that its matrix representation is simply a constant times $\mathbf{I}$. Thus, we write the spin-orbit interaction in the form

$$\tfrac{1}{3}\Delta\mathbf{I}\cdot\boldsymbol{\sigma}.$$

The Hamiltonian matrix for the six $\Gamma_5^+\times\Gamma_6^+$ states for $\mathbf{k}$ near the center of the Brillouin zone and in the presence of strain in the diamond structure is of the form

$$H=Ak^2-a\sum_i\epsilon_{ii}$$
$$-3\sum_i(Bk_i^2+b\epsilon_{ii})(I_i^2-\tfrac{1}{3}I^2)$$
$$-\sqrt{3}\sum_{i<j}(Dk_ik_j+d\epsilon_{ij})\{I_i,I_j\}+\tfrac{1}{3}\Delta\mathbf{I}\cdot\boldsymbol{\sigma}. \tag{90}$$

The calculation of the eigenvalues of H is simplified if we notice that H is invariant under the time-reversal operator, $\mathbf{I}\rightarrow-\mathbf{I}$, and $\boldsymbol{\sigma}\rightarrow-\boldsymbol{\sigma}$. Thus, the eigenvalues of H in Eq. (90) are doubly degenerate (Kramers's theorem).

The eigenvalues of this matrix to first order in $\boldsymbol{\epsilon}$ and second order in $\mathbf{k}$ are

$$-\tfrac{2}{3}\Delta+Ak^2-a\sum_i\epsilon_{ii} \tag{91}$$

and

$$E_\pm(\mathbf{k},\boldsymbol{\epsilon})=Ak^2-a\sum_i\epsilon_{ii}+\tfrac{1}{3}\Delta$$
$$\pm(R_k+R_{k\epsilon}+R_\epsilon)^{1/2} \tag{92}$$

with

$$R_k=B^2k^4+(D^2-3B^2)\sum_{i<j}k_i^2k_j^2, \tag{93}$$

$$R_{k\epsilon} = -Bbk^2 \sum_i \epsilon_{ii} + 3Bb \sum_i k_i^2 \epsilon_{ii} + 2Dd \sum_{i<j} k_i k_j \epsilon_{ij}, \qquad (94)$$

and

$$R_\epsilon = b^2 \sum_i \epsilon_{ii}^2 + \sum_{i<j} (d^2 \epsilon_{ij}^2 - b^2 \epsilon_{ii} \epsilon_{jj}). \qquad (95)$$

In the elemental semiconductors Si and Ge, the spin-orbit splitting of the $\Gamma_{25}' \times \Gamma_6$ valence band is positive so that, in the absence of stress, the top of the valence band is a quadruplet Γ_8^+. The split-off band, Γ_7^+, lies at an energy Δ below the fourfold level. In the presence of stress the Γ_7^+ shifts by an amount proportional to the dilatation. A similar shift occurs for the Γ_8^+ level but, in addition, it splits into two doublets under shear stress. The deformation potential operator of the Γ_8^+ level is

$$D = -a \sum_i \epsilon_{ii} - b \sum_i \epsilon_{ii} (J_i^2 - \tfrac{1}{3} \mathbf{J} \cdot \mathbf{J}) - (d/\sqrt{3}) \sum_{i<j} \epsilon_{ij} \{J_i, J_j\}. \qquad (96)$$

Simple examples for uniaxial stress along three high-symmetry directions are given below. The components of the strain tensor resulting from the application of a stress generated by a force **F** along [001] are $\epsilon_{xx} = \epsilon_{yy} = s_{12}T, \epsilon_{zz} = s_{11}T, \epsilon_{yz} = \epsilon_{zx} = \epsilon_{xy} = 0$. Here T is the force per unit area, taken positive for extension and negative for compression. The dilatation produces a shift as stated above but the associated shear splits the levels associated with $J_z = \pm 1/2$ from those for which $J_z = \pm 3/2$ by $\Delta E_{100} = 2b(s_{11} - s_{12})T$, the $J_z = \pm 1/2$ level lying above $J_z = \pm 3/2$ if $bT(s_{11} - s_{12}) > 0$. For a force along [111], $\epsilon_{xx} = \epsilon_{yy} = \epsilon_{zz} = (s_{11} + 2s_{12})T/3$ and $\epsilon_{yz} = \epsilon_{zx} = \epsilon_{xy} = Ts_{44}/6$, the level corresponding to $J_n = \pm 1/2$ lying above $J_n = \pm 3/2$ if $Tds_{44} > 0$. Here J_n is the projection of **J** on the [111] direction.

For a force directed parallel to [110], $\epsilon_{xx} = \epsilon_{yy} = T(s_{11} + s_{12})/2, \epsilon_{zz} = s_{12}T, \epsilon_{yz} = \epsilon_{zx} = 0, \epsilon_{xy} = Ts_{44}/4$.

In general, the splitting of the Γ_8^+ level under uniaxial stress applied along an arbitrary direction $\hat{\mathbf{e}}$ is given by

$$(\Delta E_e)^2 = (\Delta E_{100})^2 + 3(\Delta E_{111}^2 - \Delta E_{100}^2) f(\hat{\mathbf{e}}),$$

where

$$f(\hat{\mathbf{e}}) = e_y^2 e_z^2 + e_z^2 e_x^2 + e_x^2 e_y^2.$$

The quantity $f(\hat{\mathbf{e}})$ has extremal values of 1/3, 1/4, and 0 along ⟨111⟩, ⟨110⟩, and ⟨100⟩, respectively, the first being an absolute maximum and the third an absolute minimum.

These considerations are applicable not only to the band states but also to the localized levels of electrons or holes in semiconductors. Under such conditions the energy levels are classified according to the irreducible representations of the symmetry group of the site of the localized state. The results described above hold, for example, for donor and acceptor states except that there is no question of a wave-vector dependence. The single-electron or -hole states of donors and acceptors in elemental semiconductors are classified according to the irreducible representations of the double group $\overline{T}_d$ but the results are the same as in Eq. (96). Of course, the parameters a, b, and d are different for different Γ_8 levels. However, for the ground states of shallow donors and acceptors, these parameters should be approximately equal to those of the band levels.

4.2 Relative Intensities of Stress-Induced Components of an Optical Transition

Spectroscopic investigations provide information on the symmetry assignments of the quantum-mechanical states associated with the initial and final states for given optical transitions. The energies of the transitions allow us to obtain band parameters and, in the presence of strain, values for the deformation potential constants.

The magnitude and sign of the deformation potentials are obtained experimentally in conjunction with theoretical studies of the symmetry characteristics of the initial and final states of the stress-induced lines associated with specific optical transitions carried out with incident radiation of varied polarization. But this is often insufficient to obtain unambiguous results. In some cases it is useful to compare the measured relative intensities of the stress-induced components of the absorption lines with the predictions of a symmetry analysis. The relative intensities of these components can be deduced, in the absence of significant hybridization with adjacent levels, by calculating the matrix elements of the electric dipole moment **d** between initial and final states. These calculations provide both the selection rules and expressions for the relative intensities, either directly or as functions of at most two adjustable parameters.

We recall that d_x, d_y, and d_z, the components of **d** along the cubic axes, generate the Γ_5 representation of T_d and the Γ_4^- representation of O_h. For transitions between Γ_8 states, d_x, d_y, d_z are 4×4 matrices. We consider first transitions between localized states of levels where the symmetry is $\overline{T}_d$. The matrix elements of d_x, d_y, d_z for a transition between two Γ_8 levels are proportional to suitable combinations of products of the components of **J**, the angular momentum operator matrix for $j=3/2$, which transform in the same way as d_x, d_y, d_z under the operations of T_d. The two sets of matrices

$$U_x=\{J_y,J_z\},\quad U_y=\{J_z,J_x\},\quad U_z=\{J_x,J_y\} \tag{97}$$

and

$$V_x=\{J_x,J_y^2-J_z^2\},\quad V_y=\{J_y,J_z^2-J_x^2\},$$
$$V_z=\{J_z,J_x^2-J_y^2\} \tag{98}$$

transform as Γ_5. Thus, the components of **d** are linear combinations of **U** and **V** with suitable, complex valued, coefficients. It is important to recognize that the shorthand notation for these operators does not imply that they are vectors under O(3). For transitions between Γ_8 and Γ_6 or Γ_7 levels the matrix elements of **d** are proportional to

$$\begin{pmatrix} \hat{\mathbf{x}}-i\hat{\mathbf{y}} & 0 & \sqrt{3}(\hat{\mathbf{x}}+i\hat{\mathbf{y}}) & 2\hat{\mathbf{z}} \\ 2\hat{\mathbf{z}} & -\sqrt{3}(\hat{\mathbf{x}}-i\hat{\mathbf{y}}) & 0 & -(\hat{\mathbf{x}}+i\hat{\mathbf{y}}) \end{pmatrix} \tag{99}$$

for $\Gamma_8\rightarrow\Gamma_7$ transitions and to

$$\begin{pmatrix} -\sqrt{3}(\hat{\mathbf{x}}+i\hat{\mathbf{y}}) & 2\hat{\mathbf{z}} & \hat{\mathbf{x}}-i\hat{\mathbf{y}} & 0 \\ 0 & -(\hat{\mathbf{x}}+i\hat{\mathbf{y}}) & 2\hat{\mathbf{z}} & \sqrt{3}(\hat{\mathbf{x}}-i\hat{\mathbf{y}}) \end{pmatrix} \tag{100}$$

for $\Gamma_8\rightarrow\Gamma_6$ transitions.

These matrix elements between eigenvectors of J_z corresponding to the values 3/2, 1/2, −1/2, −3/2 for Γ_8 and 1/2, −1/2 for Γ_6 and Γ_7, are written in the above order.

For transitions between states whose symmetry is O_h a slightly different situation occurs. Here d_x, d_y, d_z transform as Γ_4^-. For transitions from a $\Gamma_8^\pm$ level to a $\Gamma_8^\mp$ level, the matrix elements of d_i $(i=x,y,z)$ are proportional to linear combinations of J_i and J_i^3 because the sets (J_x,J_y,J_z) and (J_x^3,J_y^3,J_z^3) transform as Γ_4^+. Note that for systems having a center of symmetry, dipole transitions can occur only between states of different parity. The matrix elements for electric dipole transitions from $\Gamma_8^\pm$ to $\Gamma_6^\mp$ are proportional to those in expression (100), while those for $\Gamma_8^\pm\rightarrow\Gamma_7^\mp$ are proportional to the quantities appearing in expression (99). For transitions between Γ_6 and Γ_7 states the matrices associated with electric dipole transitions are proportional to the components of the Pauli spin matrix $\boldsymbol{\sigma}$.

We emphasize that to obtain the relative intensities for a given set of stress-induced components of an absorption line, it is first required to obtain the energy eigenfunctions under stress and carry out the unitary transformation between the eigenstates of J_z and the actual eigenfunctions. These transformations are trivial to carry out for uniaxial stresses along high symmetry directions.

The energy eigenvalues as functions of **k** for states near the top of the valence band of the elemental semiconductors having the diamond structure have been given in Eq. (92). If Δ is large compared to the kinetic-energy terms, these levels are the eigenvalues of

$$H=Ak^2-B\sum_i k_i^2(J_i^2-\tfrac{1}{3}\mathbf{J}\cdot\mathbf{J})$$
$$-(D/\sqrt{3})\sum_{i<j} k_ik_j\{J_i,J_j\} \tag{101}$$

to which we add the deformation potential (96) in the presence of strain. For the zincblende semiconductors, lacking inversion symmetry, there is an additional term H_A, linear in **k**, namely,

$$H_A=(C/\sqrt{3})\sum_i k_iV_i, \tag{102}$$

where V_x, V_y, V_z are given by Eq. (98). However, the constant C is usually so small that for many purposes H_A can be neglected. It originates in second-order perturbation theory as a term proportional to the product of the perturbation $(\hbar/m)\mathbf{k}\cdot\mathbf{p}$ with the spin-orbit interaction so that it is expected to be small.

In general, application of uniaxial stress splits the $\Gamma_8(\Gamma_8^+)$ level at the top of the valence band of a zinc-blende (diamond) semiconductor into two Kramers doublets. The same occurs for the Γ_8 levels of an acceptor in tetrahedrally bonded semiconductors. For a force $\mathbf{F}$ applied along one of the cubic axes a Γ_8 level splits into Γ_6 and Γ_7 levels of $\overline{D}_{2d}$, the group D_{2d} characterizing the site symmetry after application of the stress. If the force $\mathbf{F}$ is applied along the [001] axis, and the deformation potential is expressed in the basis generated by the eigenvectors of J_z, namely, ϕ_μ $(\mu=3/2,1/2,-1/2,-3/2)$, the functions $\phi_{\pm 3/2}$ belong to $\Gamma_6(\overline{D}_{2d})$ while $\phi_{\pm 1/2}$ generate $\Gamma_7(\overline{D}_{2d})$. Under uniaxial stress resulting from an applied force directed along [111] the symmetry of the site becomes C_{3v} and the Γ_8 levels split into $\Gamma_4(\overline{C}_{3v})$ corresponding to $\hat{\zeta}\cdot\mathbf{J}=\mathbf{J}_\zeta = \pm 1/2$, where ζ is a unit vector parallel to the [111] direction, and $\Gamma_5(\overline{C}_{3v}) \oplus \Gamma_6(\overline{C}_{3v})$ associated with $J_\zeta = \pm\ 3/2$. Γ_5 and Γ_6 are one-dimensional irreducible representations which are each other's complex conjugate and, hence, correspond to states of equal energy eigenvalues. We represent this level by Γ_{5+6}.

For the analysis of the relative intensities of stress-induced components referred to above we use the following considerations. For transitions between Γ_8 levels the matrix elements of the i component of the electric dipole operator $(i=x,y,z)$ are linear combinations of the components of the quantities U_i and V_i, namely,

$$d_i = \frac{i}{\sqrt{3}} d_1 U_i - \frac{2}{\sqrt{3}} d_2 V_i, \quad i=x,y,z. \qquad (103)$$

We find the relative intensities of the stress-induced absorption lines by reading off the matrix elements and adding the square of the magnitudes of matrix elements of d_i between degenerate levels. The form of the matrices U_i and V_i permits the direct determination of the relative intensities for uniaxial stress along a cubic axis. The results of this analysis are given in Table 5 for incident radiation polarized parallel or perpendicular to the applied force. These results are accurate as long as hybridization with neighboring levels can be neglected. Otherwise the possibility of a transfer of intensity from one set of lines to another occurs and can also be incorporated into the formalism. Results are also displayed for transitions from a Γ_8 level to Γ_6 and Γ_7 states using the rectangular matrices in Eqs. (99) and (100). We note that the relative intensities can be expressed in terms of d_1/d_2, the ratio

Table 5. Relative intensities for stress-induced components of acceptors in tetrahedrally bonded semiconductors with $\mathbf{F}\|[001]$ and incident radiation polarized parallel to $\mathbf{E}$.[a]

Zero-stress transition $\overline{T}_d$	Stress-induced components $\overline{D}_{2d}$	Sum of the squared amplitudes for the stress-induced components		Relative intensities	
		$\mathbf{E}\perp(\hat{x},\hat{y})$	$\mathbf{E}\|\hat{z}$	$\mathbf{E}\perp(\hat{x},\hat{y})$	$E\|\hat{z}$
$\Gamma_8\rightarrow\Gamma_8$	$\Gamma_7(\pm\frac{1}{2})\rightarrow\Gamma_7(\pm\frac{1}{2})$	$6\|d_2\|^2$	0	$\frac{3}{8}u$	0
	$\Gamma_7(\pm\frac{1}{2})\rightarrow\Gamma_6(\pm\frac{3}{2})$	$2\|d_1+d_2\|^2$	$2\|d_1-2d_2\|^2$	$\frac{1}{2}-\frac{3}{8}u-\frac{1}{2}v$	$\frac{1}{2}+v$
	$\Gamma_6(\pm\frac{3}{2})\rightarrow\Gamma_7(\pm\frac{1}{2})$	$2\|d_1-d_2\|^2$	$2\|d_1+2d_2\|^2$	$\frac{1}{2}-\frac{3}{8}u+\frac{1}{2}v$	$\frac{1}{2}-v$
	$\Gamma_6(\pm\frac{3}{2})\rightarrow\Gamma6(\pm\frac{3}{2})$	$6\|d_2\|^2$	0	$\frac{3}{8}u$	0
$\Gamma_8\rightarrow\Gamma_6$	$\Gamma_7(\pm\frac{1}{2})\rightarrow\Gamma_6$	$2\|d_0\|^2$	$8\|d_0\|^2$	1	4
	$\Gamma_6(\pm\frac{3}{2})\rightarrow\Gamma_6$	$6\|d_0\|^2$	0	3	0
$\Gamma_8\rightarrow\Gamma_7$	$\Gamma_7(\pm\frac{1}{2})\rightarrow\Gamma_7$	$6\|d_0'\|^2$	0	3	0
	$\Gamma_6(\pm\frac{3}{2})\rightarrow\Gamma_7$	$2\|d_0'\|^2$	$8\|d_0'\|^2$	1	4

[a] The parameters d_1 and d_2 are defined in Eq. (103). d_0 and d_0' are the coefficients of the matrices (99) and (100) for $\Gamma_8 \rightarrow \Gamma_6$ and $\Gamma_8 \rightarrow \Gamma_7$ transitions, respectively.

of two complex numbers, and thus depends on two real parameters u and v defined by

$$u=[1+|d_1/2d_2|^2]^{-1},$$

$$v=-\frac{1}{4}\left(\frac{d_1}{d_2}+\frac{d_1^*}{d_2^*}\right)u.$$

To investigate the relative intensities of the stress-induced lines we transform U_i and V_i so that the matrix elements of **d** are referred to a coordinate system $\hat{\mathbf{z}}$, $\hat{\xi}$, $\hat{\zeta}$ in which $\hat{\zeta}$ is directed along [111]. We select $\hat{\xi}$ parallel to [11$\bar{2}$] and $\hat{\eta}$ along [$\bar{1}$10] and transform the Γ_8 states by means of the rule

$$\psi_\mu=\sum_{\mu'}\phi_{\mu'}D^{(3/2)}_{\mu'\mu}(\alpha,\beta,\gamma),$$

where α, β, and γ are the Euler angles of the rotation from $\hat{\mathbf{x}}$, $\hat{\mathbf{y}}$, $\hat{\mathbf{z}}$ to $\hat{\xi}$, $\hat{\eta}$, $\hat{\zeta}$ ($\alpha=\pi/4$, $\cos\beta=3^{-1/2}$, $\gamma=0$) and $D^{(3/2)}(\alpha,\beta,\gamma)$ is the rotation operator for angular momentum 3/2. The transformations are straightforward and the results are displayed in Table 6. We note that in this case the relative intensities depend only on the parameter u defined above.

5. CONCLUDING REMARKS

In this article we have discussed the splitting of electron levels of atoms due to the presence of external fields or to the interactions arising when they are embedded in a crystal. Topics such as the static and dynamic Jahn-Teller effects and the interaction with nuclei (hyperfine coupling) lie outside the scope of this article. Even in the area selected we have only been able to include the main relevant subjects and have illustrated them with a few significant examples.

The author is grateful to Professor A. K. Ramdas and to Dr. M. Villeret for their comments on the manuscript and for many useful discussions. Part of the examples presented here are the results of research supported by the National Science Foundation (Grants No. DMR-89-21717 and No. DMR-89-13706). The preparation of the manuscript was completed while the author was a guest of Scuola Normale Superiore (Pisa, Italy). The author is grateful to his colleagues in Pisa for the opportunity of working at the Scuola Normale. In particular, he wishes to express his appreciation to Professor F. Bassani, to Professor L. Foà, and to Professor L. A. Radicati for their kind hospitality.

GLOSSARY

Configuration: Atomic energy levels in the central-field approximation. For example, the configuration of Na in its lowest state is $(1s)^2(2s)^2(2p)^6(3s)$. (See definitions of *Term* and *Level*.)

Crystal Field: Electrostatic potential of an atom or ion in a crystal lattice.

Deformation Potential: Potential energy of a charge carrier in a crystal due to the application of external stress.

Hund's Rules: Rules for the determination of the lowest term and ground state of an atom or ion. (See text or Condon and Shortley, 1953).

Level: Energy eigenstate of an atom in a term with given orbital (L) and spin (S) angular momenta and the total angular momentum J determined using Hund's rules. (See definition of *Term* below.)

Operator Equivalent: The crystal-field potential expressed in terms of powers of angular momentum operators.

Quenching of the Orbital Angular Momentum: Expression describing the situation when the expectation value of the orbital angular momentum in the ground state of an atom vanishes as a consequence of its presence in a crystal.

Spin Hamiltonian: Operator describing the effect of the crystal potential and of an external magnetic field on an atom or ion in a crystal.

Term: Quantum-mechanical states resulting from the splitting of the configuration of an atom or ion due to the Coulomb repulsion between electrons prior to the consideration of the spin-orbit interaction and other relativistic corrections.

INTRODUCTION

Electron paramagnetic resonance or EPR (also frequently called electron spin resonance, ESR) is a radiofrequency spectroscopy in which transitions among the energy levels of a system of weakly coupled *electronic* magnetic dipole moments in a magnetic field are detected. Such *paramagnetic* electronic magnetic moments occur in solids, liquids, and gases and may belong to conduction electrons in metals, impurity ions in both insulators and metals, organic free radicals, and radiation-induced defects, to mention a few. In classical terms, in a fixed (static) magnetic field, the magnetic moments precess around the field direction at a frequency (the *Larmor frequency)* determined by the strengths of both the moment and the field. When the frequency of the applied radiofrequency (rf) magnetic field matches the Larmor frequency, transitions between the energy levels are induced. When this occurs, the frequency of the applied radiation and the precession frequency are said to be *in resonance.*

Historically, the first experimental observations were made by Zavoisky in the USSR (Zavoisky, 1945). These experiments were performed in rather weak applied fields, so that the frequency of the corresponding radiation field was essentially in the radiofrequency domain. Subsequently, Bagguley and Griffiths in England (Bagguley and Griffiths, 1947) detected the resonance of chromium ions in a chrome alum crystal using microwave radiation at a frequency of 9.43 GHz (3.18-cm wavelength), thereby initiating the application to EPR of microwave (i.e., radar) techniques developed during World War II. Because the inherent spectroscopic sensitivity

(b) Energy levels and transition frequency for spin 1/2 as functions of applied field H_0.

increases with increasing frequency of the radiation (therefore increasing the energy quantum), it is advantageous to work in the microwave (GHz) region of the electromagnetic spectrum, and most measurements are now made in the range 5–40 GHz in which the needed microwave components are readily available.

1. RESONANCE FUNDAMENTALS

1.1 Classical and Quantum-Mechanical Descriptions of Resonance

The classical representation of the resonance phenomenon is shown in Fig. 1(a). An electron having angular momentum $\mathbf{S}\hbar$ and magnetic dipole moment $\boldsymbol{\mu}$ experiences a torque, $\boldsymbol{\tau}=\boldsymbol{\mu}\times\mathbf{H}_0$, in a magnetic field $\mathbf{H}_0$. This torque causes the direction of the angular momentum vector to change. Since

rate of change of angular momentum

=torque,

or

$$\frac{d(\mathbf{S}\hbar)}{dt}=\boldsymbol{\tau}=\boldsymbol{\mu}\times\mathbf{H}_0, \tag{1}$$

and since $\boldsymbol{\tau}$ is constantly perpendicular to the plane of $\boldsymbol{\mu}$ and $\mathbf{H}_0$, the magnitude of $\boldsymbol{\mu}$ cannot change. Instead, only the direction of $\boldsymbol{\mu}$ changes as it *precesses* around the direction of $\mathbf{H}_0$. Because the electron charge is negative, its dipole moment is directed oppositely (antiparallel) to its angular momentum, so that $\boldsymbol{\mu}$ and $\mathbf{S}$ are related by $\boldsymbol{\mu}=-\gamma\hbar\mathbf{S}$, and the angular frequency of precession is $\omega_0=\gamma H_0$, known as the Larmor frequency.

In the resonance experiment, the magnetic field $\mathbf{H}_1$ of the microwave radiation ($\mathbf{H}_1\ll\mathbf{H}_0$) rotates with the angular frequency ω of the microwaves in the xy plane, perpendicular to $\mathbf{H}_0$. Here, $\mathbf{H}_1$ also exerts a torque, $\boldsymbol{\mu}\times\mathbf{H}_1$, on $\boldsymbol{\mu}$, but unless $\omega=\omega_0$, the time-average value of this torque is zero. However, when $\omega=\omega_0$, the resonance condition is established, and $\boldsymbol{\mu}$ precesses around $\mathbf{H}_1$ at frequency $\omega_1=\gamma H_1$ ($\omega_1\ll\omega_0$), as well as continuing to precess around $\mathbf{H}_0$ at the much faster frequency ω_0.

The result is that μ slowly changes its orientation in the field $\mathbf{H}_0$, tipping down until it reaches the position opposite to its original orientation. In this process, work is done on the dipole moment by the microwave field, or in other words, energy is absorbed from the microwave field $\mathbf{H}_1$ during resonance.

On the other hand, in quantum mechanics the allowed energies of the dipole μ, having magnitude $\gamma\hbar[S(S+1)]^{1/2}$, in the field $\mathbf{H}_0$ are determined by the energy operator (Hamiltonian),

$$\mathscr{H} = -\boldsymbol{\mu}\cdot\mathbf{H}_0 = \gamma\hbar\mathbf{S}\cdot\mathbf{H}_0. \tag{2}$$

By convention, $\mathbf{H}_0$ is taken in the $+z$ direction, so that $\mathbf{S}\cdot\mathbf{H}_0 = H_0 S_z$. The result is that the allowed energies are

$$E_M = \gamma\hbar H_0 M, \tag{3}$$

where the quantum number M specifies the allowed values of the z component of $\mathbf{S}$. These are $-S$, $-S+1,\dots,$ $S-1$, S, so that in the simplest case, that of a single "free" electron, for which $S=1/2$, we have $M=\pm 1/2$, and the allowed energies are just two,

$$E_{\pm 1/2} = \pm\tfrac{1}{2}\gamma_e\hbar H_0, \tag{4}$$

as shown in Fig. 1(b). Transitions between these levels due to magnetic dipole radiation require that $\Delta M = \pm 1$, so that in the resonance experiment the energy quantum $\hbar\omega$ of the microwave magnetic field must satisfy the Bohr condition that

$$\hbar\omega = E_{+1/2} - E_{-1/2} = \gamma_e\hbar H_0, \tag{5}$$

which means that $\omega = \gamma H_0 = \omega_0$, just as in the classical picture.

An order-of-magnitude indication of ω_0 results from the basic *free-electron magnetogyric ratio*:

$$\gamma_e = 2\pi(28.0246\ \text{GHz/Tesla}).$$

1.2 Relaxation Phenomena

Although the preceding section concerned the resonance behavior of a single electronic moment, or spin, real materials contain many spins. In thermal equilibrium, the relative numbers of moments in the two energy levels in Fig. 1(b) are determined by the Boltzmann distribution,

$$N^+/N^- = \exp(-\gamma\hbar H_0/k_B T) \tag{6}$$

where N^+ and N^- are the numbers of moments in the higher and lower energy states and k_B is Boltzmann's constant. This assures that $N^- > N^+$, i.e., more moments are in the low-energy state. And except at very low temperature, $\gamma\hbar H_0 \ll k_B T$ (for the "free" electron in a field of 1 T, $\gamma\hbar H_0 = k_B T$ when $T = 1.35$ K). The microwave radiation field results in both absorption and stimulated (induced) emission by the electronic moments. The transition probabilities are the same for both processes, but since $N^- > N^+$, energy absorption will predominate until $N^+ = N^-$. When this occurs the *spin system* is said to be *saturated.* No further energy can be absorbed from the microwave field, and resonance would not be detectable.

Since EPR is usually readily detected, other mechanisms acting within the material (liquid or solid) must effect energy transfer from the magnetic moments to their surroundings. These mechanisms contribute to *spin–lattice relaxation* and result from interactions of the moments with each other and with other electrons of the host molecules or solid, referred to collectively as the lattice. The magnetic fields of these interactions often fluctuate randomly in time because of thermally activated motions. In a solid, the cause may be lattice vibrations (phonons), and in a liquid, fast random tumbling of the molecules. The spectrum of the resultant fluctuating fields at a specific electronic moment will contain a component at the resonance (Larmor) frequency that is also capable of causing transitions between the energy levels in Fig. 1(b), thereby transferring energy from the moments (the spin system) to the lattice. The relaxation process usually depends exponentially on time, and its rate is characterized by the *spin–lattice relaxation time,* T_1, also called the *longitudinal relaxation time* because it concerns changes in the component of μ parallel to $\mathbf{H}_0$.

If T_1 is sufficiently short, it affects the width of the resonance line through the uncertainty-principle relation, $\Delta E\ \Delta\tau > \hbar$, where ΔE is the uncertainty (spread) of an energy level and $\Delta\tau$ is the lifetime of a state belonging to that level, i.e., T_1. If T_1 is very short, ΔE becomes large, and the transition (resonance) frequency is no longer sharp, but broadened.

In addition, the various interactions referred to above cause different moments to "see" slightly different local fields so that all moments do not precess at exactly the same Larmor frequency, resulting in broadening of the resonance. If all the moments could somehow be caused to precess in phase at exactly the same frequency, the existence of the different local fields would cause them to gradually fall out of phase. The characteristic time for this to occur is the *transverse* or *phase-coherence time*, T_2, also called the *spin–spin relaxation time.* Both times, T_1 and T_2, influence the rate at which the magnetization of the entire sample returns to its equilibrium value after a disturbance: T_1 that of the component parallel to H_0, and T_2 that of the components perpendicular to H_0. These times, and relaxation processes, are treated more quantitatively in Secs. 2.5 and 4.

1.3 Experimental Arrangements

The essential elements of a typical EPR spectrometer are a magnet to provide a homogeneous field H_0 over the dimensions of the sample, a source of microwave radiation at frequency ω_0, and a means of detecting the absorption of the radiation at resonance. By far the most frequently used microwaves are those in the so-called X band, having a nominal frequency in the range 9–10 GHz and wavelength $\lambda \simeq 3$ cm, for which the required $H_0 \simeq 0.32$ T. Since resonances can be as narrow as 5×10^{-6} T (or ~ 150 kHz), both the field and frequency must be stable to better than 2 in 10^5 in order for the resonance to be resolved without distortion.

EPR spectrometers are of two basic, complementary types, *steady state* or *continuous wave* (cw), and *pulsed* or *Fourier transform* (FT). With a cw spectrometer, the equilibrium energy-level populations, N^+ and N^-, of Fig. 1(b) are only slightly disturbed from their thermal-equilibrium values, whereas with a pulse spectrometer N^+ and N^- may be equalized or even inverted. Thus, whereas the cw system observes an EPR resonance under thermal equilibrium conditions, the FT system detects the resonance by observing the recovery of the spin (moment) system from a condition of extreme nonequilibrium. Historically, the overwhelming majority of EPR studies have been made using cw spectrometers, both because of their earlier development and because of the lesser technical demands on the microwave components.

In order to "see" a resonance using a cw spectrometer, some range of field or frequency enclosing the resonance condition must be *scanned.* For technical reasons, the microwave source, which is usually a klystron, is held fixed by *locking* its frequency to that of the sample cavity or to a high harmonic of a quartz crystal oscillator, and the magnetic field is scanned through the resonance. Additionally, a weak sinusoidal *modulation* of the field H_0 at a frequency on the order of 100 kHz is normally utilized. This is provided by small coils affixed to the cavity walls. When the amplitude of this modulation field is less than about $0.2 \times$ linewidth, the envelope of the detected signal is proportional to the first derivative of the lineshape. The derivative signal has the advantage that small changes in slope of the lineshape are more readily apparent, especially for powder samples. It is the derivative signal, rather than the lineshape itself, that is conventionally presented in the literature.

A schematic block diagram of a conventional cw spectrometer system is shown in Fig. 2 (all of the microwave waveguide circuitry is not shown). The central element of the microwave bridge is a circulator or magic tee. This yields the sensitivity of a bridge circuit by enabling the detector to respond to the signal from the sample cavity without interference from the incident microwave power. When this element is properly matched to the characteristic impedance of the waveguide, none of the input microwave power from the klystron appears at the detector (see MAGNETIC RESONANCE SPECTROMETERS and MICROWAVE CIRCUITS for additional detail). The magnetic field is stabilized and controlled by a Hall-effect probe located in the magnet gap. A nuclear magnetic resonance (NMR) fluxmeter ("gaussmeter") is employed to measure the field, and may also be used for field stabilization. In the system shown, the klystron frequency is locked to the cavity resonance frequency through auxiliary circuitry, and its frequency is measured by comparison with a quartz-crystal standard in the frequency counter. Accurate measurements of both field and frequency are essential to ensure 5-significant-figure accuracy in values of the positions of resonance features, especially the effective magnetogyric ratio γ. The voltage output of the lock-in amplifier is changed to a pulse train by a voltage-to-frequency converter

circuit, and the pulses are counted and stored in the channels of the signal averager. The signal averager enables repetitive scans to be made through the spectrum to improve the signal/noise performance. Final output is to a plotting device.

Two different methods for detection of a spectrum may be distinguished in pulsed EPR. In the first, the magnetization recovery following a pulse of microwave radiation that equalizes the populations N^+ and N^- is Fourier transformed from the time domain to the frequency domain. Such a pulse is referred to as a "$\pi/2$ or 90° pulse," since it corresponds to changing the z component of the electronic magnetization from parallel to H_0 to perpendicular. The length t (in time) of the required pulse follows from the condition $\omega_1 = \gamma H_1$ (preceding section), and the relation, $\theta = \omega_1 t$, for the angle through which μ precesses (nutates), yielding

$$\theta = \gamma H_1 t. \tag{7}$$

A typical 90° pulse length of 20 ns requires that the amplitude of $H_1 \simeq 0.45$ mT (4.5 Gauss). The magnetization recovery following a 90° pulse is called the *free-induction decay* or *FID* signal, and its Fourier transform yields the spectrum in the frequency domain. As examples, the FID signal and resulting FT spectrum of perylene ($C_{20}H_{12}$) are shown in Fig. 3. The multiplicity of lines in the spectrum results from the hyperfine interaction of the unpaired ring-electron density with the attached protons (see Sec. 2.4). In the second method, the integrated *echo* signal (see Sec. 4.2) following a 90°–180°-pulse sequence is recorded as the magnetic field is scanned. This method is free of bandwidth limitations which affect the applicability of the FT technique to broad resonances. Both techniques yield the absorption signal itself rather than its derivative.

The block diagram of a simplified pulse spectrometer is shown in Fig. 4. The pulse gate passes and shapes the microwave pulses which are then amplified by the traveling-wave-tube (TWT) amplifier unit and sent to the resonance cavity in the magnet gap. The in-phase and out-of-phase components of the magnetization recovery signal are obtained simultaneously with separate detection channels and combined in the final Fourier-transform output.

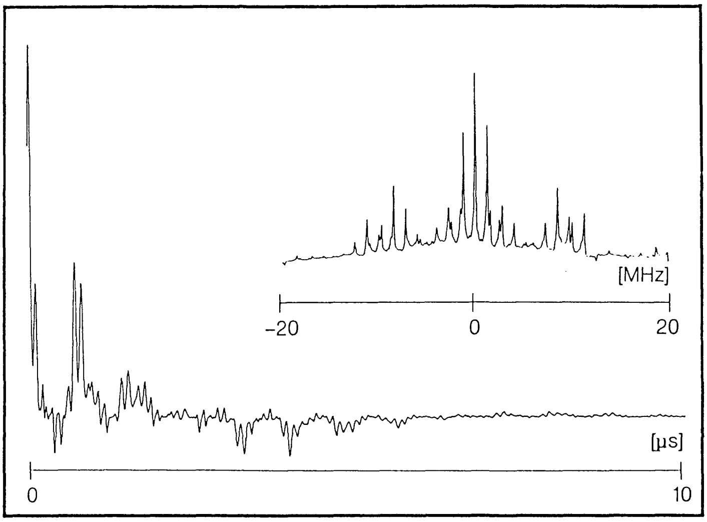

FIG. 3. Free-induction decay (FID) signal of perylene [$C_{20}H_{12}$]. The inset shows the resulting Fourier-transform spectrum. The multiplicity of lines results from the hyperfine interaction of the unpaired electron density with the attached protons.

2. BASIC FEATURES OF EPR SPECTRA

2.1 Introduction: The Spin Hamiltonian Concept

Electrons in atoms, molecules, and solids experience a variety of electromagnetic interactions that shift and split the simple energy level scheme expected solely from the electron's interaction with the applied field H_0. These effects are reflected in the EPR spectrum. In practice, it turns out that spectra can be described fairly simply in terms of transitions between energy levels that are derived from a quantum mechanical energy operator (Hamiltonian) that depends only on spin operators. The coefficients of the various energy terms may be regarded, on the one hand, as parameters derived from the measured EPR spectrum, and, on the other, as values to be calculated from theoretical (first-principles) models of the appropriate electronic structure. This so-called *spin Hamiltonian* constitutes the meeting ground between experimental measurements and basic theory. Virtually all EPR measurements are "fitted" first by an energy level scheme that results from such a spin Hamiltonian.

The interactions that enter into the spin Hamiltonian are basically three:

1. the direct magnetic interaction of the electronic dipole moment μ with the applied field $\mathbf{H}_0$,
2. the dipolar interaction of unpaired electrons with one another, and
3. the electric and magnetic interactions of the unpaired electron(s) with atomic nuclei.

The parameters that characterize these three interactions are

1. the g factor, or g tensor,
2. the fine-structure parameters D and E, and
3. the hyperfine interaction parameter A.

Each of these furnishes its own "signature" that contributes to identifying and characterizing the origin and environment of the paramagnetic entity.

In the simplest cases, only one or two parameters are needed to determine the spectrum from the spin Hamiltonian. But even quite complicated spectra frequently require not more than 8, or at most 10, parameters for their characterization.

2.2 The g factor

Quantum mechanically, μ for a single electronic entity having spin angular momentum $\mathbf{S}\hbar$ is related to $\mathbf{S}$ by

$$\mu = -g(|e|\hbar/2m)\mathbf{S} = -g\beta\mathbf{S} = \gamma\hbar\mathbf{S}, \qquad (8)$$

where $\beta = |e|\hbar/2m$ is the Bohr magneton, g is the spectroscopic splitting factor, or simply "g factor," and μ and $\mathbf{S}$ are vector operators. A truly "free" electron has only its intrinsic spin angular momentum and so $g = g_e = 2.0023$, the free-electron g value. The g factor determines the location of the resonance in the field-

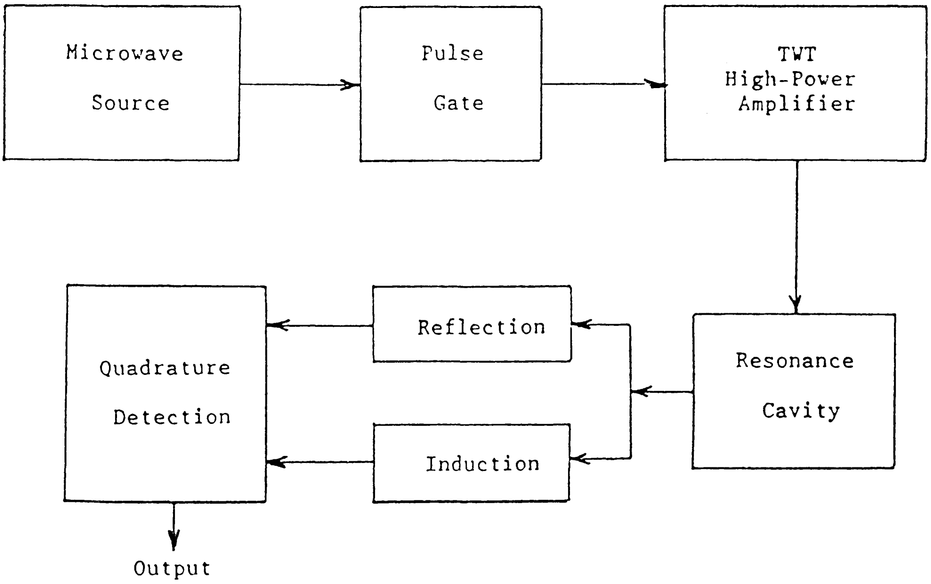

FIG. 4. Schematic block diagram of a simplified pulse EPR spectrometer.

frequency domain. It provides the first of several signatures that enable the origin of the resonance to be identified, and/or interpreted in terms of atomic (or molecular) bonding and other considerations.

Generally, the g factor is not a single number and may differ significantly from g_e. The electrostatic interactions referred to above cause the electronic environment to be determined in part by orbital as well as spin contributions. Moreover, because of the orbital contribution, μ and $\mathbf{S}$ may no longer be collinear, and g may not be isotropic, i.e., independent of the orientation of the field $\mathbf{H}_0$ with respect to the sample. Then, g becomes a tensor $\tilde{g}$ with components g_{xx}, g_{yy}, g_{zz} in its principal-axis coordinate system which is fixed in the molecule or solid. As a result, $\mu = -\beta\tilde{g}\cdot\mathbf{S}$, and the resonance field for a given microwave frequency depends on the orientation of the sample in the field. An important simplification arises, however, when the molecule or ion is in highly fluid motion. The position of the resonance is then determined by the average of g_{xx}, g_{yy}, g_{zz}, since the sum of the diagonal elements of a tensor (the trace) is invariant with respect to coordinate rotations. This average g is often called the g factor to distinguish it from the g tensor.

Shown in Fig. 5 is the orientation dependence of the spectrum of Pt^{3+} impurities present in a $ZnWO_4$ crystal grown in a Pt crucible (Watterich *et al.*, 1991). The spectrum was recorded at a temperature of 6 K as $\mathbf{H}_0$ was rotated in the (100) plane of the crystal. The three-line EPR pattern includes a central line arising from Pt^{3+} ions whose nuclei have zero spin, and two symmetrically placed hyperfine satellite lines due to Pt^{3+} ions whose nuclei (^{195}Pt) have spin 1/2 (see Sec. 2.4). In this example, $g_{xx} \neq g_{yy} \neq g_{zz}$, indicating that the site symmetry is low. Single crystals of $ZnWO_4$ have considerable interest

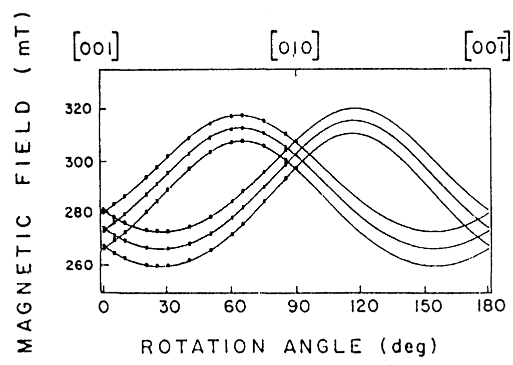

FIG. 5. Angular variation of Pt^{3+} EPR spectrum in $ZnWO_4$ measured at ~6 K and 9.2 GHz. Experimental data are shown by points, and the solid lines represent the calculated angular variation based on computer-fit spin-Hamiltonian parameters (Watterich *et al.*, 1991).

because of their potential application for x-, γ-, and particle-ray scintillation detectors. For such applications, it is desirable to have crystals that do not exhibit coloration due to impurity ions. EPR studies have identified and characterized the location of low levels of various paramagnetic impurity ions in such crystals.

In many cases, the g tensor has axial symmetry. In a powder sample, crystallites of all orientations θ contribute to the resonance, where θ is the angle between the site symmetry axis and H_0. An example of the resulting *powder pattern* is furnished by the dangling-bond EPR signal in amorphous silicon (Biegelson, 1981), shown in Fig. 6. The stronger feature in the spectrum occurs at $\theta=90°$, i.e., $g_\perp$, and the weaker at $\theta=0$, i.e., $g_\parallel$. Thus, even with a powder sample, the elements of the g tensor can be determined, although not its orientation within the material.

2.3 Fine Structure

The EPR spectra that occur when $S>1/2$ often show up to $2S$ different features, rather than a single resonance, indicating that the separations between the $2S+1$ energy levels are not equal. This *fine structure* in EPR spectra has different origins depending on the nature of the paramagnetic center. The principal characteristics of the interactions that give rise to fine structure are

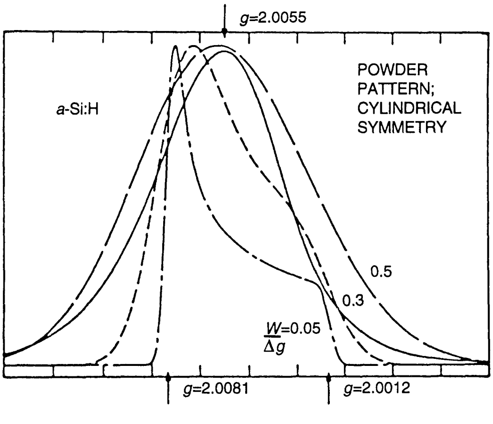

FIG. 6. Powder pattern for dangling-bond EPR using Gaussian broadening with half-width at half-height W. The solid curve is the EPR absorption signal in hydrogenated amorphous silicon (Biegelson, 1981).

1. their dependence on μ^2 (or S^2), in contrast to the simple magnetic interaction with the field H_0 which depends on μ (or S_z), and
2. the fact that they are independent of H_0.

The dependence on μ^2 (or S^2) means that the interactions are indifferent to the signs of the magnetic sublevels, so that the $M=\pm 1/2$ levels of $S=1/2$ experience the same shift in energy, for example. Consequently, fine structure only arises when $S>1/2$. When $S=1$, the $M=\pm 1$ sublevels are split away from the $M=0$ sublevel; when $S=3/2$, there will be a splitting into $M=\pm 3/2$ and $\pm 1/2$ sublevels. The second characteristic means that the splitting persists in the absence of H_0—it is "built into" the molecule or solid—and for this reason is frequently referred to as *zero-field splitting.*

In the framework of the spin-Hamiltonian approach, the interactions are represented by an energy term of the form

$$E_{\text{fs}}=D[S_z^2-S(S+1)/3]+E(S_x^2-S_y^2). \qquad (9)$$

When the interaction is isotropic or nearly so ($E \ll D$), and sufficiently weak in comparison to the magnetic dipole energy $-\boldsymbol{\mu}\cdot\mathbf{H}_0$, to a first approximation the effect on the EPR spectrum takes the form

$$E_{\text{fs}}\simeq (D/2)[3S_z^2-S(S+1)](3\cos^2\theta-1), \qquad (10)$$

where θ is the angle between the z axis of the D, E tensor and $\mathbf{H}_0$.

Briefly, fine structure in triplet states of organic molecules and biradicals arises from the dipolar interaction between two electrons whose total spin $S=1$. This is the simplest case. For EPR of complexes of transition-metal ions, fine structure is generally due to the spin–orbit interaction, but the resulting spin-Hamiltonian form is the same as for the dipolar interaction. (See Sec. 3.1 for an example.)

2.4 Hyperfine Structure
